ABSTRACT

Forest food resources contribute significantly to food supply in areas where they grow. Three fermented baobab foods were studied: Dikouanyouri (from seeds, pH = 6.5); Tayohounta (from seed kernels, pH = 7), and Mutchayan (from baobab pulp and sorghum, pH = 4.2). Bacillus spp. (8.5 and 9.5 Log cfu/g) and lactic acid bacteria (8.9 and 8.4 Log cfu/g,) dominate in Dikouanyouri and Tayohounta, respectively. In Mutchayan, lactic acid bacteria (8.1 Log cfu/g) and yeasts (7.2 Log cfu/g) predominated. The arbitrary index of protein cleavage increases from 2.3% (unfermented products) to 13.7% in Dikouanyouri and 21.3% in Tayohounta, indicating significant protein degradation. Mutchayan is the most frequently consumed product.

Key words: Baobab foods, fermentation, Bacillus, lactic acid bacteria, yeasts, chemical composition, consumption.

INTRODUCTION

Forest food resources in general and local forest fruits in particular are important sources of food and income for rural populations. Indigenous fruits are essential for food security, health, social and economic welfare of rural communities (Akinnifesi et al., 2004). Among them, baobab is one of the most important for local populations in Africa. It is widely distributed in many African countries and is used daily for food, as medicine and for other purposes (Sidibe and Williams, 2002; Wickens, 1982). Baobab fruits contain reniform seeds and a powdery pulp (Baum, 1995). The pulp is rich in vitamin C, minerals and other nutrients (Chadare et al., 2009; Nour et al., 1980; Osman, 2004) and also exhibits some
antioxidant activity (Besco et al., 2007; Vertuani et al., 2002). The seeds are rich in energy, essential fatty acids, and some minerals such as Ca and K (Glew et al., 1997; Lockett et al., 2000; Sidibe and Williams, 2002). Several indigenous foods are prepared from baobab fruits, either with the pulp or the seeds or the seed kernels (Chadare et al., 2008). Studies related to baobab species have provided data on the ecology, genetics, ethnobotanical aspects, and the chemical composition of its parts (Assogbadjo et al., 2006; Chadare et al., 2009; Diop et al., 2005) but no study specifically addressed the characterization of traditional baobab foods.

In Benin, local populations have broad knowledge on these food products, especially the Ditamari (also known as Otamari) ethnic group (Assogbadjo et al., 2008). Thirty-five baobab foods were described based on indigenous knowledge of populations from Benin; many of these are prepared from baobab fruits, either with the pulp or the seeds or the seed kernels. Among them, some fermented baobab foods have been reported (Chadare et al., 2008) but these have not yet been characterized. They are Mutchayan (fermented cereal paste with baobab pulp), Dikouanyouri (fermented baobab seeds) and Tayohounta (fermented baobab seed kernels). Mutchayan is made from cereals. In that respect it is similar to other fermented cereal doughs which have been researched for their production process, and their microbiological and physico-chemical characteristics, such as Gowe, a cooked product made from sorghum (Michodjehoun-Mestres et al., 2005), Mawè (Hounhouigan et al., 1993a) and Ogi (Agati et al., 1998) made from maize.

There are many African fermented condiments which have been thoroughly investigated for their production techniques, and their microbiological and physico-chemical properties; usually they are made from plant seeds, just like Tayohounta and Dikouanyouri. Examples are Afitin, Iru and Sonru made by natural fermentation of decorticated African locust beans.
(Parkia biglobosa) (Azokpota et al., 2006); Otiru from African yam beans (Sphenostylis sternocarpa) (Jeff-Agboola, 2007); and Dawadawa from African locust beans or soya beans (Dakwa et al., 2005; Odunfa, 1985). Fermented foods are of interest because of their desirable attributes such as attractive flavour, increased shelf life, ease of digestibility and health benefits. Detailed studies of these traditional fermented products revealed the predominance of, for example, specific microorganisms (generally Bacillus spp. in the seed-based products and lactic acid bacteria in the cereal-based products) and volatile components (Azokpota et al., 2008). Such characterizations provide basic information that is needed before follow-up research can be done into nutritional optimisation, stabilization and valorisation.

The present study is the first that investigates Mutchayan, Dikouanyouri and Tayohounta, three traditional fermented baobab foods from North Benin. We (i) document the traditional processing techniques of Mutchayan, Dikouanyouri and Tayohounta; (ii) determine the microbiological and physico-chemical characteristics of these foods; (iii) assess the effect of fermentation on their physico-chemical composition; (iv) assess their consumption patterns in rural communities in Benin, and (v) formulate options for improvement of traditional processing techniques to the benefits of the users of these baobab foods.

MATERIALS AND METHODS

Survey

In July-August 2008 a survey was conducted among 150 consumers and processors of baobab fermented foods in Natitingou region (Tagaye, Kousoucoingou), Boukoumbe, and Korontière,
three localities in northern Benin. These localities were selected as the majority of the population belongs to the Otamari ethnic group (or Ditamari), which has demonstrated broad knowledge on baobab foods in general and fermented baobab foods in particular (Assogbadjo et al., 2008). The study was based on discussions and interviews, after having obtained consent from the village chiefs and the persons involved. Volunteer informants, men and women of 25 to 60 years old, were randomly selected (50 per locality). All informants in Natitingou region and Boukoumbe belong to the Otamari ethnic group while 80% of the informants in Korontière belong to the Namba ethnic group; the others were Otamari. Individual interviews were conducted in the local language of the respondents with translation when necessary. Questions were related to traditional processing of baobab fermented foods and their consumption during periods of abundance and shortage, which are distinguished by the ample availability or shortage of raw material needed to prepare the baobab products. All the raw materials (pulp, seeds, kernels) from the baobab fruit can be freshly harvested and are thus readily available from January until May. Seeds and kernels can easily be obtained for a slightly longer period, i.e. until June. The period in which pulp is abundant corresponds to the period in which there is an ample supply of Mutchayan. When the seeds and seed kernels are abundant, Tayohounta and Dikouanyouri are easy to get. Preferences of the informants for the different foods were assessed through consumption frequencies of the fermented baobab foods.

**Process and sampling**

Baobab fruits were processed according to Figure 1. The fruit is broken and its content is ground using mortar and pestle. The ground mixture is then sieved to separate pulp, seeds and fibres. Dikouanyouri, Mutchayan and Tayohounta were prepared as shown in Figure 2. Three local processors of each of the three products were selected in the three above
mentioned localities. Village-style preparation of the 3 products was carried out in each of the 3 localities, with replications on the next day. Production was carried out during the rainy season. Since these samples were produced under local village conditions, the hygienic circumstances were uncontrolled. Unfermented and fermented samples were collected in sterile stomacher bags, packed in a thermocooler containing ice blocs, stored when necessary in a refrigerator at 4°C and transported to the laboratory for analyses.

**Microbiological analyses**

Ten grams of each sample were taken aseptically and transferred into 90 ml sterile peptone physiological saline solution (1g peptone, 8.5g NaCl and 1000 mL distilled water, pH = 7.0) and homogenized with a Stomacher Lab Blender (Type 400, Seward Medical, London, UK) for 1 min to obtain dilution $10^{-1}$. Dilution $10^{-2}$ was obtained by adding 1mL of dilution $10^{-1}$ to 9 mL sterile physiological saline solution to get the required dilution level, and so on. For the drop plate method (Herigstad *et al.*, 2001), the volume of the inoculum was 30µl on 1/2 petri dish for the Nutrient Agar or ¼ petri dish for Malt Yeast Glucose Peptone and Man Rogosa Sharpe media, respectively.

Total aerobic mesophilic bacteria were enumerated on Nutrient Agar (Remel 454182, Bie and Berntsen, Rodovre, Denmark) (37°C, 48 h), and reported as Total Mesophilic Count. Bacterial spores (mainly *Bacillus* spp.) were enumerated on Nutrient Agar (Remel 454182, Bie and Berntsen, Rodovre, Denmark) (37°C, 48 h), from a $10^{-1}$ dilution that had been heated for 10 min at 80 °C to kill vegetative cells, and were reported as Total Spores. Lactic acid bacteria were enumerated on de Man Rogosa and Sharpe Agar (MRSA, CM 361, Oxoid, Hampshire, England) containing 0.1% (w/v) natamycin (Delvocid, Gist-Brocades, Delft, The
Netherlands) after incubation at 30°C for 3-4 days. Colonies were confirmed by oxidase and catalase tests, and confirmed counts were reported as lactic acid bacteria (Nout, 1991). Yeasts were counted after incubation at 25°C for 3-5 days on a mixture -MYGP- of Malt Extract (3g), yeast extract (3g), Glucose (10g), Peptone (5g) and Agar (20g) supplemented with chloramphenicol and chlortetracycline (Jespersen et al., 1994) and reported as yeasts. Per 30 µl seeding, numbers of colonies ranging between 9 - 90 were considered for calculation (Herigstad et al., 2001). The number of microorganisms was calculated as follows:

\[ X = \frac{AV}{I} \]

with:

- \( X \) = number of microorganisms per g
- \( A \) = number of counted colonies on ½ or ¼ petri dish
- \( V \) = 1/dilution factor
- \( I \) = Inoculum volume (mL)

**Physico-chemical analyses**

The pH and titratable acidity were measured immediately on the wet samples according to Nout et al. (1989). The dry matter, crude fat, and ash contents of the samples were determined, using AOAC methods 27.005, 27.006, and 27.009, respectively (A.O.A.C., 1984). Protein contents were measured using Dumas method (Jung, 2003). Free amino nitrogen was measured using formol titration (Han et al., 1999). Protein was converted and expressed as total nitrogen using the factor of 6.25.

**Statistical analyses**
For microbiological and physical-chemical data, analysis of variance (ANOVA) was performed and least significant difference (Student–Newman–Keuls test) was determined, using SAS v8 (SAS Institute Inc.). For consumption data, analysis of variance was performed to assess the effect of the principal factors (product, area, consumption period, consumption frequency, gender) and the effect of their interactions. Prior to ANOVA, consumption data were transformed using a logarithmic function \( \ln (x+1) \) in order to have normality of the data and equality of population variance. Significance was accepted at \( P < 0.05 \).

RESULTS

Traditional manufacturing processes of Dikouanyouri, Tayohounta and Mutchayan

The flow diagram for Dikouanyouri, Mutchayan and Tayohounta processing is shown in Figure 2. Dikouanyouri is usually made from baobab seeds. Ample water is added to the seeds during cooking until they get sufficiently soft (on average this takes 5-8 hours). Approximately 12 volumes of water are needed for 1 volume of seeds, after which the remaining water is discarded. The cooked seeds are put in a pot and fermented for about 3 days at ambient temperature, i.e. ranging from 24 to 31°C (Assogbadjo, 2006; Natta, 2003). The fermented seeds are then pounded to pulp using mortar and pestle, and some potash (0.25 L / kg cooked seeds) is added to the resulting mash. The mixture is further fermented overnight at ambient temperature (24 - 31°C). The obtained product, Dikouanyouri, is usually sun dried for 5-7 days to extend its shelf life. The dried product intended for domestic consumption is usually stored in a closed vessel or wrapped in leaves and kept near
the traditional clay stoves until it is finished after 2-3 weeks. It is used as flavouring agent in sauces.

*Tayohounta* is made from kernels obtained by decortication of baobab seeds. These are roasted (5-10 min), cooked (about 20-30 min), drained off, put in a pot and covered with leaves. Usually leaves of *Annona senegalensis* are used and these are in contact with the product. The type of leaves used may affect product quality but this aspect was not studied by us. The kernels are left for about 2 days to ferment at ambient temperature (24 - 31°C) (Assogbadjo, 2006; Natta, 2003), followed by hand kneading for a few minutes to shape the product into balls with a diameter of 5-10 cm. These balls are usually sun dried to increase their shelf life; the dried balls that are intended for domestic consumption are mostly stored wrapped in leaves and kept near the traditional clay stoves until they are finished within 2-3 weeks. They are used as flavouring agent in sauce.

For the preparation of *Mutchayan*, diluted baobab pulp/baobab pulp drink is required. This can be obtained by soaking the content of a baobab fruit in water or by diluting baobab pulp in water (1 volume of pulp for 1.5 volume of water), see Figure 1. The second important ingredient for *Mutchayan* is cereal (maize, millet or sorghum) flour. In order to obtain the flour, cereal grains are sun dried and cleaned. Dry grains are then finely milled in a cereal mill to obtain the flour, which is sometimes further sieved. The cereal flour is used to prepare a cooked paste by boiling a mixture of flour and water to obtain a porridge, which is then thickened with additional flour. The paste is mixed with baobab pulp drink (Figure 1); 450 mL of baobab pulp drink (made from about 110g of baobab pulp) for 450 g of sorghum paste (Figure 2). The mixture of the paste and the pulp drink is put in a jar, covered and fermented for at least 1 day. The obtained fermented paste (*Mutchayan*) is either diluted in
water and used as a drink or consumed as a main dish with sauces. It can be preserved as such in its vessel for 1 week without spoilage.

**Microbiological characteristics of Mutchayan, Dikouanyouri and Tayohounta**

Table 1 shows that *Dikouanyouri* and *Tayohounta* contain very high levels of mesophilic aerobic bacteria (9.5 Log cfu/g). Sporeformers (8.5 and 9.1 Log cfu/g respectively) and lactic acid bacteria (8.9 and 8.4 Log cfu/g respectively) were detected in large numbers. Especially for the sporeformers, this indicates that also high levels of vegetative cells of *Bacillus* spp. may be expected (i.e. the difference between the total count and the sporeformers and lactic acid bacteria). Possibly, other microorganisms will be present in these products; this will require further investigation. *Mutchayan* contained mainly lactic acid bacteria (7.6 Log cfu/g) with a substantial amount of yeasts (7.2 Log cfu/g) (Table 1). Counts in unfermented products were below the minimum level to be considered of relevance.

**Physico-chemical characteristics of Mutchayan, Dikouanyouri and Tayohounta: impact of fermentation**

*Dikouanyouri*

As shown in Table 2, the unfermented product contained 13 g / 100g dm crude lipids, 4.7 g / 100g dm ash, 342.5 mmol total nitrogen / 100g dm and 7.9 mmol / 100g dm free amino nitrogen. After fermentation, crude lipids and ash significantly increased to 17.2 g / 100g dm, and 10.9 g / 100g dm, respectively (p<0.05). Protein degradation allowed an increase of free amino nitrogen to 39.7 mmol/100g dm. The ratio amino nitrogen / total nitrogen (i.e., an
arbitrary index of protein cleavage) rose from 2.3% in the non fermented product to 13.7% in the fermented Dikouanyouri.

Tayohounta

Non-fermented Tayohounta had a dry matter content of 49.7 g/100g, a crude lipid content of 36.9 g/100g dm a pH of 6.4; a total nitrogen content of 476.6 mmol N/100g dm and free amino nitrogen content of 11 mmol / 100 g dm. After fermentation, the pH increased to 7; crude lipids and the content of free amino nitrogen rose significantly (p<0.05) to 42.5 g/100g dm and 105.7 mmol / 100g dm, respectively. The ratio amino nitrogen / total nitrogen increased from 2.3% in the non fermented to 21.3 % in the fermented food (table 2).

Mutchayan

The impact of fermentation in Mutchayan is mild. Both the unfermented and the fermented product had a pH of 4.2 and a dry matter content of about 22.5 g/ 100g. The lipid content increased from 0.7 in the unfermented to 1.6 g/100g dm in the fermented product and the titratable acidity decreased significantly from 23.2 to 17.5 mmol NaOH / 100 g dm (p<0.05). No free amino nitrogen was present: not in the unfermented or in the fermented product (Table 2).

Use and consumption patterns of Mutchayan, Dikouanyouri and Tayohounta

The Otamari ethnic group is one of the largest consumers of baobab products in Benin. Otamari people have demonstrated profound knowledge of baobab foods, and the tree is highly important for their daily life. Baobab is used for foods, medicines and as a worship in this community (Assogbadjo et al., 2008). Mutchayan is the most widely consumed baobab
pulp product in Otamari area (Table 3). It can be consumed as a thick and nutritious drink at all times of the day. Most farmers take some Mutchayan beverage in their bottle when they go to their fields and drink it when they are thirsty or feel tired. It is also the beverage that is offered to visitors during the period when pulp is available. In addition, it is used as a local cure against cough, and appreciated as appetizer, prior to a meal. Dikouanyouri is used as a flavouring agent in sauce consumed with cooked paste of cereals (maize, sorghum, millet) during lunch and dinner. Tayohounta is a flavouring agent too, used in most sauces and stews consumed during lunch and dinner. All members of the population that eat in a family context (i.e. everybody except infants) may consume Tayohounta.

Table 3 shows the consumption frequencies of Mutchayan, Dikouanyouri and Tayohounta in the municipalities of Natitingou, Boukoumbe and Korontière in northern Benin. The quantity consumed was not specified for each product. However, because Tayohounta and Dikouanyouri are condiments, they are likely to be consumed in much lower quantities than Mutchayan. After a logarithmic transformation of the data in Table 3, ANOVA showed that the factor “consumption frequency” (p=0.01) and the interaction “consumption frequency” * ”Product” (p<0.001) are significant. The consumption frequency thus depends on the product. A high number of respondents mentioned a consumption frequency of 6-7 times per week for Mutchayan (namely 90% of informants in Natitingou region, 40% in Boukoumbe and 18% in Korontière during the pulp abundance period and 54% in Natitingou, 22% in Boukoumbe and 16% in Korontiere during the pulp shortage period), while only a few mentioned this frequency for Dikouanyouri (namely 26% of the informants in Natitingou region, 18% in Boukoumbe and 4% in Korontière during seed abundance period, and 3% of the informants in Natitingou region and none of them in the 2 other regions during seed
scarcity period). For consumption frequencies of 2-3 and 4-5 times per week, more respondents indicated Mutchayan followed by Dikouanyouri and Tayohounta. For consumption frequencies rarely and 1 time per week, Dikouanyouri is indicated by a high number of respondents followed by Tayohounta, while a low number of respondents indicated Mutchayan. All the 3 products are consumed more frequently when the required raw materials are readily available. However, when the raw materials are in short supply, the number of respondents who consume Mutchayan 6-7 times per week is almost 2 times higher, than those who consume Tayohounta and 15 times higher than those consume Dikouanyouri. In short, Mutchayan is the most popular and most frequently consumed fermented baobab food while Dikouanyouri is the least frequently consumed one.

DISCUSSION AND CONCLUSION

Dikouanyouri is made from whole baobab seeds, while Tayohounta, like several other African fermented condiments, is made with dehulled/decorticated seeds, thus resulting in a product with other sensorial and nutritional characteristics. Moreover, dehulling improves the nutritional value for most macronutrients and micronutrients except for the potassium content. A comparison between the nutritional value of seeds and seeds kernels is presented in a review by Chadare et al. (2009). Dehulling also makes it easier to extract oil from the seeds, for food and medicinal purposes. Finally, seed kernels get a better price on the market.

Mutchayan is primarily made from cereals and in that aspect it is similar to fermented cereal doughs such as Gowé, Mawè and Ogi made from sorghum or maize (Agati et al., 1998; Hounhouigan et al., 1993b; Michodjehoun-Mestres et al., 2005). However, Mutchayan is the only fermented cereal food enriched with baobab pulp juice. This addition increases the
ascorbic acid content, which may play an important role as enhancer of mineral uptake (Hemalatha et al., 2005). The consumption of approximately 300 g of Mutchayan (which is very common for adults) can provide 10.7 to 11.3 mg of vitamin C (all vitamin C is supposed to come from baobab pulp), which corresponds to 12-14% of the daily recommended intake (RDI) for pregnant women; 11.9-12.6% of RDI for an adult man and 14.3-15.1% of RDI for an adult woman. The consumption of 100 g Mutchayan by a child (4-8 years) can provide 14-15% of his daily recommended intake of vitamin C.

The consumption of approximately 300 g of Mutchayan (which is very common for adults) can provide 10.7 to 11.3 mg of vitamin C (all vitamin C is supposed to come from baobab pulp), which corresponds to 12-14% of the daily recommended intake (RDI) for pregnant women; 11.9-12.6% of RDI for an adult man and 14.3-15.1% of RDI for an adult woman. The consumption of 100 g Mutchayan by a child (4-8 years) can provide 14-15% of his daily recommended intake of vitamin C.

The dominant microflora in Tayohounta and Dikouanyouri are bacteria, especially sporeforming bacilli (Bacillus spp.) and lactic acid bacteria. The predominance of Bacillus spp. was to be expected as it the case for most fermented seed products. In such seed products the fermentation is proteolytic; the bacilli are strong producers of proteolytic enzymes. Their predominance in these fermentations may be due to their ability to survive cooking and to initiate fermentation of both nitrogenous and carbohydrate products (Omashupi et al., 1999). Abundance of Bacillus spp. was reported in fermented plant seeds such as Afitin, Sonru (Azokpota et al., 2006) and Iru (Azokpota et al., 2006; Sanni et al., 2000) made from African locust bean (Parkia biglobosa); Ogiri made from melon seeds (Citrullus spp.) or castor seeds (Ricinus communis); Ugba (Sanni et al., 2000) made from African oil bean seeds (Pentaclethra macrophylla Benth); Dawadawa (Dakwa et al., 2005) made from soya bean (Glycine max), and Kpaye (Omashupi et al., 1999) made from African mesquite seeds (Prosopis africana) seeds. Further research into the identities of the microbiota of fermented baobab seed products is necessary, and ongoing for Tayohounta.

In Dikouanyouri and Tayohounta also significant numbers of lactic acid bacteria were found, namely 8.9 Log cfu/g and 8.4 Log cfu/g, respectively. The origin of the lactic acid bacteria in
these products is presumably the vessels, utensils and other sources of post-cooking contamination during the preparation process. Lactic acid bacteria were also observed in Oturu made from African yam bean (Sphenostylis stenocarpa Harms), which also contained Lactobacillus jensenii, but in lower numbers ($3.8 \times 10^3$ cfu/g $\approx 3.6$ Log cfu/g after 72h of fermentation) (Jeff-Agboola, 2007). The microflora of Mutchayan was dominated by lactic acid bacteria but the product contained also substantial amount of yeasts. This was to be expected in such a product due to its acidic pH of 4.2, which is favourable for the development of such microorganisms. Lactic acid bacteria and yeasts were also reported as dominant microflora in Gowé, a fermented dough made from non malted and malted sorghum (Michodjehoun-Mestres et al., 2005), and in Mawè, a fermented maize dough (Hounhouigan et al., 1993b). Lactic acid bacteria also dominate in Ogi (Agati et al., 1998).

For the present study fresh Dikouanyouri and Tayohounta were used, which have a relatively high moisture content making them highly susceptible to spoilage. In order to increase their shelf life, these products are usually sun dried by the local population. The drying may induce changes in the microbiological successions which needs to be considered in further studies.

The dry matter content of Dikouanyouri is quite stable and increases slightly from 36.6 g/100g dm to 37.5 g / 100g. This could be due to limited evaporation of water during the fermentation process (4 days in total), which occurred in covered vessels. A more important increase was reported by Azokpota et al. (2006) during the fermentation of African locust bean. In contrast, a significant decrease in dry matter content was observed in Tayohounta, namely from 49.7 to 46.1 g / 100 g (p<0.05). This was also reported in the fermentation of Prosopis africana seeds for Kpaye production and the fermentation of African locust bean for Daddawa production (Omafuvbe et al., 1999; Omafuvbe et al., 2000) and can be related
to uptake of water during fermentation periods in conditions where covering with leaves favours exchange with the environment.

With respect to the pH of Dikouanyouri and Tayohounta (6.5 and 7.1, respectively), similar or slightly higher values are encountered in foods fermented by Bacillus spp.: 8.2 to 8.3 in Dawadawa from roasted and boiled soya beans (Dakwa et al., 2005); 7.9 in Iru from African locust beans; 7.6 in Ugba from African oil bean seeds and 8.0 in Ogiri from castor seeds (Sanni et al., 2000). Such pH values are typical for proteolytic fermentation, also referred to as “alkaline fermentation” (Steinkraus, 1995). Whereas the pH of Dikouanyouri remained stable after the fermentation, there was an increase in pH (from 6.4 to 7.1) and of titratable acidity (from 11.6 to 17.5 mmol NaOH/100g dm) in Tayohounta. The simultaneous rise in pH and acidity observed in Tayohounta has been reported for fermentation of legume seeds (Dakwa et al., 2005). This may be due to the high buffering capacity of legume beans and microbial proteolytic activity leading to ammonia release, which is characteristic for most vegetable protein fermentations (Hesseltine, 1965). For such a proteolytic type of fermentation, protein degradation is to be expected. Proteolysis is the enzymatic degradation of proteins leading to formation of water-soluble peptides and amino acids, thereby improving the bioavailability of proteins for human metabolism (Odunfa, 1985). The increase of the ratio free amino nitrogen/total nitrogen from 2.3% in the unfermented products to 13.7% in fermented Dikouanyouri and 21.3% in fermented Tayohounta is an expression of protein cleavage. The phenomenon is less pronounced in Dikouanyouri, probably due to the presence of the seed coats in the product, which might hinder more active protein degradation. The other differences in chemical composition between Dikouanyouri and Tayohounta are also possibly due to the presence of the seed coat in Dikouanyouri, which is rich in fibrous compounds and lignin and probably other
compounds. Proteolysis leads to an increase of free amino acids such as lysine (Odunfa, 1985). In *Soumbala* (also known as *Afitin* and very similar to *Tayohounta*) made from African locust beans, the quantity of total free amino acids and essential free amino acids such as lysine increased sharply between 24 and 48h of fermentation; cysteine, methionine, leucine, isoleucine, tyrosine and phenylalanine appeared during fermentation. These changes were mainly induced by strains of *Bacillus subtilis* and *Bacillus pumilus* (Ouoba et al., 2003). We expect that strains of microorganisms that improve the nutritional quality through fermentation by inducing an increase of free amino acids, including essential free amino acids, are also present in *Tayohounta* and *Dikouanyouri*. Ash content increases only slightly in *Tayohounta* after fermentation, whereas a 2.3 fold increase was found for *Dikouanyouri*. We ascribe this to the addition of potash to *Dikouanyouri* during the fermentation process.

Apart from the fat content that increases from 0.7 to 1.6 g/ 100g dm, the characteristics of *Mutchayan* before and after 1 day of fermentation are quite unchanged. The increase in the fat content may be due to possible metabolism of carbohydrates to fat as noticed in the fermentation of cassava and African locust beans (Oboh et al., 2002; Oboh et al., 2008). *Mutchayan* is characterised by an acidic pH (4.2) and relatively low dry matter content (22.5 g/ 100g). The acidity is mainly caused by the addition of baobab pulp, which has a low pH (about 2.9-3.3) and by the effect of lactic acid bacteria. The free amino nitrogen content *Mutchayan* was not detectable, both before and after fermentation. This may in part be explained by the much lower protein content (Table 2), as well as the inability of lactic acid bacteria to degrade protein.
The most frequently consumed product is *Mutchayan*, followed by *Tayohounta*. *Dikouanyouri* is the least frequently consumed. *Mutchayan* is used as a drink (during the day) as well as for lunch or dinner, while *Dikouanyouri* and *Tayohounta* are only used in smaller quantities for flavouring of stews and sauces. Moreover, the preparation of *Mutchayan* is easier than that of the other foods. In general, every Otamari is able to prepare *Mutchayan*, while the preparation of *Tayohounta* and *Dikouanyouri* is done by experienced people, mainly women. The use of *Mutchayan* as anti-fatigue is not surprising, considering the ascorbic acid content of baobab pulp, most of which is in the reduced form (Carr, 1955). Most traditional foods are still well appreciated by urban consumers, who, however, usually do not have the required skills to prepare them and therefore rely on the market. Their increasing interest in these products may boost the improvement of traditional techniques to facilitate production at a larger scale and make traditional foods accessible for a larger public who can pay a better price for them.

The preparation of *Dikouanyouri* requires much time due to a long cooking process, which is needed to soften the seed coats, but the preparation of *Tayohounta* may require as much time when the seed decortication process is included in the calculation. This high energy consumption for the preparation of *Dikouanyouri* contributes to the use of fire wood and thus to deforestation. Therefore it is desirable to find another way of softening the seed coats that will require less use of fire wood. At present the use of vinegar or fermentation of the seeds with some pulp are investigated as aids to soften the seed coats (Debròci *et al.*, 2008). This will help to find an easier way to soften the seed coats and thus promote the utilisation of baobab whole seeds e.g. production of *Tayohounta*. 
It is suggested that future studies address the identification of the most important microbial strains in baobab fermented foods, which is necessary for specification of authenticity and future development of starter cultures for controlled fermentation. Controlled fermentation is necessary to produce more standardized, hygienic and stable products with an improved nutritional composition. Moreover, starter culture development will facilitate the production of *Mutchayan* during pulp shortage period. The present study provides new knowledge about traditional fermented baobab foods and sets research priorities for further studies that should lead to an improvement of the processing techniques for the nutritional and economic benefits of local populations. Similar work should be done on other baobab foods identified in Benin, also to stimulate research projects in other African countries where the tree is important for food purposes.

**Acknowledgement**

We thank NUFFIC and Codesria SGTR-04/T07 for their financial support. We are also thankful to local populations in Northern Benin for their cooperation.
