ABSTRACT BOOK
SETAC Europe 24th Annual Meeting

TABLE OF CONTENTS

This book composes the abstracts of the presentations for the platform and poster sessions of the 24th Annual Meeting of the Society of Environmental Toxicology and Chemistry (SETAC), conducted at the Congress Centre Basel, MCH Messe Schweiz (Basel) AG, in Basel, Switzerland from 11-15 May 2014.
The abstracts are reproduced as accepted by the scientific committee of the meeting and appear in order of abstract code, in alphabetical order per presentation type. The poster spotlight abstracts and poster corners abstracts are included in the list of poster abstracts. The presenting author of each abstract is underlined.

SOCIETY OF ENVIRONMENTAL TOXICOLOGY AND CHEMISTRY

In the 1970s, no forum existed for interdisciplinary communication among environmental scientists—biologists, chemists, toxicologists—as well as managers and engineers others interested in environmental issues.. The Society of Environmental Toxicology and Chemistry (SETAC) was founded in North America in 1979 to fill the void. Based on the dynamic growth in the Society's membership, meeting attendance and publications, the forum was clearly needed. SETAC has two administrative offices, in Pensacola, Florida, USA, established in 1990, and in Brussels, Belgium, established in 2003.

A unique strength of SETAC is its commitment to balance the scientific interests of government, academia and business. The Society by-laws mandate equal representation from these three sectors for officers, World Council, Geographic Unit Boards of Directors and Councils, and Committee members and governance of activities. The proportion of members from each of the three sectors has remained nearly equal over the years.

SETAC publishes two globally esteemed scientific journals and convenes annual meetings around the world, showcasing cutting-edge science in poster and platform presentations. Because of its multidisciplinary approach, the scope of the science of SETAC is broader in concept and application than that of many other societies.

The Society is concerned about global environmental issues. Its members are committed to Environmental Quality through Science®, to timely and effective communication of research, and to interactions among professionals so that enhanced knowledge and increased personal exchanges occur. SETAC's growth has been marked the establishment of geographic units around the world: SETAC Europe in 1989, SETAC Asia/Pacific in 1997, SETAC Latin America in 1999 and SETAC Africa in 2012. As evidence of international acceptance of the SETAC model and of the great interest at the local level, regional chapters of the geographic units are being considered for a number of countries.

Publications

Environmental Toxicology and Chemistry, an internationally acclaimed scientific journal, has grown from a quarterly publication of fewer than 400 pages annually in 1980 to a monthly publication of nearly 3,000 pages annually.

Integrated Environmental Assessment and Management, launched in 2005 to bridge the gap between scientific research and it application in environmental decision-making, regulation and management, has become a well-respected quarterly publication of 700 pages annually.

SETAC Books total more than 100, encompassing workshop results and other scientific studies.

Keynote Abstracts

Persistent Organic Pollutants in Switzerland and globally: problems solved?
Martin Scheringer

Persistent Organic Pollutants (POPs) have been a topic of environmental chemistry and toxicology since the 1960s. This year, we celebrate the 10th anniversary of the Stockholm Convention on POPs. Why should POPs, after so many years, still be a research priority within SETAC? First, POPs still cause serious environmental impacts and will continue to do so. Emission sources of POPs are active in many countries and need to be identified and eliminated. The global distribution and long-term fate of POPs poses many open questions; it is currently not known if and under what conditions the environmental reservoirs of POPs may be relevant as secondary emission sources. Moreover, the total number of POPs that need global action is unknown; there might be (many) more than the 23 POPs currently covered by the Stockholm Convention - but which ones? Finally, how can we determine whether the Stockholm Convention is effective? Does our POPs monitoring have sufficient spatial and temporal coverage?

About Martin Scheringer
Martin Scheringer works with the Swiss Federal Institute of Technology (ETH) in Zürich, Switzerland. His field of research is hazard and risk assessment for chemicals with a focus on environmental exposure assessment. Martin Scheringer has developed a suite of multi-media mass-balance models for analyzing the environmental fate of chemicals on various scales from local to global. Key areas of his work are the persistence and long-range transport of chemicals in the environment and the assessment of chemical property data for hazard assessment under REACH. In addition to his research, Martin Scheringer has worked extensively on the science-policy interface. He has conducted several projects with UNEP and is a co-author of a chapter on Chemicals and Waste in UNEP's 5th Global Environment Outlook and a chapter on Minimizing Chemical Risks in UNEP's Year Book 2013. Martin Scheringer is a founding member and currently the chair of the International Panel on Chemical Pollution, IPCP.

Epigenetics in Environmental Toxicology and Chemistry
Juliette Legler

How is possible that exposure to a chemical during development affects a tissue in a way that its function is changed long after the exposure has stopped? How do chemicals program an organism during development, making it more susceptible to diseases later in life? If we are to understand this we must dig down into the very basics of life and how genes work. The central dogma that genes flow in a linear fashion from DNA sequence to messenger RNA to protein is clearly too simplistic. One area of molecular biology where new discoveries are made at an astonishing rate is the field of epigenetics. Epigenetics describes the array of chemical markers and switches that lie along DNA providing instructions to genes for what to do, and where and when to do it. Newfound insights in this field will help us understand how chemicals may alter basic processes in development at levels that may not produce overt toxicity. It is an exciting time in molecular and evolutionary biology, and role of epigenetics in toxicity is the challenge than now lies with us as environmental toxicologists and chemists.

About Juliette Legler
Juliette Legler is a Professor of Toxicology and Environmental Health at the Institute for Environmental Studies of the VU University Amsterdam. With a background in environmental toxicology and molecular biology, she has developed test methods to identify the effects of endocrine disrupting chemicals. Her research with zebrafish and in vitro models has expanded to understanding the effects and underlying mechanisms of chemical exposure during development in both fish and in humans. As coordinator of the EU project OBELIX and recipient of a Netherlands Organization for Scientific Research VIDI grant, she is examining the role of chemical exposure in the developmental origins of health and disease. Legler also coordinates the VU's Master program in Environmental Chemistry and Toxicology and has served on various advisory and review boards, including the Dutch Health Council and OECD.

Sufficiency: Enough but Not Too Much
Thomas Princen

Growth. Efficiency. Consumer sovereignty. These principles served the 20th century well. Resources were abundant, waste sinks vast, demand unyielding. But this is the 21st century. We need to figure how to live within the regenerative capacities of biophysical and social systems. We need to put a brake on endless expansion and consumption. For that, new principles are needed to guide human organization onto a sustainable path. Among them are sufficiency: living well now and into the future by living on less than the most possible now. Thomas Princen will develop the notion of sufficiency grounding it at three levels of behavior—the individual, the organizational, and the societal. He will argue that sufficiency is but one element in a broader "politics of urgent transition.

About Thomas Princen
Thomas Princen explores issues of social and ecological sustainability at the School of Natural Resources and Environment at the University of Michigan. He works on principles for sustainability (e.g., sufficiency), overconsumption, the language and ethics of resource use, and the transition out of fossil fuels.
Princen is the author of Treading Softly: Paths to Ecological Order (2010/2013), author of The Logic of Sufficiency (2005), and lead editor of Confronting Consumption (2002), all three published by MIT Press. The last two were awarded the International Studies Association's Harold and Margaret Sprout Award for the "best book in the study of international environmental problems."
He is co-editor of The Localization Reader: Adapting to the Coming Downshift (MIT Press, 2012), co-author of Environmental NGOs in World Politics: Linking the Local and the Global (Routledge, 1994) and author of Intermediaries in International Conflict (Princeton University Press, 1992/1995).
*Princen is currently working on three book-length projects: *Ending the Fossil Fuel: Keep Them in the Ground (contract, MIT Press), *Distant Horizons: An Ethic of the Long Term *The Politics of Urgent Transition*
He was recently awarded a writing fellowship at the Rachel Carson Center in Munich. Before that he was named an Aldo Leopold Leadership Fellow, sponsored by the Packard Foundation, and before that was a Pew Faculty Fellow for International Affairs.
Princen received his Ph.D. in Political Economy and Government from Harvard University in 1988 and a Bachelor of Arts in biology from Pomona College in 1975. He was a MacArthur Foundation Post-Doctoral Visiting Research Fellow in International Peace and Security at Princeton University from 1988 to 1989. He serves as Faculty Associate, Program in the Environment; Faculty Affiliate, Erb Institute for Global Sustainable Enterprise; Co-Director, Workshop on Urgent Transitions; and Associate Professor of Natural Resource and Environmental Policy; all at the University of Michigan.

Ecotoxicology in tropical and polar regions (I)

1

The Laguna Madre de Dios, a Costa Rican tropical coastal lagoon ecosystem at risk

L.E. Castillo, Universidad Nacional Costa Rica / IRET; C. Ruepert, Universidad Nacional / IRET; F. Ramirez, Universidad Nacional / Central American Institute for the study of toxic substances IRET; G. Moraga, D. Ballestero, C. Brenes, S. Vargas, R. Benavides, Universidad Nacional; F. Mena Torres, Universidad Nacional / IRET; M. Arias, Universidad Nacional; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP

The Laguna Madre de Dios is a coastal lagoon located in the Caribbean watershed of Costa Rica. The lagoon has great ecological value but is submitted to anthropogenic stress mainly because of an intensive use of fertilizers and pesticides in the banana, rice and pineapple plantations located upstream. The study presented here is part of a broader study on pesticide risk assessment that includes pesticide runoff, a toxicity assessment of pesticides used in plantations in the area of the RMD Basin; an *in situ* toxicity and ecological assessment of pesticide run-off and the application of the PERPEST and TRIAD methodology. Land and pesticide use studies were carried out using GIS. Pesticide use information was collected through interviews. An hydrological and bathymetric study were carried out at the lagoon in dry and rainy weather.. Sampling sites for pesticide residues and nutrient analysis were selected to cover canals and creeks that flow into the River Madre de Dios (RMD) collecting runoff from the agricultural areas. The main pesticides found in the area include insecticides/nematicides, herbicides and fungicides (amethrine, chlorpyrifos, chlorothalonil, diazinon, diuron, epoxiconazole, ethoprophos, hexazinone and pirimetanil) in concentrations frequently higher than the Water Quality Criteria for the protection of aquatic organisms. Twenty three marine, estuarine and freshwater fish species were identified during one sampling occasion in the lagoon in 2012. Reports of 18 fish kills have been documented in the area for the years 2007-2009, several insecticides and difenoconazole were present in the samples analyzed, reported in the area per year between 2007-2012. The analysis of several fish kills reported during 2013 show the presence of 5-6 pesticides present in those samples including organophosphates such as terbufos and fenamifos as well as diazinon, which are highly toxic compounds. The frequent ocurrence of pesticides in the lagoon in concentrations over the criteria for the protection of aquatic organisms points out the risk of ecological damage to this ecosystem as is confirmed by the fish mortalities ocurrig in the area.

TIER I Toxicity assessment of pesticides used in banana and pineapple plantations detected on the Río Madre de Dios watershed, Costa Rica

M. Arias, F. Mena-Torres, R. Ugalde, Universidad Nacional; R. Ramo, Stockholm University; L. Grandas, Universidad Nacional; C. Ruepert, Universidad Nacional / IRET; L. Castillo, Universidad Nacional; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP

Pesticide runoff in developing countries of tropical regions pose high risks to aquatic ecosystems, due to poor agricultural practices and the use of highly toxic compounds. Costa Rica is among the countries that import higher amounts of agricultural pesticides and environmental toxicity to aquatic ecosystems have long been a concern for communities near intensive areas of banana and pinneaple production. The Río Madre de Dios (RMD) watershed in the Caribbean lowlands is one of the aquatic ecosystems in the Caribbean area where extensive banana and pinneaple plantations exist. This ecosystem has been the focus of attention for several years now as a consequence of fish kills reported with a certain frequency and potentially associated with pesticide runoff. The purpose of this work was to perform a first tier assessment of the toxicity risks of the maximum pesticide concentrations (MEC) found at RMD, by using acute toxicity hazard concentrations for 5% of the species (HC5) and native species toxicity values. Risk Quotients (MEC/HC5≥1.00) were found for the insecticides carbofuran, chlorpyrifos, diazinon, ethoprophos, carbaryl and terbufos and for the herbicide diuron. Toxicity values (LC50-96hrs) for *Parachromis dovii* (fish) were 242 (179-328 95%CI) μg/L for ethoprophos, 202 (140-242 95%CI) μg/L for carbofuran and 117 (87-158 95%CI) μg/L for clorpyriphos. In the case of crustaceans, for *Daphnia ambigu a*EC50-48hrs values of 1.1 μg/L (± 0.8, SD), 0.3μg/L (±0.2, SD) and 0.14 (± 0.001, SD) were found for carbofuran, diazinon and clorpyriphos respectively. Meanwhile, for *Macrobrachium* sp. values of 20 μg/L (12 – 3395%CI), 23.8μg/L (13.4 - 35,895%CI) and 24μg/L (15 – 3895%CI) were found for ethoprophos, carbofuran and diazinon. Finally, the acute toxicity (EC-7d) of diuron to *Lemna* sp. was found to be 31μg/L (±12, SD) and 16μg/L(±3.2, SD) based on reproduction and dry weight measurements.According to acute environmental quality criteria derived from ecotoxicological databases and from the sensitivity of native species measured in the lab, the pesticide concentrations in the RMD basin can have toxic effects on aquatic biota. An ecotoxicological evaluation is the next step to corroborate if the toxicity potential seen can be measured in the field, and if other impairments on community structure and/or function can be detected. **\n**

Integrated ecological risk assessment of pesticide run-off using the TRIAD weight-of evidence approach: a case study in the Rio Madre de Dios River, Costa Rica

J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; M. Arias, Universidad Nacional; F. Mena Torres, Universidad Nacional / IRET; S. Echeverria Saenz, Universidad Nacional / Instituto Regional de Estudios en Sustancias Toxicas IRET; C. Ruepert, Universidad Nacional / IRET; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra; M. Tedengren, Department of Ecology Envionment and Plant Sciences DEEP; L. Castillo, Universidad Nacional

The “TRIAD” an ecological risk assessment (ERA) tool based on the combined weight of evidence (WoE) from several lines of evidence (LoE) was used in order to assess the ecological risks from pesticide contamination in the Rio Madre de Dios (RMD), a watershed that drains water from banana and pineapple plantations in the Caribbean lowlands of Costa Rica. The TRIAD is a tiered ERA method, where contamination risks are assessed based on the integration of data from three independent LoE from: 1) chemistry, 2) toxicology, 3) ecology. Within a research project called “TROPICA” (Tiered Risk Assessment of Pesticide Use in Costa Rican Agriculture) chemical, toxicological, and ecological measurements were carried out ca 2-3 times a year in the Rio Madre de Dios, a river system that receives drainage water from banana and pineapple plantations. In two companion studies of the TROPICA project, TIER 1 and TIER 2 ERA analyses were done using toxicity testing in the laboratory and *in situ* respectively, in order to assess the risks from pesticide contamination in the RMD watershed. In this study we gathered all chemical, toxicological and ecological data from these two studies over a sampling period of 3-4 years, scaled all the data from 0-1 values, where 0 corresponds to the minimum and 1 to the maximum risk values, using various scaling techniques. Then the scaled data from the three independent LoE were integrated using geometric means and contamination risk values and their standard deviations were calculated for each sampling season and for the total project duration. Our results show that the RMD river is at high chemical risks from both pesticides (0.7) and nutrients (PO_4) (0.6 - 0.7), that the toxicity risk to aquatic organisms is low (0.1 - 0.2) (based on biomarker and toxicity tests), and that the ecological risks to benthic invertebrates is relatively high (0.5 – 0.7), but not due to pesticide concentrations but rather due o low oxygen levels and eutrophication. Overall the integrated contamination risk to native aquatic organisms in the RMD was moderate (0.4) to high (0.6) indicating that mitigation measures are imperative and urgently needed in order to protect the native wildlife from pesticide and nutrient contamination.

4

Integrated Ecological Risk Assessment (ERA) of aquaculture and anthropogenic pollution in the Phu Long commune, Hai Phong city, Vietnam

P. Bruce, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; V. Le, Stockholm University / Ecology Environment and Plant Sciences; H. Than Thi, MCD Vietnam; L. Nguyen Thi Tuyet, HACEM; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP

With increased globalization, climate change, high development rates and a growing population several Southeast Asian countries, such as Vietnam, face increasing environmental threats with a following need for preventive and remediation strategies. For the first time in Vietnam, we have applied an adapted version of the TRIAD, an ecological risk assessment (ERA) tool based on the combined weight of evidence (WoE) from several lines of evidence (LoE) and tiered approach ensuring an effective use of resources in order to assess the risks from anthropogenic pollution on the marine environment off Cat Ba island Biosphere Reserve. In a TRIAD data from different LoE were collected and then scaled from 0-1. Integrated risk values were then determined to provide evidence based management options. In the present study the TRIAD method was modified in order to also include socio-economical data, gathered from interview studies Physico-chemical measurements (nutrients, contaminants, O2, suspended solids) together with ecological/biological measurements (community structure of phyto-, zooplankton and benthic fauna) were gathered from three different coastal sites with various aquaculture pressures, and integrated with the TRIAD to interview data from the local population.The results show medium to high risk for several physico-chemical properties and concentrations such as heavy metals, nitrogen and coliforms. The ecological LoE shows low to medium risks for zoobenthic- and plankton communities and abundance and high risk for economic activities such as aquaculture and fishery. When the LoE are integrated, the environmental risk seems to be intermediate or low with acceptable levels of uncertainty. The quality of the assessment relies on good references, such as comparable sites with desirable

environmental status, earlier studies for background levels and relevant environmental quality criteria (EQC). Since a majority of the environmental quality criteria used in Vietnam derive from studies conducted in temperate regions it is questionable if they are suitable criteria in the tropical environment of Southeast Asia and this study shows that local site-specific environmental criteria as well as more background data from monitoring programs are needed in order to assess the ecological risks from growing human activities on coastal marine resources in Vietnam.

5

Ecological risks of antibiotics applied in freshwater cage aquaculture – a case study in tropical Thailand

A. Rico, Wageningen University / Aquatic Ecology and Water Quality Management; R. Oliveira, University of Brasilia / Department of Genetics and Morphology; I. Domingues, University of Aveiro / CESAM Department of Biology; M.R. Dimitrov, Wageningen University and Research Centre; R. van wijngaarden; K. Sataporvanit, Kasetsart University; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra

Intensive aquaculture relies on the use of chemicals for the prevention and treatment of disease outbreaks, and constitutes one of the most important pathways for antibiotics into the environment. In this study we investigated the use, environmental fate and ecological risks posed by the use of antibiotics in tilapia cage farming in tropical Thailand. The use of antibiotics was investigated through interviews to 29 farmers, and concentrations of the most commonly used antibiotics, enrofloxacin (ENR) and oxytetracycline (OTC), were monitored in water and sediment samples collected in the Tha Chin and Mun Rivers. The toxicity of ENR and OTC was assessed by performing laboratory experiments with tropical freshwater invertebrates. Furthermore, the toxicity of ENR was assessed on five structural (macroinvertebrate, zooplankton, phytoplankton, periphyton and bacterial communities) and two functional (organic matter and nitrogen cycling) ecosystem endpoints by performing a microcosm experiment simulating the antibiotic exposure patterns found in the environment. All the interviewed farmers reported to routinely use antibiotics. Maximum antibiotic concentrations in the river water were 1.6 and 49 μg/L for ENR and OTC, respectively. Antibiotic residues were found in all the collected sediment samples, with concentrations between 1.4-2,339 μg/kg d.w. for ENR, and 4.5-4,062 μg/kg d.w. for OTC. The results of the laboratory experiments showed that tropical invertebrates are only moderately sensitive to water ENR and OTC concentrations. The results of the microcosm experiment did not show consistent treatment-related effects on the structure of the primary producer and invertebrate communities, however, demonstrated a reduction on the abundance of ammonia-oxidizing bacteria and archaea at measured environmental concentrations. Nitrification was only affected at concentrations above 100 μg/L, indicating that the aquatic exposure to ENR might have limited or no significant consequences for ecosystem functioning. We conclude that the ecological risks posed by antibiotic residues to primary producer and pelagic invertebrate communities seem to be minimal, however, more research is needed to assess the effects on benthic communities chronically exposed to antibiotic mixtures. The results of this study can be extrapolated to other tropical regions and contribute to further our understanding on the ecological risk assessment of antibiotics for tropical aquatic ecosystems.

Effects of Chlorpyrifos ethyl on cholinesterase activity in Climbing perch (Anabas testudineus , Bloch, 1792), from rice-fields in the Mekong Delta, Vietnam

T.T. Nguyen Thanh, Nong Lam University / fisheries; H. Berg, Orebro University; C. Hguyen, Can Tho University / College of Env Natural Resources; H.T. Nguyen, Nong Lam University / Faculty of Fishery

Abstract Climbing perch (*Anabas testudineus,* Bloch, 1792), is commonly harvested in rice-fields in the Mekong delta. Despite its importance in providing food and income to local households there is little information about how this species is affected by the high use of pesticides in rice farming in the Mekong Delta. Organophosphate insecticides, such as chlorpyrifos, are commonly used and are highly toxic to aquatic organisms. This study show that brain AChE activity of climbing perch fingerling placed in cages within rice fields was significantly inhibited by single application of chlorpyrifos The water concentration of chlorpyrifos dropped below the detection limit within 3 days, but the inhibition of brain AChE activity remained for several more days. In addition, the chlorpyrifos treatments had a significant impact on survival and growth rates of climbing perch fingerlings, which was proportional to the exposure level. The results indicate that the high use of pesticides in the Mekong Delta could have negative impact on aquatic organism, fish yields and the aquaculture industry in the Mekong Delta.
Keywords: *Climbing perch; Chlorpyrifos; acetylcholinesterase, Mekong Delta*

Marine and coastal ecotoxicology and risk assessment (I)

7

Combined effects of two emerging environmental stressors (PFOS and CO2) on estrogenic and biotransformation responses of Atlantic cod (G. morhua)

A. Arukwe, NTNU / Department of Biology; G. Preus-Olsen, Norwegian University of Science and Technology NTNU / Biology; M. Olufsen, Norwegian University of Science and Technology NTNU; S.A. Pedersen, Norwegian University of Science and Technology NTNU / Biology; R.J. Letcher, Environment Canada / Ecotoxicology and Wildlife Health Division

Until now, little effort has been put into investigating interactive effects between POPs and elevated CO2 levels (hypercapnia) in the aquatic environment. In the present study, juvenile Atlantic cod were exposed to PFOS (0, 100 and 200 µg/L) for 1 hour/day in 5 days, followed by changes in elevated water CO2 saturation (0, 0.3 and 0.9%) for 3, 6 and 9 days. Endocrine disrupting potential of PFOS and elevated CO2 levels, both singly and in combination, were examined, in addition to steroid and xenobiotic metabolism (CYP1A, CYP3A) and HIF-1a. Elevated CO2 produced increased levels of E2, T, 11-KT with concomitant increases in mRNA expression of estrogen responsive genes. PFOS produced a weak time- and concentration-dependent estrogenic effect, but no effect on steroid hormone levels. Exposure to combined CO2 and PFOS produced gene expression patterns that are different from the effects observed for CO2 or PFOS alone, indicating interactive effects. Principal component analysis (PCA) did not produce significant components at day 3. The PCA for day 6 and 9 produced the best model fit, where particularly, the individual scores from the different CO2 scenario exposure groups tended to group separately. The resulting model contained three principal components (PCs) explaining a total of 56.4% of the total variation. When pooling the various exposure groups within each CO2 exposure scenarios, scores of three resulting CO2 groups were significantly separated along the first principal component (PC1; Q^2=0.064) with increasing CO2 saturation (p[normal vs moderately increased CO2]=0.029, p[moderately vs highly increased CO2]=0.020), p[normal vs highly increased CO2]=0.000). PC1 mainly explained the individual variation within transcript levels of the estrogenic response genes, followed by levels of sex steroid hormones. These observations suggest that hypercapnia and emerging POPs such as PFOS in combination could modulate the estrogen signaling in juvenile Atlantic cod, with potential consequences for sexual development and reproduction. These findings suggest a potential for adverse effects of increased anthropogenic CO2 emissions on fish reproduction. This also raises the question whether such interactive effects might be observed in other aquatic species and with other endocrine disrupters and POPs as well. Such findings could have implications for the accuracy of current risk assessments of emerging POPs, under changing climatic conditions.

Parental exposure to environmental concentrations of diuron leads to aneuploidy in embryos of the Pacific oyster as evidenced by fluorescent in situ hybridization

A. Barranger, F. Akcha, IFREMER / Department of Biogeochemistry and Ecotoxicology; R. Brizard, E. Maurouard, IFREMER; T. Burgeot, IFREMER / BIOGEOCHIMIE ECOTOXICOLOGIE; A. Benabdelmouna, IFREMER

Over 80% of marine pollution comes from the mainland and originates from industrial, agricultural and urban activities. France is the leading user of agrochemicals in Europe. As a result of this high consumption of phytosanitary products, pesticides can contaminate coastal waters through various processes, including run-offs, leaching and spray drift. Genotoxicity is common to several families of major environmental pollutants, among them pesticides, which represent therefore a potential major environmental hazard for marine organisms. To investigate these points, the GIMEPEC (Genotoxicity, IMmunotoxicity and rEprotoxicity of Pesticides in *Crassostrea gigas*) project has been set up to study in the Pacific oyster the genotoxic effects of an herbicide, diuron, on the genome of genitors and, the possible transmission to the offspring of damaged DNA and its consequences on oyster fitness. Following exposure of genitors in active gametogenesis to environmental concentrations of diuron to two 7 day-exposure pulses, the genotoxicity of diuron was observed in both genitors, their gametes and the offspring using two complementary approaches, comet assay and flow cytometry. In spat from diuron-exposed genitors, a significant decrease in nuclear DNA content was measured, with over 15% of individuals showing DNA hypodiploidy. In this study, fluorescent *in situ* hybridization (FISH) was used to further characterize at the chromosomal level this diuron-induced DNA damage. rDNA genes (5S and 18-5.8-28S), previously mapped onto *C. gigas* chromosomes 4, 5 and 10, were used as probes onto interphase nuclei preparations. Results conclusively show higher aneuploidy (hypo- or hyperdiploidy) level in embryos from diuron-exposed genitors with damages on the three studied chromosomal regions. This work suggests that sexually developing oysters are vulnerable to diuron exposure, leading to negative impact on reproductive success and recruitment of oyster.

Single and mixture effects of selected emerging pollutants studied in Precision-cut liver slices of Atlantic cod (Gadus morhua)

C. Bizarro, Dept of Zoology and Animal Cell Biology; M. Eide, A. Goksoyr, University of Bergen Bergen / Dept of Biology; M. Ortiz-Zarragoitia, University of the Basque Country

Pollutants affect aquatic life in many different ways, causing toxicity, disrupting the reproduction and development, and reducing the survival of organisms. Some mechanisms of action of certain pollutants have already been assessed, but one of the greatest emerging challenges is to understand the effects of mixture toxicity. The Atlantic cod (*Gadus morhua*) is an economically important species widely distributed in the North Atlantic, which is vulnerable to discharges from human activities, such as coastal industries and expanding offshore activities. In fact, adverse effects of discharges on cod reproduction and health, e.g. by disrupting endocrine signalling pathways have been demonstrated. The liver is the organ mainly responsible for metabolizing xenobiotic compounds through the biotransformation pathway and that makes it an attractive model for toxicological studies in fish. Thus, in the present study, we aimed to apply the precision-cut liver slices (PCLS) method as a tool to test the effects of common pollutants of distinct chemical origin, such as chlorpyrifos, bis(2-ethylhexyl)phthalate (DEHP), perfluorooctanoid acid (PFOA) and 17α-ethynylestradiol (EE2), individually and in mixtures, on cod liver, using gene level biomarkers (*vtg, cyp1a, fabp, cyp7a1, cyp24a1, hmdh)*. No significant differences were observed in the transcription of any of the target genes when exposed to single chemicals. Only *vtg* and *fabp* genes were up-regulated when exposed to EE2. Similarly, this both genes were also up-regulated when exposed to mixtures. But in addition, transcription of *hmdh* and *cyp24a1* was significantly down-regulated in the mixtures. Additive effects of selected compounds in both tested mixtures were detected, in comparison to single exposure conditions. Previous studies showed that most genes altered by exposure to a certain single chemical, may not be useful for diagnostic chemical causation in a mixture exposure situation, where a “something from nothing”-effect could be observed. The application of cod PCLS for screening complex environmental samples was demonstrated as a valuable tool. Further works are necessary to improve the sensitivity of this bioassay, in order to implement its application in future marine environmental risk assessment scenarios. Keywords: PCLS, pollutants, mixtures, cod

Toxic pressure in Dutch estuarine and coastal waters by chemical stressors inhibiting photosynthesis of marine microalgae

P. Booij, Institute for Environmental Studies; P. Leonards, VU University Institute for Environmental Studies / Chemistry Biology; M. Lamoree; P. de Voogt, University of Amsterdam / IBED; S. Sjollema, H. van der Geest, W. Admiraal, University of Amsterdam; R. Laane, D. Vethaak, DELTARES

In recent years sources, types and levels of chemicals in estuarine and coastal waters have increased as a consequence of anthropogenic activities. These chemicals can affect primary production at the basis of the marine food chain. Chemicals stressors are hypothesized to disturb the photosynthesis of phytoplankton and, therefore, the carrying capacity of coastal and estuarine waters. In our study we identified and confirmed the main contributors to the toxic pressure on microalgae in Dutch estuarine and coastal waters and investigated the toxic pressure on marine microalgae of these compounds under environmental conditions. Effect-Directed Analysis was performed with passive samplers at three estuarine and coastal locations in The Netherlands. Passive sampler extracts were tested for toxicity on marine microalgae using the Pulse Amplitude Modulation (PAM) fluorescence assay. To reduce the complexity of the extracts micro-fractionation in 96 well plates was performed using an UPLC-UV system. Compounds were identified and confirmed using LC-ToF-MS. In addition, spot water samples were taken at the three study locations, extracted with solid phase extraction and the confirmed compounds were quantified with LC-ToF-MS. To determine the toxic pressure, measured concentrations in spot water samples and water concentrations from monitoring data were used and dose-response curves of the confirmed compounds were determined in the PAM assay. Concentrations from monitoring data showed that for the toxic pressure at different locations along the Dutch estuarine and coastal waters in 2012 a low risk is expected. However, concentrations can occasionally reach potential effect levels. Based on our results the identified and confirmed biocides contribute to the toxic pressure in Dutch estuarine and coastal waters. *Acknowledgement* - This project is financed by DELTARES, NL.

Impact of pollutants and climate change stressors on embryo-larval development of the Pacific oyster Crassostrea gigas in the Arcachon Bay

P. GAMAIN, EPOC; J. Cachot, Université Bordeaux / EPOC; P. Gonzalez, Géochimie et Ecotoxicologie des Métaux dans les systèmes Aquatiques GEMA team UMR CNRS Université Bordeaux; B. Morin, EPOC

The Pacific oyster, *Crassostrea gigas*, is the main cultivated species in the Arcachon bay. In recent years, problems of recruitment and mortality of juvenile or adult oysters occurred. These crises can be indicative of changes in Arcachon bay’s water quality. Previous studies have highlighted the presence of many molecules, with significant concentration in water, mainly herbicides, such as metolachlor and its metabolites, and "anti-fouling" compounds such as copper (Cu). Occurrence of these molecules in the Arcachon bay could explain some of the problems encountered. In the context of global climate change, the effects of rising temperatures and salinity changes could alter development and survival of embryos and larvae. This study aims to assess the combined effect of contaminants, temperature and salinity on the early growth phase of Pacific oyster larvae. Embryotoxicity bioassay has been used. Spawning was triggered by thermal stimulation of male and female oysters. Eggs were fertilized with sperm to obtain embryos. Oyster embryos were then exposed to concentrations of 1 $\mu g.L^{-1}$ (corresponding to environmental concentration) 10 and 50 $\mu g.L^{-1}$ of Cu. Metolachlor was tested at 10 $ng.L^{-1}$ (environmental concentration) 100 and 1000 $ng.L^{-1}$. During exposure, embryos were incubated at different temperatures (18 °C, 20 °C, 22 °C, 24 °C, 26 °C, 28 °C and 30 °C) and different salinities (23, 27, 30, 33 psu). After 24h, developmental abnormalities of D-larvae were analyzed. Salinities from 23 to 33 psu, which are currently encountered in the Arcachon Bay, did not affect normal development of embryos. However, environmental concentrations of Cu and metolachlor increased developmental abnormalities. In addition developmental abnormalities increased in a dose-dependent manner. Larval development was also affected by temperature. Below 24 °C, there was no development of D-larvae. Beyond 24 °C, especially at 30 °C, there was an increase in developmental abnormalities in control and contaminated conditions. No difference observed between control and contaminated condition suggested a predominance of temperature effect. The present study confirmed the high sensitivity of Pacific oyster embryos to heavy metals, pesticides and increasing temperatures. Toxicity threshold were in the range of concentrations currently measured in the Arcachon bay. High temperatures seemed to have more effect than contamination.

Gut passage of microplastics and bioavailability of co-contaminants associated with microplastics in organisms exposed via diet or aqueous phase

T.B. Henry, HeriotWatt University / School of Life Sciences; H. Hatfield, V. Sleight, Plymouth University; A. Bakir, University of Plymouth Enterprise ltd / Science and engineering; R.C. Thompson, University of Plymouth / School of Biological Sciences

Microplastics contaminate marine environments and can have various toxicants (termed here co-contaminants) ad/absorbed to them that can be transferred to organisms. The association of model co-contaminants 17α-ethinylestradiol and phenanthrene with polyethylene microspheres was evaluated by assessing changes in expression of biomarker genes [vitellogenin (*vtg*) and cytochrome p450 1A (*cyp1A*) respectively] in larval zebrafish *Danio rerio* exposed in the aqueous phase. Zebrafish were used as an analytical tool to identify changes in the associations of the co-contaminants during ad/absorption reactions with microplastics. Gut retention and the time required for microplastics to pass through the gut of *C. maenas* was investigated according to microplastic diameter (45-55 μm & 850-1000 μm) and compared to coarse sand control (1000-1230 μm). Crabs were fed particles embedded in a gelatine pellet and uneaten pellets and faecal material were collected and particles enumerated over 240 hours after exposure. At a phenanthrene concentration of 0.5 mg/L the mean expression of *cyp1A* was 3.3 relative fold induction (RFI) and the RFI was 2.2 (lower, but not significant) after 5 d mixing with microplastics. In contrast, the results of 17α-ethinylestradiol (1 μg/L) experiments indicated a significant and up to 70% lower *vtg* expression in presence of microplastics. We found that *C. maenas* ingested microplastics in gelatine pellets, but that ingestion was inversely related to particle size and crabs did not distinguish between coarse sand and microplastics. The majority of all particles ingested by crabs were egested within 48 h, and near 100% recovery of all ingested particles indicated that absorption of microplastics was minimal (not detectable). The time taken for ingested particles to be egested differed among particle types (i.e., coarse sand compared to microplastics). Mean gut retention time (GRT) required for 50% of particles to be egested (i.e., the GRT_{50}) was lowest for coarse sand and significantly higher for both sizes of microplastics. Association with microplastics was related to physicochemistry of co-contaminants. *C. maenas* ingested food with microplastics and increased gut retention time for microplastics compared to other particulates (i.e., sand) suggests greater potential for associated co-contaminants to be released into organisms.

Waste and Wastewater effluents: chemical and ecotoxicological characterisation (I)

13

Taking the Chemical Pulse of a Nation by Example of the U.S.A.

R.U. Halden, Arizona State University / Center for Environmental Security

Municipal wastewater treatment plants (WWTPs) are designed first and foremost to protect human populations and the ecosystems humanity relies on. Yet, they also offer additional functionality in serving as chemical observatories for the sewersheds they service. If data are compiled from a large enough and representative sample of WWTPs, it becomes possible to determine the chemical

mass flow of large cities, regions, states and even a nation as a whole. By example of the United States of America, a case study is provided, demonstrating the utility and informational power of chemical monitoring at WWTPs. Aside from observing chemical mass flow through society, monitoring at WWTPs also enable the identification and characterization of the behavior of established and emerging pollutants. Harmful chemicals, which travel through the treatment process without undergoing any appreciable degradation, are of particular concern. They may be discharged into surface waters during reclamation of treated effluent or find their way into terrestrial environments via applications of treated municipal sludge, the semi-solid by-product of wastewater treatment. In the U.S., sewage sludge is routinely applied on land for inexpensive disposal of this abundant, unwanted material that also features desirable constituents, such as a high content of nutrients and organic carbon. Wastewater-borne chemicals of concern covered in this study include traditional environmental pollutants, such as toxic organohalogens (polychlorinated biphenyls, brominated flame retardants, perfluorinated surfactants, etc.) as well as a large number of pharmaceuticals and personal care products (PPCPs), whose adverse impacts on human health and ecosystems are still emerging. Data from meta analyses are provided, informing on the occurrence, removal, biodegradability, persistence, and mass flux of organohalogens and emerging contaminants through WWTPs. Case studies show that mass balances on chemicals during municipal sewage treatment may serve as a powerful tool for identifying unsustainable chemistry and for studying chemical consumption and disposal patterns. Effective utilization of this information by regulatory agencies can aid in curtailing environmental pollution, thereby limiting adverse ecological and human health effects.

14

Fate of pharmaceuticals in urine treatment

C.S. McArdell, Eawag / Department of Chemical Pollution; B.D. Oezel, A. Hug, L. Strande, K. Udert, Eawag

Urine has a large potential to be an effective fertiliser due to its rich nutrient content, specially in developing countries. Since the majority of the pharmaceuticals taken by humans are excreted via urine, major concerns over the recycling of urine nutrients arise from the uncertainty whether pharmaceuticals contained in the fertiliser could have adverse effects on the soil or food. Therefore, research on the pharmaceutical content and possible removal processes is important. Biological treatment of urine with nitrification is a recommended technique for the stabilisation of nitrogen in urine and the removal of easily degradable organic substances. In this study, selected pharmaceuticals were investigated during urine treatment to elucidate whether a pharmaceutical free treated urine can be achieved. Based on preliminary urine screening results in Durban (South Africa), a representative mixture of 12 pharmaceuticals was chosen for batch experiments under anaerobic condition to simulate storage and during urine treatment under nitrifying conditions. Furthermore, sorption to activated carbon as post-treatment was also evaluated. This study is embedded in the VUNA project (www.vuna.ch, financially supported by the Bill & Melinda Gates Foundation), where a dry sanitation system was developed and is installed in South Africa to recover nutrients from urine in small decentralized reactors to produce a valuable fertilizer, affordable for the poor, to promote entrepreneurship and to reduce pollution of water resources. The experiments show that long-term storage is not sufficient to substantially remove the amount of pharmaceuticals in urine. However, in aerobic biological processes, as they occur in a reactor for nitrification of urine, elimination of several pharmaceuticals was observed. Since the main purpose of nitrification is the stabilisation of nitrogen in urine and the removal of easily degradable organic substances, pharmaceutical removal is a beneficial side-effect. A post-treatment of the nitrification effluent by adsorption to powdered activated carbon could reduce the content of all pharmaceuticals to acceptable low levels.

15

Multivariate Workflow for the Screening of Nontarget Peaks from Biologically-Treated Wastewater

J. Schollee, Eawag Swiss Federal Institute of Aquatic Science and Technology; R. Ottermanns, RWTH University; J. Hollender, Eawag / Environmental Chemistry

It is known that transformation products (TPs) may be formed during biological treatement of wastewater (WW). Together lab studies and targeted screening offer a limited picture of the compounds in treated WW. In this project, samples were collected from the influent and effluent of an activated sludge treatment process and analyzed with liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS). For data processing, a combined nontarget screening and multivariate analysis approach was applied to select peaks of possible TPs for structure elucidation. A validation of the workflow was also done. Two sets of 48-hr composites were collected from a WW treatment plant in Duebendorf, Switzerland. These sets of composites were analyzed separately and were further subdivided into a validation set of samples, which were spiked with parent and TPs, and an unspiked set, used for nontarget analysis. Samples were filtered and enriched with an off-line solid-phase extraction (SPE) cartridge containing the following three layers: reverse phase, ionic exchange, and activated carbon. Samples were measured with LC-HRMS using electrospray ionisation (ESI). Data processing of the validation set was done with Thermo QuantBrowser while data processing of the nontarget set was done with R statistical software. Semi-quantitative target screening of over 300 compounds was done with EnviMass. Results from the EnviMass screening showed that while many target compounds were removed, a number also showed persistance over the treatment. Analysis of the validation set showed that principle component analysis (PCA) was successful in distinguishing influent and effluent samples in the first principle component (PC1). Additionally, the loadings indicated that generally parent compounds were associated with the influent samples, while TPs with the effluent samples. Similar analysis was carried out with the nontarget data. The PC1 explained 60% of the variance and could separate influent and effluent. But selection of the peaks at this stage was still difficult; therefore further selection of peaks was done using cluster analysis, multiresponse permutation procedure (MRPP), and indicator species analysis. This workflow generated a list of 2867 peaks associated with the influent and 759 peaks associated with the effluent ($p < 0.01$). These peaks can then further be selected based on chemical information (*i.e.,* isotope and/or adducts) for structure elucidation and identification.

16

Removal of Parabens and Benzophenone-4 from wastewater and environmental impact assessment

D. Molins-Delgado, Environmental Chemistry; E. Pastoret, S. Diaz-Cruz, IDAEACSIC / Environmental Chemistry; D. Barcelo, IIQABCSIC / Environmental Chemistry

Parabens (PBs) are chemicals widely used as preservatives by personal care products, pharmaceutical and food industries. Sunscreens are also important chemicals in these industrial sectors. Most organic sunscreens are oils soluble; however, Benzophenone-4 (BP-4) is water soluble and is used in the products called “oil-free”, formulated to feel less oily. PBs are becoming increasingly controversial, because some studies have shown that low level exposure cause weak estrogenic activity at environmentally relevant concentrations [1]. As a consequence of its widespread use and its chemical stability and resistance to biodegradation, BP-4 is being increasingly detected in surface waters [2]. The BP-4 levels that are commonly found in surface waters are generally too low to cause acute toxicity, but chronic effects cannot be ruled out. Indeed, *in vitro* tests have shown that BP-4 has multiple endocrine disrupting activities in fish [3]. Data on the removal efficiency of these compounds in WWTPs is still scarce. The aim of the present study was to investigate the presence of the 4 most used PBs, i.e. *methyl-, propyl-, butyl- and benzylparaben* and the most water soluble benzophenone derivative, BP-4, in wastewaters of a network of 20 WWTPs located in Spain. Samples were analyzed by a fully automatic on-line SPE-HPLC-QqTRAP-MS/MS method. Results confirmed the wide presence of PBs in both matrices, being the highest concentrations found for propylparaben in influent samples. Removal efficiencies for this set of compounds were extremely high (90-100%). Similarly, the UV filter was observed in all wastewater samples. Its elimination was pretty variable depending on the WWTP, showing removal efficiencies in the range 8-91%. The relationship among its half-life time, removal rate and the WWTP hydraulic retention time will be discussed. The risk posed for the aquatic organisms exposed to the effluents discharge was estimated, and the eco-toxicological implications will be discussed in the presentation, as well. **References** [1] P. Advanced treatment for removal of micropollutants in municipal effluents by fungal laccases

F. Spina, University of Torino / Dep of Life Sciences and Systems Biology; C. Cordero, University of Torino / Department of Drug Science and Technology; T. Schiliro, University of Torino; B. Sgorbini, University of Torino / Department of Drug Science and Technology; R. Degan, G. Gilli, University of Torino / Department of Public Health and Microbiology; C. Bicchi, University of Torino / Department of Drug Science and Technology; C. Varese, University of Turin

Pollution of water courses is generally caused by dyes, amines, phenols, heavy metals and surfactants as well as newly discovered contaminants as Endocrine Disrupting Chemicals (EDCs). Recently, the environmental concern rose since commonly used treatment processes are only partially effective towards these molecules, causing their progressive and constant accumulation into the environment (wastewaters, river waters and drinking water). A biological approach opens new scenarios for the treatment of wastewaters contaminated by micropollutants: enzymes are indeed able to degrade a wide spectrum of xenobiotics operating at various pH, temperatures and ionic strength. In the present study, a *Trametes pubescens* strain was opportunely stimulated in order to produce the necessary bulk enzymes. Thus the laccase-mediated treatment was used towards

model and real solutions containing recognized EDCs, pharmaceuticals, PCPs, pesticides, etc. A multishot stir bar sorptive extraction with targeted in-situ derivatisation and a gaschromatography-mass spectrometric was used for analytes detection. This analytical method represents an innovative approach, enabling the contemporary detection of several target analytes in real municipal wastewaters: the matrix effect of the samples was negligible and micropollutants were quantifies up to ppt level (ng/l). Laccases demonstrated to be strongly active towards different molecules in spiked samples, being able to degrade at least 19 EDCs, belonging to different chemical classes. In most of the cases, the minimal effective enzymatic concentration was lower than 50 U/l and the analytes initial concentration was halved within the first 24 h. Due to the expected reduction when laccase crude extract is added to a complex matrix (i.e. wastewaters) with variable pH and active microflora, higher enzyme concentration (100 U/l) were adopted for the treatment of real wastewater sample. Laccases degraded most of the detected compounds in a range of 50-96% within 24 h. Besides, the analytes enzymes-catalysed conversion was followed by a significant abatement of the ecotoxicity and the estrogenic activity by means of different model bioassays. Further studies are in progress to optimize the operative parameters (i.e. working pH, laccase concentration, enzyme immobilization), in order to enhance the stability and the efficiency of the laccase-mediated system.

Treatment of micropollutants in municipal wastewater using white-rot fungi

J. Margot, EPFL / Ecological Engineering Laboratory; M. Vargas, A. Contijoch, A. Barry, C. Holliger, École Polytechnique Fédérale de Lausanne

Treatment of micropollutants such as pharmaceuticals and pesticides in municipal wastewater is challenging due to their very low concentrations (ng/l to μg/l), their relatively low biodegradability, and their different physico-chemical characteristics. One potential way to improve micropollutant biodegradation in wastewater treatment plant (WWTP) effluent is by using microorganisms such as white-rot fungi that produce powerful unspecific oxidative exo-enzymes (laccase, peroxidase) that are able to oxidize several micropollutants recalcitrant to bacterial degradation. The goals of this study were (i) to evaluate the ability of white-rot fungi to degrade pharmaceuticals and pesticides and (ii) to develop a fungal treatment which allows removal of a broad range of pollutants but also long-term survival of the fungus in the system. For the first objective, batch experiments with the white-rot fungus *Trametes versicolor* were conducted first in defined medium containing glucose and spiked with 10 mg/l of pollutant (naproxen, sulfamethoxazole or isoproturon), and then in real unsterile WWTP effluents (not spiked) with wheat straw as sole carbon and energy source. *T. versicolor* was able to remove over 90% of naproxen in less than 24 h, and sulfamethoxazole and isoproturon in less than 4 d in defined media spiked with these pollutants. In real unsterile biologically treated wastewater, *T. versicolor* could remove over 90% of the anti-inflammatory drugs diclofenac and mefenamic acid in less than 24 h, and naproxen in less than 48 h, despite their low concentrations (400-800 ng/l). These good removal rates were however not observed for other compounds that needed longer reaction times, due to the short survival (one week) of the fungus in unsterile wastewater. To increase the chance to maintain this organism in the treatment, we designed a fungal unsaturated biotrickling filter composed of wood chips colonized by the mycelium of the white-rot fungi *T. versicolor* or *Pleurotus ostreatus*. Unsterile tap water or treated wastewater spiked with pollutants (10 mg/l) were then trickled with recirculation through the wood-mycelium support. This system allowed a much better survival of the two fungi and was able to remove almost completely naproxen, diclofenac, mefenamic acid, paracetamol, bisphenol A, and triclosan in less than 8 h. Future experiments will show whether the oxidation potential of these fungal filters is applicable to a wider range of pollutants.

Fate and effects of nanoparticles under environmentally realistic conditions (I)

19

Nanomaterials in the aquatic environment: status and challenges ahead

H. Selck, Roskilde University / Dept Environmental Social and Spatial Change; R. Handy, University of Plymouth / School of Biomedical and Biological Sciences; T.F. Fernandes, HeriotWatt University / School of Life Sciences; S.J. Klaine, Clemson University / Institute of Environmental Toxicology CUENTOX

Nanotechnology is expanding rapidly, thus increasing the release of engineered nano-materials (NMs) to the aquatic environment. Sediment is likely to be the environmental compartment most exposed to NMs, and organisms that feed on or live in sediment are likely to be particularly at risk from NM exposure. Due to their increased surface area and reactivity, NMs may be more bioavailable and toxic than their macroscale counterparts. However, very little is known about the environmental impact of NMs and whether they behave similarly in the environment compared to their macroscale counterparts. These factors make it difficult to perform environmental risk assessments and to set quality standards for NMs. Some of the questions we are facing are whether ***nano-specific properties lead to unexpected and new biological effects? If so, is the potential for such effects diminished when NMs are introduced to a complex environment such as the sediment compartment?*** The US-EU Community of Research (CoRs) was established in 2012 to provide a platform for scientists to develop a shared repertoire of protocols and methods to overcome nanoEHS research gaps and barriers. The overall goal of the Ecotoxicity Testing and Predictive Modeling CoR (Ecotox CoR) is to encourage the evolution of i) hazard assessment methods and predictive models built on the foundations of fundamental research characterizing fate (including ageing) of nanomaterials in different environmental compartments and the interactions of nanomaterials with biota and ecosystems, and ii) communication among regulators, experimentalists, modellers e.g., to make data available/presented in a useful data format to help modellers, experimentalists and risk assessors. Based on ongoing work in the Ecotox CoR and two Ecotox CoR workshops we here provide an overview of the state-of-the-art of NMs in the aquatic environment and discuss the challenges ahead by providing suggestions for future research needs that will enable us to perform sound risk assessment and set quality criteria for NMs.

20

Engineered nanoparticles interactions with the environment: towards an understanding of the risk they pose (ENPERA): realism Vs regulation

A. Macken, NIVA / Ecotoxicology and Risk Assessment; I. Nerland, Ecotoxicology and Risk Assessment; A. Laycock, Imperial College London; K. Ndungu, NIVA; K. Thomas, NIVA / Product Metabolism

At present, there is a worldwide focus on engineered nanoparicles (ENPs) in the environment, the possible risks they pose and the potential need for nanospecific environmental risk assessment and legislation. The ENPERA project (Engineered nanoparticles interactions with the environment: towards an understanding of the risk they pose) specifically targets engineered nanoparticles and how they influence “system and process understanding” and “what are the effects of distribution of NPs and how can these be dealt with”. The project has focussed on establishing a knowledgebase that will inform the process of understanding the risks posed to the environment from ENPs, specifically focusing on environmentally relevant exposure scenarios and consideration of fate and effects of ENPs in the environment and within target organisms. Over the past 3 years we have undertaken several projects under the auspices of ENPERA looking at varying environmentally factors and conducting exposure scenarios that best reflect the natural environment (e.g. varying environmental parameters, mixture toxicity with other contaminants of concern in the environment). Another important part of this project has been the involvement in risk assessment and regulation of nanomaterials and the difficulties of coupling both a realistic evaluation and best reflecting the future regulatory requirements for nanomaterials. This presentation summarises the results of the 3 year project and presents a position on the future direction of the assessment and regulation of nanomaterials in the aquatic environment.

21

Modelling fate and transport of engineered nanoparticles in the aquatic environment

A. Markus, University of Amsterdam / IBEDESS; J. Parsons, University of Amsterdam / IBED; E. Roex, DELTARES; P. de Voogt, University of Amsterdam / IBED; R. Laane, DELTARES

Nanoparticles in the aquatic environment are subject to a variety of\nprocesses, such as aggregation to suspended matter and subsequent\nsedimentation or dissolution and chemical transformation. Several\nresearch groups have reported the development of the concentration of\nnanoparticles over time as a result of these processes. This contribution presents a mathematical model for the behaviour of\nnanoparticles in the aquatic environment based on laboratory experiments\ndescribed in the literature. In these experiments the aggregation and\nsedimentation of nanoparticles in water were investigated using different\ntypes of water and different initial concentrations. The mathematical model describes such processes as homoaggregation\n(clustering) and heteroaggregation (adsorption to suspended matter)\nand sedimentation by accounting for various fractions.\nAfter calibrating the model, it was able to adequately describe the\nexperimental data that covered a wide range of initial concentrations.\nUsing the model it is possible to determine which of the processes have\nmost influence on the nanoparticles. For instance, homoaggregation and sedimentation of the clusters of\nnanoparticles thus formed turn out to be the dominant processes if the\nconcentration in the water is of the order of 10 mg/l or more. Only when\nthe concentration is much lower, aggregation (adsorption) to suspended\nmatter becomes appreciable. More experimental datasets are required, however, to determine if the\nprocess parameters that were found here are generally applicable and to\nrefine the model.

22

Spatially explicit fate modelling of engineered nanoparticles

J.T. Quik, RIVM / Aquatic Ecology and Water Quality Management Group Department of Environmental Sciences; J. de Klein, Wageningen University / Aquatic Ecology and Water Quality Management Group; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group Department of Environmental Sciences

Spatially explicit modeling approaches describing the fate of engineered nanoparticles (ENPs) are crucial to advance the site-specific risk assessment of ENPs. Here we introduce a spatially and temporally explicit aquatic fate model for ENPs. This allows for linking ENP fate processes to key hydrological characteristics, e.g. resuspension is linked to the flow rate and aggregation rates are related to the shear stress, which in turn are governed by flow rate. The model further accounts for advective transport, homo- and hetero-aggregation, sedimentation-resuspension, particle degradation, dissolution and burial. Because these processes greatly depend on local conditions, they need to be taken into account for the assessment of site specific risks. Five ENP size classes and naturally suspended solids (NSSs) are considered, returning 25 different hetero-aggregation interactions among different size classes of ENPs and NSSs. Spatially explicit scenario studies were performed for the Dutch river Dommel. Spatially heterogeneous versus uniform scenarios, different emission scenarios and different ENP-type scenarios are compared. As an example outcome: modeling with spatially uniform conditions predict that 99% of the ENPs reach the end of the canal. In the same scenario using the actual characteristics of the Dommel catchment, only 30% of ENP heteroaggregates reach the end of the modeled stretch. This illustrates how important spatially explicit modelling is of site specific exposure- and risk assessment of ENPs.

23

Transformations of silver nanoparticles relevant to product use: exposure to disinfectants and washing solutions

D.M. Mitrano, EMPA Technology Society Lab / Environmental Risk and Management; B. Nowack, EMPA

In the context of assessing the potential risks of nanomaterials (NMs), a life cycle approach (covering production, use and disposal of the NM or nano-product) can represent a holistic view of their potential impacts. Considering that the NM life cycle is determined by their application within a product, relevant exposure scenarios and particle aging/transformations are strongly dependent on the life cycle of nano-enhanced products themselves. For example, treated surfaces will be subjected to oxidants during disinfection and cleaning while nanomaterials embedded in textiles would transform after exposure to detergents during washing. Here, we simulated the aging of Ag engineered nanoparticles (ENP) of different sizes (20 and 40 nm) and surface chemistries (uncoated, citrate, PEG and fulvic acid) through storage, exposure to oxidants (H_2O_2 ranging from 0.03% to 3%) and/or to suspension in standard detergent formulations. Transformations over multiple exposures (e.g. aged suspension in detergent and subsequent exposure to oxidants) were also investigated. Observations of transformation to Ag ENPs from the various physical and chemical treatments included measurement of particle dissolution (Ag^+ release, primary particle diameter reduction), characterization of surface transformation(s) and precipitation of “new” Ag NP from Ag^+. All particles that experienced product-use relevant ageing underwent transformations that changed their fundamental starting characteristics. Furthermore, exposure of a particle to one treatment greatly affected the rate and extent of further transformation(s) upon a second treatment step. This work highlights the fact that since Ag ENPs will readily be aged/transformed during a products life cycle and it is be prudent to consider how these by-products differ from pristine ENPs. This is especially true when attributing toxicity or safety assessments to materials, which may be best done to the (relevantly) transformed particles rather than to the pristine version.

Human exposure to emerging contaminants: monitoring and modeling (I)

24

Does foam application reduce aerosol formation?

A. Bitsch, Fraunhofer ITEM / Chemical Risk Assessment; K. Schwarz, Fraunhofer ITEM / Aerosol technology; S. Hahn, Fraunhofer ITEM / Chemical Risk Assessment; M. Ehni, D. Holthenrich, Federal Institute for Occupational Safety and Health BAuA; W. Koch, German Federal Environment Agency (UBA)

Foam spraying is often used as an alternative to droplet spraying for the treatment of surfaces. It is generally assumed that aerosol exposure is considerably smaller for foam sprays compared to conventional droplet mists. This especially refers to the application of biocides in the occupational section, e.g. the disinfection in the food industry as well as in the consumer section, especially for cosmetics and household cleaning agents (“convenience products”). While there is a well-developed quantitative understanding on the physical and technical parameters determining the exposure risk when using droplet sprays, the characterization of potential aerosol exposure for the application of foams has received little attention so far. In this study the current state of knowledge on the use of foam sprays for biocide application was surveyed from the literature. In addition some exploratory aerosol measurements were carried out for typical biocide products to compare aerosol release from foam and droplet spraying. More than 55 biocidal substances, such as QAV or peracidic products as well as pyrethrins and courmarins comprising products for disinfection, insecticides and rodenticides, are used in foams. The foaming technologies can be classified as mechanical foam generation using low and high pressure and blowing agent foam generation. Since no information on aerosol formation during foam spraying was found in the literature, exploratory aerosol measurements were performed in a laboratory set-up. A reduction of a factor of three was determined for aerosol release in the three health-related size fractions (respirable, thoracic, inhalable), when the biocidal product was sprayed as a foam compared to droplet spraying. Generation of semi-solid, highly-viscous foams using physical blowing agents lowered aerosol formation more than hundred fold. The experiments show that aerosol exposure cannot generally be ruled out when using foams but increasing foam viscosity seems to reduce aerosol release. Thus, further investigations should specify to what extent foam could be explained by physical chemical data of biocidal products by using specific application techniques. These factor determine not only the primary aerosol inhalation exposure but also the risk for exposure and mobility of the environment. Correlations allowing for a prediction of aerosol release from process and product parameters have to be established in future more comprehensive experiments.

25

Sorption of SVOCs to fabrics: Towards determining the role of clothing in human exposure

A. Saini, J. Okeme, University of Toronto / Department of Physical and Environmental Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences; C. Rauert, University of Birmingham; S.J. Harrad,

The indoor environment, with its limited air exchange rate and degradation pathways, holds a large inventory of products and materials that contain SVOCs like flame retardants and plasticizers. These chemicals are released into air by degassing followed by partitioning into dust according to their physical-chemical properties (Shoeib et al, 2012). We hypothesize that clothing acts as a platform for the deposition and re-suspension of particle-phase SVOCs and as a sorbent for the gas phase. To test this hypothesis, studies were conducted to determine the difference in sorption behaviour of cotton and polyester for SVOCs in chamber experiment and to study the sorption of SVOCs from ambient indoor air to pre-cleaned fabrics deployed in homes. The results from chamber experiment suggest that uptake of SVOCs by polyester is faster than cotton, but over time cotton sorbs more because of its large micro-surface area. Also, SEM images of cotton showed its large micro surface area which would provide more area for sorption in contrast to polyester. In case of the fabrics deployed in homes, cotton and rayon showed sorption of mainly BDE-209 along with some BDE-47 and DBDPE in living rooms whereas, those deployed in the bedrooms were dominated by the congeners of penta-BDE that is used in flexible foam furniture. Cotton and rayon which is "regenerated" cellulose fabric (Shaikh et al, 2012), showed similar sorptive behaviour. This study provides evidence for the sorption of gas-phase SVOCs to fabrics under controlled and ambient conditions. Sorption is influenced by the physical-chemical properties of SVOCs (as expected) and fabrics, as well as the morphology of the fabrics.

Heavy metals are naturally occurring and can cause serious adverse effects especially during early fetal development. Lead and mercury have long been suspected for various health effects ranging from endocrine disruption to neurodevelopment. This study was conducted to determine the levels of lead and mercury among sensitive human populations including pregnant women and newborn infants. The levels of both metals were also determined in placental tissue. For this purpose, a total of 105 pairs of pregnant women and their matching infants were recruited from four university hospitals during 2011 and 2012. Blood samples were withdrawn from pregnant women a day before delivery. Cord blood and placental tissue were collected during delivery. Samples were stored at -70 oC until analysis. Auto mercury analyzer (SP-3DS, Nippon) and Graphite Furnace Atomic Absorption Spectrometer (AA6800, Shimadzu) were used for the analysis of merucury and lead, respectively. Lead and mercury were detected in 98.7%, and 100% of the samples, respectively. Lead was detected in the maternal blood, placenta and cord blood 2.62±1.14 ug/dL, 6.85±7.93 ng/g, and 1.91±1.18 ug/dL, respectively. Mercury was detected at 4.83±2.45 ug/L, 9.82±5.48 ng/g, and 7.84±3.55ug/L, respectively. The concentrations of the heavy metals in placenta were significantly correlated with those in maternal bloods as well as in cord blood. The placental tissue contains about 2-3 times greater concentrations of lead and

mercury compared to maternal blood. For mercury, the levels among three types of biological samples showed significant correlations ($p < 0.01$), however for lead significant correlation was only detected between maternal and cord blood, suggesting different kinetics in the pregnant women. Further studies on sources of exposure to these metals and their potential health consequences are warranted.
Keywords Metal, placenta, transfer, newborn

Human exposure to UV filters in personal care products

E. Manova, N. Von Goetz, K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

Organic ultraviolet (UV) filters are designed to protect our skin from UV-induced damage. Apart from sunscreens, they are found in many other categories of personal care products (PCPs) that are often concurrently used by the same consumer. The potential endocrine-disrupting effects attributed to organic UV filter ethylhexyl methoxycinnamate (EHMC) are being debated. EHMC can be systematically absorbed through the skin from PCPs, therefore aggregate exposure to EHMC from the use of multiple PCPs and the relative contribution of different PCP categories to the aggregate exposure need to be determined to enable concerned consumers to take steps to reduce their exposure. PCP use and co-use patterns and EHMC concentration data are key input variables to our exposure model. To date, publicly available PCP use and co-use patterns are limited. Moreover, in Europe, EHMC concentrations in PCPs are kept confidential. Therefore, in this study, PCP use and co-use patterns were determined by a postal questionnaire in the German-speaking part of Switzerland (1196 respondents), which included, for the first time in Europe, very young consumers, who may be more vulnerable to adverse effects attributed to endocrine disruptors. EHMC concentrations were measured in 116 PCPs that were frequently used by the survey respondents. In general, EHMC concentrations in PCPs applied regularly throughout the year are similar or higher than those in sunscreens that are used for sun protection and applied only on selected days. For each respondent, the aggregate exposure was estimated at an individual level by combining the self-reported PCP use patterns with the EHMC concentrations measured for the self-reported products. Overall, Swiss-German consumers are selecting sun-protection products in their daily lives as shown by the highest relative contribution to EHMC internal aggregate exposure levels from the use of face cream. Detailed distributions of internal aggregate exposure levels of EHMC along with the human health risk characterisation will be presented at the conference. Our study also highlights the urgent need to determine both EHMC metabolism in humans and its transdermal penetration.

28

Integrated External and Internal Exposure to Chemicals: the INTEGRA method

D.A. Sarigiannis, denisengauthgr / Chemical Engineering; S.P. Karakitsios, AUTH / Chemical Engineering; A. Gotti, Aristotle University of Thessaloniki; G. Loizou, Health Safety Laboratory / Computational Toxicology Team Mathematical Sciences Unit; J. Cherrie, Institute of Occupational Medicine; R. Smolders, VITO / Environmental Health Unit; K. Galea, Institute of Occupational Medicine; K. Jones, Health Safety Laboratory / Biological Monitoring; E. Handakas, K. Papadaki, Aristotle University of Thessaloniki / Chemical Engineering; A. Sleeuwenhoek, Institute of Occupational Medicine

INTEGRA brings together all available information within a coherent methodological framework for assessing the source-to-dose continuum for the entire life cycle of substances covering an extensive chemical space. The major component of INTEGRA is a unified computational platform that integrates environmental fate, exposure and internal dose dynamically in time, including also inverse modeling for exposure reconstruction and HBM data assimilation. The INTEGRA method was applied on assessing exposure to bis(2-ethylhexyl)phthalate (DEHP). The aim of the study was the identification of potential exposure scenarios (or combinations) among intended uses of DEHP and how these are translated into internal exposure, as well as they are reflected into biomonitoring data. The magnitude of exposure scenarios was estimated based on extensive literature review in DEHP manufacturing and processes for intended uses, residues in food and existing biomonitoring data. Intended uses of DEHP include building and construction materials, car interior (vinyl upholstery), clothing (footwear, raincoats), food packaging, children's products (toys, grip bumpers), gloves, medical devices, PCPs and cosmetics. Scenarios related to the overall cycle assessment of DEHP in building materials were of interest. The overall life cycle assessment of vinyl flooring manufacturing showed that the environmental contribution to the total exposure to DEHP is negligible. Exposure to DEHP is attributed to vinyl flooring emissions. In a residential dwelling (surface area of 270 m^2 and air exchange rate of 0.5 h/r) characterized by DEHP gaseous emissions of 200 µg/h (vinyl flooring and other plastic materials), the concentrations of DEHP in the gaseous, particles and dust phase are equal to 1.5 $\mu g/m^3$, 21 $\mu g/m^3$ and 4400 µg/g settled dust. Overall daily intake varies between 0.2 to 10 µg/kg-bw, depending on the exposure scenarios considered. The latter are age-dependent: adults are exposed mostly through inhalation and infants through non-dietary ingestion. For a common repeated aggregate exposure scenario of 2 µg/kg-bw, the DEHP internal dose in venous blood and in adipose tissue (where bioaccumulation is clearly observed) reach a quasi-state equilibrium of 0.07 and 0.4 µg/L respectively. The expected urinary concentrations of MEHP, 5-OH MEHP and 5oxo-MEHP are 3.1, 16 and 8 µg/gCr respectively. The modeled data agree nicely with extensive HBM data from the USA and Europe.

Advancing Adverse Outcome Pathways for Integrated Toxicology and Regulatory Applications (I)

29

Advancing Adverse Outcome Pathways for Integrated Toxicology and Regulatory Applications

Recent regulatory efforts in many countries have focused on a toxicological pathway-based vision for human health assessments relying on *in vitro* systems and predictive models to generate the toxicological data needed to evaluate chemical hazard. A pathway-based vision is equally applicable to ecological risk assessment. Pathway-based analysis of chemical effects opens numerous opportunities to apply non-traditional approaches for understanding the risks of chemical exposure. Similarities in molecular initiating events and key events that lead to toxicological outcomes provide a defensible framework for extrapolating chemical effects across species, even if the specific adverse outcomes differ between species. This opens the door for much more integrated approaches to chemical hazard evaluation in support of either human health or ecological risk assessment, that are based on consideration of pathway-conservation rather than the taxonomic origin of the text system. The objective is to maximize the predictive utility of available information and those data that can be generated most efficiently and cost effectively. However, these promising concepts and approaches for using pathway-based data in hazard screening and risk assessment need further development in order to realize their full potential. This talk will be an overview of the outcomes from an international workshop held in Somma Lombardo (Italy) in March 2014 exploring how to advance the use of AOPs for integrated toxicology and regulatory applications.

30

OECD Activities on Adverse Outcome Pathways

h. aizawa, OECD / Environment Health and Safety Division; A. Gourmelon, OECD; J. de Knecht, J. Filipovska, OECD / Environment Health and Safety Division; R. Diderich, OECD

1. Introduction Developing An Adverse Outcome Pathways (AOPs) requires gathering and organising large amounts of information from molecular initiating events to toxicological effects, which can only be achieved through international and interdisciprinary cooperation. In 2012, the Organisation for Economic Co-operation and Development (OECD) launched a new programme on the development of AOPs. 2. OECD AOP Development Programme The OECD published guidance on developing and assessing AOPs in 2013. It provides an insight into which pieces of information are necessary to identify and document an AOP and how to present them, and provides initial assistance on how to undertake the assessment of an AOP. A template has been included allowing authors to develop thorough AOPs and to improve consistency in AOPs. The OECD published the first AOP for skin sensitisation in 2012, describing the state of knowledge of the AOP for skin sensitisation initiated by covalent binding to proteins, assessing the weight-of-evidence supporting the AOP, identifying the key events. A format for an AOP project proposal has been developed. As of November 2013, more than 20 projects have been includeded in the programme, of which 17 are AOP development projects, three are case studies, one is a knowledge management tool, and one other project. 3. Process for the Development of AOPs at OECD The proposed process can largely be categorized into three phases: 1) submission of a project proposal, 2) development phase, and 3) endorsement phase for a publication. Most of the development and review is intended to take place via a web-based IT tool, AOP wiki, which is in development and testing. The Wiki provides developers the necessary steps to capture the scientific information in a user-friendly manner. 4. Conclusions and Next Steps The OECD, supported by its members and other stakeholders, is actively preparing a comprehensive framework as well as guidance, the IT platform and the process for developing AOPs. The potential issues to be considered are: (1) how to link the quantitative information from a key event to a key event in a meaningful way; (2) how to use the AOP concept to harmonise national integrated approaches to testing and assessment, thereby decreasing reliance on animal testing; and (3) how to build confidence that AOPs are also useful for negative predictions.

31

Using Adverse Outcome Pathways for regulatory applications

E.J. Perkins, Us Army Engineering Research Development / Environmental Laboratory; C. Willett, the Humane Society of the United States / Regulatory Testing; M. McBride, Agilent Technologies / Director Government Relations; S. Gutsell, Unilever / SEAC; S.E. Belanger, The Procter Gamble Company / Environmental Stewardship and Sustainability Organization; F. Falciani, The University of Birmingham / Institute of Integrative Biology; G. Hodges, Unilever Research; P. Antczak, University of Liverpool; A. Kienzler, European Commission Joint Research Centre; D. Knapen, University of Antwerp / Biology department; N. Vinas, Mississippi State University

In principle, AOPs offer a scientifically-credible foundation that supports greater use of predictive, mechanistic, data concerning the initiation or progression of a toxic insult for hazard assessment and regulatory decision-making. However, in practice, before the predictive relationships represented as AOPs are likely to be widely used for regulatory applications, there is a need for the scientific and regulatory community to indicate "acceptance" of those relationships. This involves generating confidence by showing that the relationships represented are consistent and reproducible and understanding mitigating factors and variables which can influence the outcome(s) or contribute uncertainties to the AOP-based extrapolation or predictions. Recognizing that different types of regulatory decisions require different levels of confidence or certainty, it also involves understanding the relative levels of uncertainty that make an AOP fit- or unfit-for-purpose, for a given regulatory application. This concept of AOP "acceptance" is incorporated into OECD's process for the development of AOPs (http://www.oecd.org/env/ehs/testing/moleculars creeningandtoxicogenomics.htm) . Specifically, it has been proposed that once an AOP description document has been developed by a stakeholder group or organization, those AOPs would be reviewed by OECD expert groups, and revised as necessary, before endorsement by the WNT (National Coordinators on Test Guidelines) and the Task Force on Hazard Assessment. However, the details of how AOPs would be reviewed, how suitability-for-purpose for different regulatory applications would be considered in applying AOPs, and how they would be used in quantitatively predicting hazard or risk due to activation of an AOP remains unclear. As part of the international workshop "Advancing Adverse Outcome Pathways for Integrated Toxicology and Regulatory Applications" held in Somma Lombardo, Italy a group of experts from academia, government and industry selected a set of well-developed AOP descriptions to serve as examples to examine how AOPs could be approved for use in a regulatory application. Case examples were developed using existing data for chemicals in that act through the AOPs. The ability to quantitatively estimate hazards and the uncertainty associated with different levels of pathway information present for an AOP were also assessed. Finally, recomendations were given as to how AOPs can be used in a regulatory context.

32

Use of weight of evidence for characterizing adverse outcome pathways in risk assessment

K.R. Solomon, University of Guelph / School of Environmental Sciences; G.J. Van Der Kraak, University of Guelph / Department of Integrative Biology; M.L. Hanson, University of Manitoba / Department of Environment and Geography; W. Kloas, Liebniz Inst of Freshwater Ecology Inland Fish; A.J. Hosmer, Syngenta Crop Protection Inc

Information and data on chemicals from studies published in the open literature are increasingly being used for assessment purposes by regulatory agencies in many jurisdictions, including North America and Europe. As most of these studies are not conducted to the Good Laboratory Practices (GLP) standards as required by regulatory agencies, there is a need to assess their quality and relevance in light of the regulatory endpoints being considered. These data need to be integrated into lines of evidence that inform adverse outcome pathways (AOPs) and lines of evidence related to apical endpoints such as survival, growth, development, reproduction. Specifically, the strength of the experimental methods, and the ecological relevance of the observed responses were scored. The strength of the methods was scored based on various aspects, such as the experimental design and conduct, the use of appropriate controls, measures of exposures, the inclusion of environmentally realistic concentrations, number of concentrations, quality control, and transparency of data. The relevance of the each response was assessed by scoring statistical significance, concentration or dose-response, its relevance to an appropriate apical endpoint, and a biologically plausible mechanism. The WoE process was inclusive and no studies were excluded, except those with mixtures where the individual components were not tested individually. Results were presented graphically for easy interpretation. Where responses are relevant, understanding or explanation of the mechanisms at lower levels of organization is possible. This might facilitate extrapolation to other organisms/taxa or identify reliable and robust biomarkers that can be used in place of the apical endpoint. If one or more apical endpoints have been assessed under WoE, and the combination of these indicates no or *de minimis* effects, an analysis of AOPs is not needed. However, if one or more of the apical endpoints indicates relevant effects, then a characterization of AOP might be useful to better understand the response. The need for WoE and an illustration its application will be presented with the herbicide atrazine as the case-example.

33

Development of an alternative testing strategy for the Fish Early Life-Stage (FELS) test using the AOP framework

D. Knapen, L. Vergauwen, University of Antwerp / Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences; S. Verstraelen, VITO Flemish Institute for Technological Research; F. Dardenne, Universiteit Antwerpen; H. Witters, VITO; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; D.L. Villeneuve, US EPA / Midcontinent Ecology Division; G.T. Ankley, US EPA / National Health and Environmental Effects Research Laboratory

Currently, the Fish Early Life-Stage (FELS) test (OECD 210) is the primary guideline used to estimate chronic toxicity of regulated chemicals to fish. Both industry and regulatory institutions have recently expressed their interest in developing an alternative testing strategy for the FELS test with specific focus on non-animal alternatives and including mechanistic information. Our lab recently started a project funded by CEFIC (LRI-ECO20-UA) that uses the adverse outcome pathway (AOP) framework to classify chemicals according to the toxicity mechanism and predict chronic adverse outcomes based on early events. We propose a combination of refined 5 day ZebraFish Embryo Toxicity (ZFET) tests and *in vitro* tests to study events at lower levels of biological organization along the AOPs and investigate the predictivity of these events for FELS toxicity. Exchanging data between toxicological and ecotoxicological studies offers the potential to find new clues to develop AOPs. Here, we present a case study in which we use *in vitro* data from the US EPA ToxCast™ program to support ecotoxicological risk assessment. We hypothesize that specifically acting chemicals (e.g. pesticides) also induce baseline toxicity (non-polar narcosis) depending on their octanol-water partition coefficient ($\log K_{ow}$). The goal of this case study is to use the ToxCast™ dataset to investigate which endpoints are dependent on the $\log K_{ow}$, reflecting a high probability that they are linked to the narcosis mechanism. We identified 49 ToxCast phase I *in vitro* assays in which the probability of a hit increased with increasing $\log K_{ow}$ of the chemical. Apart from assays measuring general cytotoxicity, 36 of these assays reported gene expression changes relevant for different biological processes including a.o. drug metabolization and transport, immunity and cell migration. In a next step, we will translate these *in vitro* assay endpoints to *in vivo* QPCR targets to include as endpoints in the 5 day ZFET test to investigate their potential in predicting chronic toxicity of non-polar narcotics. Although the selected endpoints are often referred to as aspecific, they are probably most important for predicting chronic toxicity through narcosis. An important aspect in risk assessment of chemicals remains to identify which AOP will most likely dominate the adverse outcome.

34

Development of Adverse Outcome Pathways for Endocrine Disruption in Daphnia Magna

Y. Song, Norwegian Institute for Water Research NIVA / Ecotoxicology and Risk Management; M. Cronin, Liverpool John Moores University; O. Evensen, Norwegian School of Veterinary Sciences; F. Falciani, The University of Birmingham / Institute of Integrative Biology; T. Hogaasen, Norwegian Institute for Water Research; T. Iguchi, Natl Institutes of Natural Science; K. Langford, Norwegian Institute for Water Research / Ecotoxicology and Risk Assessment; A. Lillicrap, NIVA / Ecotoxicology and Risk Assessment; E.J. Perkins, Us Army Engineering Research Development / Environmental Laboratory; K. Petersen, Norwegian Institute for Water Research; B. Salbu, Norwegian University of Life Sciences UMB / Department of Plant and Environmental Sciences; I. Sylte, University of Tromsø; K. Thomas, NIVA / Product Metabolism; N. Vinas, Mississippi State University; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment

A number of exogenous compounds have the potential to interfere with the endocrine system of animals and may perturb vital endocrine processes to a degree causing an adverse effect (outcome) on ecologically relevant endpoints such as growth, development and reproduction. These endocrine disrupting (ED) effects have been well characterized in aquatic vertebrates and mammals due to a well-defined endocrine system and substantial research effort in the last decades, but knowledge on ED effects in a larger range of species are still poorly characterized. Lack of knowledge on ED effects in invertebrates is currently a major limiting factor to properly perform risk assessment of endocrine disrupting chemicals (EDCs) across taxa. The present project aims to develop and evaluate adverse outcome pathways (AOPs) for ED in the freshwater crustacean *Daphnia magna* by linking responses at the molecular level with adverse outcomes (AOs) relevant for regulatory processes. A literature survey was performed first to collect existing knowledge of ED effects on *D. magna* or closely related crustaceans.

Putative AOPs were assembeled to identify knowledge gaps prior to experimental studies. Computational and experimental methods were additionally used to identify possible ED targets in *D. magna* and discover novel EDCs in crustaceans for subsequent verification of potential mode of action (MoA). I*n vivo* exposure studies were then conducted with standardized test protocols, modified to accommodate sampling and toxicogenomics analysis, functional and apical toxicity endpoints that potentially perturb key molecular inititating events (MiEs), key events (KEs) and AOs of regulatory relevance. A custom *D.magna* oligoarray was deveploped to study the stress-responses at the transcriptomic level and to characterize potential MoAs of selected EDCs. In these experimetnal studies, juvenile *D. magna* were exposed to the endogenous crustaceans hormones methyl farnesoate and 20-hydroxyecdysone and the two pesticides fenoxycarb and fenarimol that are known to interfere with the normal function of the endocrine system in *D. magna*. Results from chemica exposure were compared with the reference hormones to obtain relative efficacy and potency of their ED effects. More in-depth characterization of the ED MoAs were obtained by transcriptomic analysis. The present project used several advanced tools to link the MiEs to adversity in *D. magna* and may inform future hazard and risk assessment of EDCs.

Modelling techniques for future-oriented LCA and forecasting scenarios (I)

35

How to define future LCA scenarios addressing the effect of climate change in crop production

M. Niero, Technical University of Denmark / Department of Chemical and Biochemical Engineering Department of Management Engineering; C.H. Ingvordsen, R.B. Jorgensen, Technical University of Denmark / Department of Chemical and Biochemical Engineering; M.Z. Hauschild, Technical University of Denmark / Department of Management Engineering

When LCA is intended to be used to affect strategic long term decisions, the challenge of defining future systems with many uncertain and unknown aspects needs to be faced. One important contribution is provided by scenario analysis. This paper elaborates on this issue, addressing scenario analysis in LCA with regard to one of the most debated issues in the climate change debate, i.e. climate change effect on primary agricultural production. Considering the case study of future barley production in a changing climate we aim to address the following question: how can future scenarios be performed in LCA when addressing climate change effects on crop production? We performed a cradle to farm gate study of 1 kg dry matter spring barley for malting in Denmark, focusing the definition of scenarios at the life cycle inventory level through a three steps-approach: (1) definition of the current baseline scenario and hot-spots analysis; (2) identification of the main deviations from the current production based on the best available data and knowledge; (3) suggestion of adaptive measures to compensate for possible changes due to the changing climate. Results show that priority in the definition of future adaptive measures should be put on crop yield. Data on crop yields come from cultivation experiment where the performance of the crop is investigated under the predicted climatic conditions. These data are therefore associated with relatively small uncertainty. On the contrary, the estimation of other parameters, such as pesticide treatment index and leaching from fertilizer application is affected by many unknown factors and should be addressed with sensitivity analysis. The definition of the range of variability of sensitive parameters should be based on best estimate from expert judgements from breeders and farmers. Furthermore, when presenting the results of a multiple scenario study focusing on different adaptive measures, the issue of uncertainties included in each of the scenarios should be addressed by parameter uncertainty analysis. The proposed approach can be implemented using the tools already included in the interpretation step, i.e contribution analysis, sensitivity analysis and uncertainty analysis. The output of long term scenarios based on LCA results is only effective in informing policy makers, if criteria to detect sensible aspects are taken into account, then the risk of defining unrealistic scenarios is minimized.

36

Modeling technique for territorial LCA applied to urban water systems: evaluation of prospective scenarios in megacities

P. Loubet, Veolia Eau dÎledeFrance / UMR ITAP ELSA; P.C. Roux, Irstea / UMR ITAP ELSA; V. Bellon-Maurel, Irstea

There is a need for future-oriented LCA and forecasting scenarios assessment for managers of water systems in big cities, mainly because of water scarcity and population growth. Urban water systems environmental performance have already been assessed with LCA focusing only on the technological part of the systems. New LCI and LCIA developments regarding water use impacts and territorial assessment are of great importance to increase the relevence of urban water systems LCA. The objective of this study is to develop a generic model for the environmental evaluation of prospective scenario of urban water systems. The model is developed at a city scale combining impact assessment with the calculation of provided services following the framework of territorial LCA. An urban water system includes three types of subcomponents: technologies (drinking water production, waste water treatment, etc), users (domestic, industrial, etc) and water resources. The proposed model allows the inter operation of these types of subcomponents in an integrated approach. For that purpose a generic subcomponent model that can be customized is established. From the combination of the different subcomponents that defines a scenario, direct water flows (quantity and quality) entering and leaving the system are directly modeled. Background LCIs concerning energy, chemicals and infrastructures of technologies and services provided to users are generated from litterature. Impact assessment phase takes into account new methods for water use impact. The model scales have been chosen to address water management stakeholders main issues: (i) temporal scale should allow differentiating the seasonal effect on water scarcity (ii) the spatial scale should discriminate at the sub-river basin scale the cascade effects on downstream users. Impacts of background processes are assessed with generic impact assessment methods. The model provides indicators at midpoint or endpoint level as well as water footprint. The model is first applied to the actual urban water system of the Paris suburbs area. Then several different scenarios coupling management options are defined and modeled based on the combination of the subcomponents. It demonstrates the applicability of the model: the creation of models for various scenarios is quite simple and the LCI effort is reasonable. Results are analyzed for the evaluation of the urban water system giving information for eco-design, planning and decision-making.

37

Using time-dynamic LCA and probabilistic analysis for prediction of future impacts

J. Gantner, Fraunhofer Institute for Building Physics IBP; J. Lindner , Fraunhofer IBP; M. Fischer, Fraunhofer Institute for Building Physics IBP

In the last 50 years new technologies and social developments change the world drastically. Due to a more and more rapidly changing and evolving world the environmental assessment and rating of future technologies, uncertainties and decision become more and more important. Currently, LCA is a static methodology related to boundary conditions of a certain time and based on evaluations done for a certain time period. Especially uncertainty in future decisions is so far not assessed. Decisions made in the present are supposed to be carried out the same way in the future. At best several static LCAs with different scenarios are conducted to show the range of possible results. All of this is not yet sufficient due to the large range of possible results and not captured changes of future events (e.g. technology, regulations, etc.). In order to transparently and consistently assess these previously mentioned future events a time-dynamic, probabilistic Life Cycle Assessment has to be conducted for LCA studies with a long timescale, rapidly changing technologies or a possible change in usage. Using time-dynamic parameterized LCI-models by integrating time related dynamic changes in physical or technical systems leads to more significant LCA results. Therefor a time-dynamic, probabilistic LCA study not only foresees changes regarding the LCA datasets (e.g. electricity mix) - that can be assessed by means of a time-dynamic LCA - but also future uncertainties in the decision process can be implemented with the help of probabilistic representation (e.g. decision trees). As a result not only can future tendencies be assessed but also a range can be given for the uncertainty of future impacts due to the possible future changes. Moreover sensitivity analysis can be applied to check the robustness of the final results. By means of this approach the final model can also be used for later monitoring of future events and the results can be adapted on the latest occurring circumstances. This can be important for companies that set themselves an environmental goal for their product and want to assess how probable a compliance of that goal is. Therefore decision makers can dispose based on more reliable, consistent and transparent results. All in all time-dynamic, probabilistic Life Cycle Assessment could help to better understand the effect of future technologies and support decision makers today.

38

Assessing the prospective environmental impacts of photovoltaic systems based on a simplified LCA model

C. Marini, Mines ParisTech; P. Padey, EDF Mines ParisTech; I. Blanc, Mines ParisTech / Centre for Energy and Processes; D. Le Boulch,

The increasing electricity demand and the limited fossil energy resources require the development of new energy policies, based on more environment-friendly electricity-production technologies. Assessing the environmental impacts of these technologies is thus a central issue to design the future electricity mix. This can be done using life cycle analysis (LCA). However, LCA requires the collection of a large amount of data and is thus time-consuming. Besides, LCA results found in the literature related to one energy pathway show a large variability, reflecting the heterogeneity of systems and their modeling within this pathway. To address these issues, Padey *et al.* (2013) developed a generic methodology, based on the definition of a simplified parameterized model estimating the environmental performances of a set of systems as a function of their key parameters. This methodology first characterizes the environmental profile of one energy pathway, by setting a reference LCA model. The latter generates the environmental performances distribution, representative of the potential configurations for the

studied pathway, by taking into account the different sources of variability (technological, geographical …). The ones explaining most of the performances variability are identified as key parameters using global sensitivity analysis. A simplified model function of these key parameters is then defined to estimate the environmental performances of the studied pathway. In this study we apply this methodology to the photovoltaic (PV) energy pathway for monocristalline, polycrystalline, and thin-film technologies, and extend it to assess their prospective environmental impacts. More precisely, the methodology is adapted to investigate whether possible future changes in the parameters characterizations, such as the manufacturing origin of PV modules, could lead to significant modifications of the environmental performances. A new parameter is defined (e.g. “manufacturing scenario”) and characterized by two states: the current state (e.g. current manufacturing origin) and the future state (e.g. future manufacturing origin) with a given probability distribution between the different states. Global sensitivity analysis is used to determine whether this new parameter induces a significant part of the performances variance. A new simplified model is then constructed to assess the prospective impacts of the considered energy pathway.

39

Will organic photovoltaic technology render benefits in a 30-year horizon?

N. Espinosa, Technical University of Denmark DTU / Energy Conversion and Storage; A. Laurent, Technical University of Denmark / DTU Management QSA division; F.C. Krebs, Technical University of Denmark DTU / Energy Conversion and Storage; M.Z. Hauschild, Technical University of Denmark / Department of Management Engineering

Today, worldwide energy production is largely relying on the use of fossil fuels, which pose significant environmental problems and emphasize the need for an increasing utilization of renewable energy sources. By 2060, solar generators are foreseen to take up a major share of the world’s energy supply. From that scenario, organic photovoltaics (OPV) have recently emerged as promising solar technologies for large-scale energy supply systems. However, they will only have a key role if they are engineered to ensure sustainable and efficient power networks in the long term. Therefore, when applying life cycle assessment (LCA) to quantify their environmental impacts, a dynamic perspective is required. In this study, we aim to assess the life cycle environmental performances of an average annual supply of 6 PJ_{el} of electricity to the grid from an OPV-based solar park within the coming 30 years. Because of the intermittent nature of the energy supply, alternative sources are included in the modeled system for compensating the lack of solar electricity generated in days with no sufficient sunlight. We set up a large set of forecasting scenarios to account for temporal variations in (i) the efficiencies and lifetime OPV modules, (ii) the different average and marginal energy mixes used for both energy requirements and crediting, and (iii) the end-of-life scenarios, e.g. recycling efficiencies. Our results can demonstrate that a number of parameters have a large influence on the LCA results. For example, trade-offs and burden-shifting may occur between the increasing efficiencies of the OPV system and the decreasing impact savings from incineration with energy recovery as crediting energy mixes increasingly include more renewable sources over time. Based on a comprehensive overview of the key parameters that lead to such trade-offs and burden-shifting within the considered 30-year time horizon, we provide recommendations to technology designers and decision-makers for them to anticipate and tackle potential environmental impacts as early as possible in the development and deployment of the OPV technology for large-scale energy systems.

How can scientific advances support regulatory risk assessment for pesticides? (I)

40

Sloped mesocosms: a new design to evaluate macrophyte community effects

H. Walton, ADAS UK Ltd; S. Priestly, Cambridge Environmental Assessments

Recent guidance on the conduct and interpretation of mesocosm tests highlights the importance of using the most appropriate aquatic communities for the chemical being investigated. In addition, it is equally important that for robust effects assessments, the selection of appropriate measurement endpoints and ecological evaluations is critical to the derivation of powerful statistical results. Here we will show the progress that has been made in this area of mesocosm study design using examples drawn from recent state of the art regulatory tests with herbicides. When conducting a mesocosm study it is essential that a sufficient number of representative macrophytes from sensitive taxonomic groups are included. We identified eight macrophyte species suitable for use in mesocosm testing that represent a range of functional groups and morphological traits such as rooted floating leaved monocotelydons and rooted submerged dicotelydons. In order to include sufficiently diverse taxa, marginal plant populations have traditionally be raised in the water column of deep mesocosms to facilitate their growth. However, this approach does not allow for true community effects to be determined. To rectify this, CEA have developed sloping mesocosms that enable macrophytes to be planted at water depths that most accurately reflect natural edge of field water-bodies allowing for true communtiy effects to be evaluated. Finally, for a robust assessment of macrophyte health we identified a need to collect quantitative as well as qualitative data. We did this by developing a range of assessment criteria based on macrophyte morphological characteristics and ecological functions e.g. percentage of chlorosis, stem length, and number of flower spikes, leaves or stems. in order to allow for true community effects to be evaluated Minimum Significant Difference classes for macrophyte assessments in this study were generally Class 3 or Class 4 with some occasional higher values. As a result, the endpoints for macrophytes were considered to be robust and reliable for evaluating the effects of a comprehensive and diverse macrophyte community. In addition to this; effects followed by recovery were also demonstrated for phytoplankton and zooplankton, indicating the use of sloped mescosms can allow for highly reliable and robust effects to be determined.

41

Addressing mesocosm data requirements in the new EFSA Aquatic Guidance Document

T. Bennett, Cambridge Environmental Assessments; S. Taylor,

The new EFSA Aquatic Guidance Document was published in August 2013 (EFSA, 2013). This document makes some new recommendations for designing and interpreting mesocosm studies. Changes include: the use of species sensitivity distributions (SSD) to identify organisms which should be present in the study based on lower tier work to ensure the establishment of a representative and sensitive aquatic community; the use of Minimum Detectable Difference (MDD) calculations to allow results based on low and variable data to be identified in order to avoid basing endpoints on results which are not statistically valid; new guidance for evaluating mesocosms studies and the identification and acceptability of threshold (ETO) or recovery (ERO) endpoints from these studies. A number of state of the art mesocosm studies have been conducted at CEA in which novel sampling and evaluation methods have been developed to produce data ranges with low MMD’s. Techniques have also been developed to improve the scope of organisms enumeration to provide the range of species data required in the new guidance.We will use these data to present reccomnedations for the acceptability of MDDs for different organisms groups e.g. zooplankton, algae and aquatic plants used in mesocom studies. We will also make further recommendations for the interpretation of these data and demonstrate how reliability indicies could be employed for the different groups evaluated in order to give anoverall assessment of the quality and reliability of mesocosm endpoints.

42

A proposal to address the minimum detectable difference (MDD) for the interpretation of treatment-related effects in micro-/mesocosm experiments

T.C. Brock, Alterra Wageningen University and Research Centre / Alterra; M. Hammers-Wirtz, Research Institute gaiac; U. Hommen, Fraunhofer IME; T.G. Preuss, Bayer CropScience / Institute for Environmental Research; H. Ratte, RWTH Aachen University Institute for Environmental Research / Institute for Environmental Research; I. Roessink, Alterra; T. Strauss, Research Institute gaiac / Research Institute Gaiac; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra

In the European registration procedure for pesticides, microcosm and mesocosm studies are the highest experimental tier to assess the environmental effects of pesticides in edge-of-field surface waters. Evaluations of micro-/mesocosm studies are heavily relying on effect class concentrations based on NOECs calculated for different measurement endpoints. Ideally a power analysis should be reported to allow the identification of valid concentration-response relationships. The aim of this paper is to expand on the Aquatic Guidance Document published by the European Food Safety Authority [1] and to propose a procedure to report and evaluate the minimum detectable difference (MDD) in a harmonised way to facilitate the interpretation of micro-/mesocosm studies, with special reference to identify threshold concentrations of treatment-related effects and recovery potential of populations. Proposals for two decision schemes are presented that make use of MDD information to evaluate the reliability of a micro-/mesocosm study for the assessment of treatment-related effects of pesticide exposure on populations of water organisms and to derive effect classes that can be used in the derivation of Regulatory Acceptable Concentrations.

43

Assessing the environmental partitioning behaviour of pesticides: Polyparameter linear free energy relationship approach

A. Stenzel, Analytical Environmental Chemistry; K. Goss, Department of Analytical Environmental Chemistry; S. Endo, Helmholtz Centre for Environmental Research UFZ / Department of Analytical Environmental Chemistry

To assess potential risks is an essential step in the registration of pesticides. A key property for risk assessment is the partitioning behaviour of pesticides. Experimental measurements are often prone to large errors and require large efforts demanding time, costs, and resources. An alternative option is to predict equilibrium partition coefficients (*K*) using a model, such as a poly-parameter linear

free energy relationship (pp-LFER). The pp-LFER provides accurate predictions for various environmentally relevant systems. However, the necessary descriptors are often missing for pesticides. Hence, we determined pp-LFER substance descriptors for 86 pesticides and pesticide transformation products in this work as well as descriptors for 25 other environmentally relevant compounds. The complete set of descriptors for 50 compounds incorporating 47 pesticides was determined for the first time. The experimental determination is based on GC-retention times (log t_{net}), organic liquid/organic liquid and PDMS/water partition coefficients. The determined substance descriptors are internally consistent indicated by a root mean squared error (rmse) between experimental and pp-LFER predicted log *K*/ log t_{net} of 0.07 on average. The determined descriptors were validated by comparison of predicted and experimental literature partition coefficients for the systems octanol/water (K_{ow}), water/air (K_{wa}), and organic carbon/water (K_{oc}), resulting in a reasonable prediction accuracy, e.g., the rmse is 0.39 for log K_{ow}. This agreement can be regarded as high because our descriptor determination is independent of K_{ow} and the literature values originate from diverse sources. Comparing our descriptors to previously published ones reveals an improvement in accuracy in most cases, if published descriptors were available at all. For instance, the rmse for log K_{wa} using descriptors determined by Tülp et al. is 1.39 for the 26 compounds present in both data sets. Applying our descriptors results in an rmse of 0.89 log units. The presented descriptors substantially extend the descriptor availability toward the types of chemicals that are different from typical neutral organic chemicals in terms of solvation properties.

44

Histochemistry as a post-mortem diagnostic tool for organophosphate toxicosis in birds, implemented within a monitoring program in citrus orchards in Spain

M. Foudoulakis, Dow Agrosciences / RSGAACES; C. Balaskas, Agricultural university of Athens / Department of Anatomy and Physiology of Farm Animals Faculty of Animal Science and Aquaculture; S. Norman, RidgewayEco; F. Sotti, Tier3 Solutions GmbH; R. Dittrich, Tier Solutions GmbH / Wildlife Ecology; N. Poletika, Dow Agrosciences / RSGAACES; G. Weyman, Makhteshim-Agan

Cholinesterases are ubiquitous enzymes which are present in abundance in animals, in particular in the nervous system. The activity of cholinesterases, inclusive of both acetyl-cholinesterase and butyryl-cholinesterase, has been commonly used as a biomarker for exposure evaluation and risk assessment. Ten citrus orchards in Spain treated with chlorpyrifos were selected as sites for a 3-year monitoring to provide information on diversity and abundance of bird communities. Within this program, on one site, there were incidental observations of spray solution being spilled during sprayer-filling, and also spraying whilst puddles of water were present due to leaking irrigation pipes and overwatering. On this site, bird carcasses were discovered, mostly of blackbirdsand it was considered likely that the poor practises lead to the deaths. The carcasses were collected, stored at -20ºC and subsequently processed for post mortem examination and histochemistry in order to ascertain the cause of death. Following a strict protocol of post mortem, tissue samples (brain, liver, heart, duodenum and kidney) were collected and fixed in paraformaldehyde. Brains were sectioned in a cryotome and then processed for haematoxylin-eosin staining and acetyl- and butyryl-cholinesterase histochemistry using various substrates and inhibitors. Most birds appeared normal during post mortem, with no evidence of disease or parasitic infection; some cases of parasitic worm infections, which visibly interfered with the overall poor condition of the birds, were detected. These parasitic worms completely blocked the gastrointestinal tract of the infected birds, rendering them unable to pass food and thus resulting in low body and fat scores, possibly even to death. The histochemical analysis of the "normal in post mortem" carcasses revealed, for some birds, evident signs of organophosphate poisoning. The cyto-architecture of the brain was disrupted (haematoxylin-eosin staining) while esterase histochemistry confirmed toxicosis presumably by chlorpyrifos. It is concluded that the combination of post mortem and brain section haematoxylin-eosin staining and acetyl- and butyryl-cholinesterase histochemistry using various substrates and inhibitors, constitute a useful novel approach for determining organophosphorus-related toxicosis in birds tissues. These results lead to implementation of stewardship measures at the orchard in question. *Keywords: birds; chlorpyrifos; cholinesterase; histochemistry*.

45

Varying levels of protection in current risk assessment of birds and mammals: How to reach harmonisation

M. Wang, WSC Scientific GmbH / Dept Efate Modelling

In current risk assessment, practical approaches are preferred, sometimes based on rather simple calculations, which shall ensure that no unacceptable risk is posed on non-target organism. Since it is difficult to take account of all biological diversity (regarding the toxicity of different species, exposure or behavior) with simple approaches, safety factors are added. However, these safety factors were not always derived based on scientific evidence. Safety factors may be very protective in one species and less protective in another species. Based on examples for the risk assessment of birds and mammals, in the present study we show how the level of protection varies. The application of the same risk assessment approach for different species and application types results in different levels of protection. Especially, when using higher tier approaches, additional safety factors are sometimes proposed, although the overall uncertainty of the approach is reduced by including more scientific evidence. As a consequence, the level of protection of such approaches is often increased by additional safety factors. This is demonstrated based on different examples from standard risk assessment, refined risk assessment and mechanistic modeling studies. We show how the level of protection could be harmonized.

Plants and pollutants in the environment (I)

Impact of single and multiple pesticide pollution on various endpoints in Myriophyllum spicatum cultivated in sediment-water or culture medium only

E.M. Gross, University of Lorraine / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR; M. Traore, A. de Junet, D. Billet, Université de Lorraine LIEC CNRS UMR; A. Nuttens, UMR CNRS; S. Dousset, Université de Lorraine LIEC CNRS UMR

To reduce pesticide contamination of aquatic systems, buffer zones are recommended. In Lorraine, drainage ditches have been installed at the outflow of agricultural sites to reduce pesticides export. To evaluate risks emerging from pesticide run-off for aquatic systems, we exposed *Myriophyllum spicatum* to three pesticides (flufenacet/FA, isoproturon/IP, mesosulfuron-methyl/MSM) typically found in Lorraine. We tested how culture condition (sediment-water, medium, nutrient availability) affect common and new endpoints in this potential new OECD test system. Apical shoots of *M. spicatum* were cultured in sandy sediment and artificial freshwater. Pesticides were dosed at 100 μg/L in single exposure, and 3x33 μg/L or 3x100 μg/L to each 2 apical shoots per beaker, with sampling at days 0, 3, 7 and 21. We determined pesticide concentration in water, plant growth (length & biomass of shoots and roots), chlorophyll, anthocyanin and phenolic compounds. All herbicides were degraded but with different kinetics. Biomass did not increase much in all treatments due to nutrient limitation. Root biomass reacted much stronger than shoot biomass, and was significantly lower for all single and mixed pesticides treatments, but specifically in all treatments containing MSM, resulting in root:shoot ratios of 1.0-1.3 for control, IP, or FA, but only 0.2-0.3 for MSM and mixed treatments. These findings support prior notions that roots are a very sensitive endpoint for *Myriophyllum*, even when pesticides were applied via water. We strongly encourage to keep root biomass and root:shoot ratio as further endpoint in the sediment-water bioassay. IP caused sometimes higher chlorophyll, anthocyanin and TPC levels. The latter two are plausible considered the potential antioxidative action of phenolic compounds. The next series of experiments will include a sediment-water test based on enhanced nutrient availability, but also liquid-only tests with axenic cultures. We expect that culture conditions will affect the plant's response towards pollutants. The rather low effects observed here – with exception of the root response – might result from nutrient limitation. We finally aim to test the use of *M. spicatum* in situ in drainage ditches to monitor the effects of pesticide multi-contamination. The combination of various test systems should allow us to evaluate the best *M. spicatum* test system for pesticide run-off in agricultural areas.

47

Myriophyllum spicatum's polyphenols as a new sensitive and informative parameter for pollutant impact assessment on aquatic ecosystems

A. Nuttens, UMR CNRS; J. Masfaraud, UMR CNRS LIEC; E.M. Gross, University of Lorraine / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR

The quest for environmental relevance is shaping contemporary ecotoxicology. It is no longer sufficient just to measure the effects of a pollutant on a given organism, but rather to assess the effects of environmental pollution on community interactions and ecosystem functions. Ecosystem level consequences can only be extrapolated from simplified systems, such as micro- or mesocosm studies or field experiments. These tests, however, are complicated to set up. We propose another possibility: to study species known for their biotic interactions, and see if a disruption of these interactions will induce functional changes at the community or ecosystem level. In this context, *Myriophyllum spicatum* proposed by the OECD as future test organism is a good candidate. This plant produces large amounts of polyphenols involved in multiple responses towards abiotic and biotic stressors, i.e. they are effective allelochemicals. The pro- or antioxidant properties of these polyphenols also make them a parameter which may vary in response to environmental stressors such as pollutants. We thus propose to analyse these molecules, in addition to endpoints commonly used in ecotoxicology such as growth and pigment content. We thus performed two experiments with axenic cultures of *M. spicatum* in liquid medium, using factorial designs, to investigate a) the effect of cadmium (Cd) and sucrose-addition to the medium, and b) the impact of arsenic (As) depending on the nitrogen to phosphorus molar ratio (N:P) of the medium. The results show that (i) both Cd and As as well as the composition of the medium can significantly affect the metabolism of *M. spicatum*, and that (ii) depending on the parameter considered, the composition of the medium modified the effects of the pollutant. Polyphenols increased under all conditions with Cd exposure, and with As but only under high N:P ratios. Modifications of these allelochemicals will likely affect the impact of Eurasian watermilfoil on other organisms. Bioassays with algal competitors and herbivores are currently being developed. Our first results support our initial hypothesis that *M. spicatum* is a good candidate for risk assessment at the ecosystem level because of the indirect effects of pollutants on allelochemical interactions. The variable responses in result of the variations of the culture medium may help to understand variable responses found in situ, where conditions such as resource availability, also vary.

48

Simplifying the application of a Myriophyllum spicatum TK/TD growth model by estimating chemical specific, toxicokinetic parameters

S. Heine, RWTH Aachen University / Institute for Environmental Research; G. Goerlitz, Bayer CropScience AG / Environmental Safety; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; T.G. Preuss, Bayer CropScience / Institute for Environmental Research

Toxicokinetics of chemicals are a key component for evaluating the effects of time variable exposure, especially in aquatic systems, where organisms are regularly exposed to pulsed concentrations of chemicals, such as plant protection products. Mechanistic, toxicokinetic and toxicodynamic models offer a promising approach to increase the knowledge of effects caused by time variable exposure by extrapolating constant exposure profiles to more complex ones. Instead of considering concentrations in the water phase, outside organisms, TK/TD models can link effects to concentrations within organisms, thereby increasing the realism in the effect assessment of chemicals. This work shows how toxicokinetic parameters, necessary to use a previously developed TK/TD growth model of *Myriophyllum spicatum*, can be estimated for chemicals without conducting additional experiments by using physicochemical properties of the respective chemicals. The parameterized TK/TD growth model of *M. spicatum* can be used to predict uptake and elimination patterns of chemicals, as well as their distribution between plant compartments. By using the model, we show that the lag in the onset and the disappearance of effects can be explained by toxicokinetics, at least for a sufonyl-urea compound. A general approach is presented how complex exposure profiles of chemicals might be evaluated, in respect to the growth of *M. spicatum*, without conducting additional experiments considering individual exposure profiles.

49

The use of Ceramium tenuicorne growth inhibition test for testing chemicals, products, effluent waters as well as contaminated soil and sediments

B. Eklund, Stockholm University

The marine red macroalga *Ceramium tenuicorne* is cosmopolitan and naturally found in temperate waters in both brackish and marine environment. A growth inhibition test has been developed based on two clones, one originating from 7 ‰ and the other from 20 ‰. This test became an ISO standard in 2010 (ISO 107 10) for testing of chemicals and water effluents. The test has now been further developed for soil and sediment samples. This test has been used for testing of single chemicals exhibiting high sensitivity, e.g. EC50 of 20 – 33 μg Zn^{2+}/L in 7‰ and 32-61 μg Zn^{2+}/L in 20 ‰ and for copper 1.9-3.8 μg Cu^{2+}/L in 7 ‰ and 7.9-13 μg Cu^{2+}/L in 20 ‰. The species is highly sensitive to effluent waters from pulp mills. The Ceramium growth inhibition test was used in a test battery together with a life cycle test with the crustacean *Nitocra spinipes* and a 2-generation test with the zebrafish. The alga was the most sensitive of these species to all 14 tested effluent waters. Leachates was prepared from different anti-fouling paints and used for ranking different paints according to their toxicity to non-target organisms. The alga was generally more sensitive to the compounds leaking from the paints than the crustacean *N. spinipes*. Sediments from small town harbours and from natural harbours used for anchoring by pleasure boats, was collected and leachates were prepared and tested with the growth inhibition method with *C. tenuicorne*. The result show that this method could rank the harbours according to their toxicity and proved the small town harbours to be most toxic and that compounds originating from antifouling paints was responsible for a large part of the inhibiting effect. Soil from boatyards was used for preparing lecahates, which was tested with the bacterium *Vibrio fisherii* in the Microtox test, growth inhibition of the macrophyte *Myriophyllum aquaticum* and the alga *C. tenuicorne* and larval development rate of *N. spinipes*. The alga proved to be the most sensitive species to the contaminants found at such places. *C. tenuicorne* has been exposed to many different types of pollutants both single chemicals and mixtures in effluent waters, sediments and soils and shown high sensitivity to all tested applications. Because of the sensitivity of the alga, its relevance for large areas, the high reproducibility of the test, the ease of performing the test and the cost efficiency this test may be useful in a number of test batteries.

50

Accumulation of lead, zinc and copper in different organs of Typha domingensis grown in an abandoned mining area

M.A. Lominchar Izquierdo, CIEMAT / Department of Enviornment; R. Millan, CIEMAT / Department of Environment; E. Garcia-Ordiales, J. Loredo, University of Oviedo / Mining Exploration and Prospecting Department; M. Sierra, CIEMAT / Department of Environment

Studies based on the absorption and accumulation of heavy metals in macrophytes as *Phragmites australis* or *Bolboschoenus maritimus* are increasing due to its use as a low-cost and ecological alternative to decontaminate effluents and sediments affected by this kind of pollutants. The aim of this study is to know the ability of *Typha domingensis* to accumulate Pb, Zn and Cu in different organs under field conditions, and its possible application as phytoextraction technology in mining regions. The study area was located along the Valdeazogues River which flows through the Almadén mining district, where among the mercury extraction, other important mining activities where performed to obtain metals such as Pb, Zn, Cu and Fe. In this way, samples of *T. domingensis* and sediments under the plant samples were collected along the river basin to know their contents in heavy metals. The samples of Typha were divided in four fractions: leaves, rhizomes, root and root cores (the joining point of rhizome, roots and leaves). The results obtained for each studied heavy metal, showed that roots and root cores were the organs with the highest accumulations, followed by rhizomes, and ultimately, by leaves. Furthermore, the concentrations of metals in all tissues were several times higher than the concentrations of available metal in the environment, reaching, in the case of lead in roots, up to 6 times higher than the surrounding sediment, and up to 180 and 23 times higher for zinc and copper, respectively. Therefore, these results have demonstrated that *Typha domingensis* can be a good candidate to be used in phytoextraction technology under real conditions in semiarid areas affected by lead, zinc and copper.

51

Uptake kinetics of inorganic and methyl mercury by two representative aquatic primary producers

R. Flueck, Institute Forel Earth and Environmental Sciences; V.I. Slaveykova, University of Geneva / Institute Forel Earth and Environmental Sciences; C. Cosio, Geneva University / Aquatic Biogeochemistry and Ecotoxicology Institute FA Forel Earth and Environmental Sciences Faculty of Sciences

Understanding uptake and fate of metals in organisms is essential to predict the risk they represent in the environment.Mercury (Hg) is a toxic element which can be found as methylmercury (MeHg) and as inorganic form (IHg) in aquatic ecosystems. *Elodea nuttallii* is a submerged plant rooted in sediments, which has often been described as a tolerant species to metal contamination, with a high ability of bioaccumulation [1]. *Chlamydomonas reihnardtii* is a model microalgal species commonly used in ecotoxicity assessment. Both are representative of primary producers (macrophytes and phytoplankton) controlling Hg bioaccumulation and biomagnification in the food web in freshwater systems [2]. The aims of this study is to: (i) Assess if MeHg and IHg follow a similar uptake kinetics, and compare it to Cu. (ii) Localize subcellularly bioaccumulated metal, notably in cell wall and cell sap. (iii) Compare metal accumulation kinetics in two organisms that differ in their habitat, morphology, and tolerance, hence in their exposure. Exposure experiments were realised in the laboratory at 10^{-9} M IHg, 10^{-10} M MeHg or 10^{-6} M Cu during 10, 20, 30, 45 min, 1, 2, 4, 6 or 8 hrs. This study highlights the fact that in *Elodea nuttallii* IHg and MeHg may bioaccumulate by different pathways or be reagulated by different mechanisms, because their kinetics, as well as their subcellular distribution are different. We will then compare this result with Cu and with bioaccumulation kinetics in *Chlamydomonas reinhardtii*. References: [1] Regier N *et al*.. 2013. Mercury bioaccumulation in the aquatic plant *Elodea nuttallii* in the field and in microcosm: Accumulation in shoots from the water might involve copper transporters. Chemosphere 90(2): 595-602. REACH after the second registration deadline: Environmental challenges (I)

52

REACH related environmental information: status and prospects for its availability and quality

H. Braunschweiler, ECHA

The European Commission review of the REACH Regulation in 2013 indicated a marked increase in the quality of data as a result of the first REACH registration phase as well as a marked decrease in the risk associated to substances already registered. For example, increased information is resulting in changes in hazard classification, with the majority becoming more stringent. However, the Commission review also indicated that many registration dossiers have been found to be non-compliant with regard to their information, as well as containing insufficient assessments by registrants of persistent, bioaccumulative and toxic (PBT) and very persistent, and very bioaccumulative (vPvB) properties. Improved

quality of the information in the REACH registration dossiers is one of the strategic objectives of ECHA to enable the safe manufacture and use of chemicals. High quality information is scientifically sound, understandable and reliable. In ECHA's view industry needs to take full ownership of its registration dossiers and proactively work on their quality, even after submission to ECHA. ECHA has strengthened and continues to enhance its dossier compliance check activities and other measures to improve the dossier quality. ECHA has by the end of 2013 concluded compliance checks for over 1 000 registration dossiers over 100 tonnes submitted for the first REACH registration deadline. 69% of these evaluated dossiers were found to be non-compliant. ECHA is focussing it compliance checks on the dossiers of highest concern with initial focus on the endpoints of highest relevance for safe use, later address exposure and chemical safety assessment. Second related ECHA's strategic aim is to mobilise EU authorities to use the REACH registration data intelligently to identify and address chemicals of concern. The REACH Registration Database maintained by ECHA contains currently information on 12 276 unique substances from 47 097 registration dossiers (including ones from previous legislation). The information is a valuable resource for advancing the safe use of chemicals and for the replacement of the most hazardous ones by safer alternatives. The latest new type of information made available is whether a chemical safety assessment was performed and the results of the PBT and vPvB assessments. ECHA plans next to improve the way the information is presented in the search results: it will be short substance summaries. Information on chemical and (eco)toxicological properties of REACH registered substances per endpoint is accessible via eChemPortal.

55

Strengths and weaknesses of implementation of bioavailability correction tools for metals

H. Waeterschoot, Eurometaux; P. Van Sprang, M. Vangheluwe, K. Oorts, ARCHE

The bioavailability of metals in different environmental compartments depends on the physico-chemical properties of the environmental media and on competition for binding at the biological membrane level. Bioavailability explains to a great extend the variation in toxicity response of standard toxicity tests using media with different physico-chemical properties and the often observed discrepancy in metal toxicity between laboratory and field conditions. Normalizing these responses using bioavailability correction models is therefore a crucial step in the determination of environmentally safe levels for the various environmental compartments and should hence be applied in metals hazard and risk assessments, for example under REACH. Such models have been developed for several representative biological species for the aquatic ecosystem (Biotic Ligand Models), for the sediment compartment (AVS-SEM correction model) and more empirically based regression models for sediment/soil organisms. While the application of such models will reduce the variability caused by varying abiotic conditions, their application for regional or continental scale environmental risk assessments like used under REACH, can be challenging. Aspects like, the selection of bioavailability models, the representativity and applicability of the models available for the overall species biodiversity, the spatial and temporally variability of abiotic factors, as well as co-exposure to other metals raise the need for strategic concepts and uncertainty management to define the conditions under which they can be applied in a standard way for chemicals management. This presentation aims for demonstrating such experience with case studies for a series of metals for the aquatic, sediment and soil compartments.

56

Experiences from regulatory risk assessors on Environmental Hazard and Risk Assessment

E. Verbruggen, RIVM Expertise Centre for Substance / Centre for Safety of Substances and Products; T. Traas, National Institute for Public Health and the Environment RIVM

Experience gained in the past few decades on hazard and risk assessment of chemical substances for regulatory purposes is usually documented in guidance documents (GD's). To fill some data gaps for more complex substances and topics that are not covered by available guidance documents, conceptual models have been specifically developed. For example, models based on hazardous properties and chemical fate have been developed and used to prioritize substances for regulatory purposes and for risk assessment. Both regulators and industry apply such models. RIVM has developed the PB score, a model that ranks substances along a persistence and a bioaccumulation scale. Industry applies specific models for the risk assessment of difficult substances such as complex mixtures and metals. Examples of these are the PETROTOX model and the target lipid model for petroleum hydrocarbons and the biotic ligand models applied to several metals. \n The use of such models for hazard and risk assessment should comply with the general requirements of Annex XI of REACH, namely that i) they should be adequately and reliably documented ii) the scientific validity of the model should be established in a validation study \n and iii) they should be be adequate for the purpose of risk assessment and classification and labelling. The remaining uncertainty in a modelling exercise should be taken into account. Each modelling approach will bear some inherent uncertainty that should be adequately addressed. This can be done according to various degrees of refinement, ranging from the use of pragmatic assessment factors or taking statistical and inherent prediction of uncertainty into account. This presentation will focus on principles of model application and will identify success factors as well as limitations for regulatory risk assessment.

DDT Dynamics in a Tropical Floodplain Lake

A. Mendez, ETH Zurich / Safety and Environmental Technology Group; C.A. Ng, ETH Zurich / Institute for Chemical and Bioengeneering; J. Torres, Universidade Federal do Rio de Janeiro; K. Hungerbuhler, ETH Zurich

Monitoring and modeling of persistent organic pollutants (POPs) have mostly centered in temperate and cold regions, neglecting tropical and dry subtropical zones, which account for nearly half of the earth's surface and are critical for the support of biodiversity. DDT is an organochlorine POP, whose use is currently restricted to indoor residual spraying (IRS) for malaria vector control. DDT use in IRS in Brazil was reduced in the mid-90s and definitively banned by federal law in 2009. However, studies in an Amazonian settlement around Lake Puruzinho have found elevated DDT concentrations in fish and breast milk, which result in an infant daily intake four times higher than the World Health Organization standard. To describe the sequence from DDT emissions in the Puruzinho environment to human exposure, a dynamic multimedia mass balance environmental model was coupled to simple steady-state fish bioaccumulation and human pharmacokinetic models using the fugacity approach. The temporally resolved environmental model effectively captured the seasonality of the hydrological cycle and floodplain dynamics, which influence the distribution of DDT in the Puruzinho environment. DDT concentrations in the different environmental compartments followed a yearly seasonal pattern, with elevated water and sediment concentrations, but low soil and air concentrations during the high water season. As expected from its high octanol-water partitioning coefficient, DDT accumulated in the soil and sediments. The main processes driving intermedia DDT fluxes were soil runoff, deposition of suspended particles in the water column, and gaseous and wet deposition from the air. Water and sediment concentrations from the environmental model were used to calculate DDT concentrations in fish, which in turn were used as to calculate the DDT human body burden, as fish is the main source of protein for the Puruzinho inhabitants. Lipid normalized concentrations in humans based on the model results revealed that fish intake accounts for less that 10% of the DDT found in breastmilk in Puruzinho. By developing the first multimedia environmental model that describes POP dynamics under the highly variable environmental conditions that characterize tropical floodplain lakes, we have made an important step towards filling in significant knowledge gaps about the fate and transport of POPs in tropical ecosystems.

59

Biota-sediment accumulation factors and trophic magnification factors: evaluation of the applicability for subtropical and tropical aquatic systems and a comparative study between the two regions

V. Verhaert, University of Antwerp / Department of Biology Systemic Physiological and Ecotoxicological Research group; A. Covaci, University of Antwerp / Toxicological Centre; S. Bouillon, University of Leuven / Department of Earth and Environmental Sciences; M. Dieudonne, University of Kinshasa / Department of Environmental Science; V. Wepener, NorthWest University / Biological Sciences; A. Jooste, University of Limpopo / Department of Zoology; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; L. Bervoets, University of Antwerp / Biology

The fate and trophic transfer of persistent organic pollutants (POPs) in aquatic ecosystems are intensively investigated in temperate regions, but for (sub)tropical regions a large data gap still exists. Subsequently, risk assessments in (sub)tropical countries often rely on temperate toxicity data, although it may be debatable whether the fate of chemicals is comparable among geographically distinct ecosystems. Two risk assessment tools which are used in temperate aquatic ecosystems to investigate bioavailability, bioaccumulation and bio-magnification of POPs are (1) the biota-sediment accumulation factor (BSAF) and (2) trophic magnification factors (TMFs). The present study aims to evaluate the applicability of these two tools for subtropical and tropical aquatic systems. In addition, a comparative study of the TMFs in those two regions is presented. Samples of sediment and biota (i.e. invertebrates and fish species) were collected in a tropical (Congo River, DR Congo) and a subtropical river (Olifants River, South Africa). POPs (PCBs, PBDEs, DDTs, HCHs, CHLs and HCB) were determined by GC-MS. Stable isotope ($\delta^{13}C$ and $\delta^{15}N$) measurements were performed using an EA-IRMS. For both rivers, BSAFs were higher than BSAFs found in temperate regions, probably caused by different mechanisms. POP levels in sediment are a poor indicator of the real exposure and bioavailability in these environments, because different dissipation processes (volatilization, atmospheric dispersal and faster rates of degradation) may play a significant role in (sub)tropical areas. For all POPs, no or inverse relationships were found between the sediment concentrations and BSAF values. This implies that, in the conditions of the present study, the BSAF concept appears to be a poor predictor of the bioavailability of POPs in subtropical and tropical rivers. In both rivers, significant positive relationships between relative trophic level and lipid-normalized POP concentrations were observed so trophic levels play an important role in the movement of contaminants through the food web. TMFs were > 1, indicating biomagnification of POPs. For PCBs, no differences in TMFs were found between the two rivers. For p,p'-DDT, a higher TMF value was observed for the subtropical Olifants River (5.2) than for the tropical Congo river (1.7). This observation can be caused by a higher degree of transformation of p,p'-DDT to the corresponding metabolites in the Congo River compared to the Olifants River.

Distribution, mobility, and pollution assessment of Cd, Cu, Ni, Pb, and Fe in intertidal surface sediments of Sungai Puloh mangrove area, Malaysia.

B.E. Udechukwu, Universiti Putra Malaysia / Biology; A. Ismail, Universiti Pertanian Malaysia; S.Z. Zulkifli, Universiti Putra Malaysia / Biology

Sungai Puloh mangrove supports a great diversity of macro benthic organisms and provides social benefits to the local community. Recently, it has become a major recipient of heavy metals as a result of industrialization and urbanization. This study was conducted to evaluate mobility and pollution status of heavy metals (Cd, Cu, Ni, Pb, Zn, and Fe) in intertidal surface sediments of this area. Surface sediment samples were collected based on four different anthropogenic sources: (I) effluents from recycling factory, (II) urban runoffs and effluents from coal-fired power plant, (III) fishermen activities, and (IV) Shipping activities. The heavy metals concentrations were analyzed using an atomic absorption spectrophotometer (AAS). Results revealed that the mean concentrations were Zn (1,023.68±762.93 μg/g), Pb (78.8±49.61 μg/g), Cu (46.89±43.79 μg/g), Ni (35.54±10.75 μg/g), Cd (0.94±0.29 μg/g), and Fe (7.14±0.94%). Several quality guidelines and environmental indices were used to evaluate the levels of heavy metals concentrations. Most of the mean values of analyzed metals were below both the Interim Sediment Quality Guidelines (ISQG-low and ISQG-high) except for Pb concentration (above ISQG-low), and Zn concentration (above ISQG-high), thus suggesting Pb and Zn may pose some environmental concern in this study area. Cadmium, Pb, and Zn concentrations were above the threshold effect level (TEL), indicating seldom adverse effect of these metals on macro benthic organisms. Pollution Load Index (PLI) indicated deterioration, while other contamination indices showed that the intertidal surface sediment is moderately polluted with Cd, Pb, and Zn. Therefore, the mangrove area requires urgent attention to mitigate further contamination. Finally, this study being a base line study with detailed contamination assessment indices, will contribute to data sources for Malaysia in establishing her own Interim Sediment Quality Guidelines.

Aluminium toxicity in tropical montane forest soils: Response of nutrient uptake to elevated Al concentrations

A. Rehmus, University of Berne / Institute of Geography; M. Bigalke, University of Bern / Institute of Geography; C. Valarezo, National University of Loja; J. Mora Castillo, Technische Universität München; W. Wilcke, University of Bern / Institute of Geography

An undesirable feature of acid tropical soils (pH < 5.5) is high aluminium mobility in soil solution, which, depending on plant sensitivity, may cause phytotoxicity. In southern Ecuador, Amazonian forest fires lead to increased H and N deposition, which cause acidification of the ecosystem and could result in increased Al mobility and thus, increase the risk of phytotoxicity to Al-sensitive plants. To investigate the impact of Al on selected tree species in southern Ecuador, an hydroponic experiment was conducted. Seedlings of *Cedrela odorata* L., *Heliocarpus americanus* L., and *Tabebuia chrysantha* (Jacq.) G. Nicholson were treated with an Hoagland nutrient solution containing 0, 300, 600, 1200, and 2400 μM Al. Additionally, we grew seedlings of the same tree species in native litter leachate. Nutrient solutions were sampled and replaced weekly. After seven weeks, roots, stem, and leaves were separated and digested. Macro and micro nutrient concentrations in nutrient solutions before and after treatment and in plant tissue were determined with AAS, ICP-MS, and TOC and CNS analyzers. After treatment, concentrations of remaining macro and micro elements and TOC in nutrient solution at the end of the experiment increased with Al concentration illustrating decreasing plant uptake. Concentrations of Mg and Ca in plant tissue decreased with increasing Al concentration and those of P, Fe, and Ni showed first enhancement at 300 μM Al and then decreased at higher Al concentrations. Aluminium stress affected nutrient uptake negatively and thus reduced biomass production of tree seedlings. Yet, Al toxicity occurred at Al concentrations between 300 and 600 μM, which is far above usual total Al concentrations (< 60 μM) in native litter leachate, the plant-available Al pool. We conclude that at the present concentration levels of Al in litter leachate, Al toxicity to the investigated tropical montane tree species in southern Ecuador is unlikely.

Organic pollutant effects on the photosynthetic gene expression of natural communities of Prochlorococcus sp.

M. Fernandez-Pinos, IDAEACSIC / Environmental Chemistry; M. Casado, Environmental Chemistry; B. Pina, J. Dachs, IDAEACSIC / Environmental Chemistry

Semivolatile persistent organic pollutants are introduced into remote oceanic regions by atmospheric transport and deposition, with the subsequent effects on aquatic organisms. Previous studies proved that organic pollutants present in seawater affect abundance, growth rate and cell viability of phytoplankton, suggesting that mixtures of contaminants could influence ecosystem functions like oceanic CO_2 fixation or productivity. The cyanobacterium *Prochlorococcus* numerically dominates the photosynthetic community in the tropical and subtropical regions of the world's oceans, so its contribution to primary production is significant. Being the smallest known photosynthetic organism, its tiny size and spherical shape provide a high surface to volume ratio, making it very prone to acumulate organic chemicals and particularly sensitive to pollutants. . As a part of a large project to evaluate the effects of organic pollutants on the marine carbon cycle, the potential impact of organic pollutants on photosynthetic function of phytoplankton was performed during the Malaspina circumnavigation cruise (December 2010 - July 2011). A total of 16 experiments were performed in the Indian, Pacific and Atlantic Oceans. Natural communities from the deep chlorophyll maximum (DCM) depth were challenged with three different organic pollutant mixtures (PAHs; HCB+HCHs; and a complex mixture form concentrated seawater) and incubated at 4 exposure times. To monitor the effects of the treatments on the photosynthetic function, mRNA abundances of *rbc*L (RuBisCO), *psb*A (D1 protein) and *rnp*B (reference gene) for each of the two major *Prochlorococcus* clades (high light and low light), were assessed by qRT-PCR for each experiment. Preliminary results show that the complex mixture of pollutants produced a decrease of *rbc*L expression after 6h and 24h of exposure, particularly for the high light clade, whereas the other two mixtures tested did not induced any effect. This confirms an effect of cocktails of pollutants at environmentally relevant concentrations that it not observed when we tested single families of them at similar concentrations. The downregulation was only found in *rbc*L while *psb*A remained unaltered, which suggests a specific effect on the CO_2 fixation but no on the complete photosynthetic apparatus. The decrease of *rbc*L expression together with effects at cellular level could exert a perturbation on the marine carbon cycle.

Marine and coastal ecotoxicology and risk assessment (II)

The toxicity of chemical warfare agent mixtures on the Baltic mussel Mytilus trossulus

N. Höher, Alfred Wegener Institute; R. Turja, Finnish Environment Institute SYKE / Marine Research Centre; J. Rattfelt Nyholm, A. Ostin, Swedish Defence Research Agency; M. Brenner, Alfred Wegener Institute / Biosciences; J. Barsiene, University of Vilnius; U. Bickmeyer, Alfred Wegener Institute; R.S. Berglind, Swedish Defence Research Agency

After the World War II, approx. 40.000 tonnes of chemical munitions containing about 13.000 tonnes of chemical warfare agents (CWAs) were dumped in the Baltic Sea. As the artillery shells, aircraft bombs and containers are corroding, the contents are leaking into the environment contaminating the surrounding sediments and beyond dumpsite boundaries. Thus, the necessity of investigations on the impact of chemical warfare on biota is increasing. Here, we present the first approach to investigate biological effects of CWA mixtures on the health of blue mussels (*M. trossulus*). The evaluation of the health status was based on a wide array of biomarkers at various biological levels ranging from molecular to cellular

and functional endpoints; encompassing immunocompetence, oxidative stress defence and pathological alterations in different tissues. Chemical analysis of tissue and water samples facilitated an integrated assessment. Individuals of the Baltic blue mussel (*M. trossulus*), collected at a pristine site in Åland (SW Finland, 5.4 ‰ S, 8°C), were randomly distributed and exposed to 13 differing mixtures of the CWAs Clark I, Adamsite and Chloroacetophenone at environmentally relevant concentrations (from 1.25 μg/L to 50 μg/L), solvent controls (50 μl/L methanol) and controls (no added chemicals) for 96 hours. Each treatment consisted of 8 glass aquaria (12 L) containing 7 mussels. Water change (artificial seawater: Coral Pro Salt, Red Sea) and re-dosing was conducted daily. Preliminary results suggest a differing impact of CWA mixtures on biochemical and functional endpoints. Whilst, the antioxidant glutathione reductase activity was affected by the arsenic compounds Clark I and Adamsite, all three CWAs had a stimulating impact on phagocytic activity based on the respective multiple linear regression model. Thus, reflecting differing modes of action of the CWA mixtures. Further data assessment of the above-mentioned toxicity endpoints is still ongoing, which will be presented at the conference. Results obtained in the present study, combined with results of a previous mussel transplantation study as well as spatial information of dumped CWAs, shall support and enable the establishment of CWA leakage models in the Baltic Sea and improve the risk assessment models. The present study was conducted within the framework of the CHEMSEA project, which was part-funded by the European Union (Baltic Sea Region Programme 2007-2013)

Effects of persistent organic pollutants on marine primary production: a modelling approach

G. Everaert, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology; F. De Laender, Université de Namur ASBL / Lab of EnvToxApplEcol; P. Goethals, C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology

Due to their ability to accumulate in fatty tissues, persistent organic pollutants (POPs) are an issue of environmental concern. The presence of POPs in the marine environment may be a potential driver impacting primary production [1], but their the role as a growth-limiting factor has rarely been explored [2]. In this study we assessed to what extent POPs impact the phytoplankton dynamics in the southern part of the North Sea. Our approach consisted of fitting a nutrient-phytoplankton-zooplankton (NPZ) model to *in situ* data and testing whether the extension of this model with POP toxicity improved the model fit. The NPZ model was run for four different model configurations, one model configuration contained no POP toxicity and three configurations included POP toxicity, being (1) the ambient POP concentration (1TOX); (2) a tenfold of the ambient POP concentration (10TOX); and (3) a hundredfold of the ambient POP concentration (100TOX). All model configurations predicted the chlorophyll a concentrations reasonably well, as most observed data were situated between the 2.5% - 97.5% confidence interval of the NPZ simulations. The inclusion of organic pollutants did not improve predictions. When the POP concentrations were multiplied by 10 (10TOX) and 100 (100 TOX), the median model deviation remained unchanged, but the variance of the model deviation decreased. This can be explained by the fact that at 10TOX and 100TOX, the POP toxicity forcing function in the NPZ-model became relatively important compared to the dynamics of the conventional phytoplankton drivers such as solar radiation, nutrients and water temperature. Based on the methodology presented in this paper, the relative importance of POP toxicity on marine primary production was assesed. Along the Belgian coast, it was found that accounting for POP toxicity did not improve predictions of chlorophyll a dynamics, but reduced the variability of these predictions. Biomarkers of oxidative stress as indicators of reproductive effects in the benthic amphipod Monoporeia affinis

S. Furuhagen, R. Martin, Stockholm University / Department of Applied Environmental Science ITM; M. Breitholtz, Inst för tillämpad miljövetenskap / Department of Applied Environmental Science ITM; E. Gorokhova, Stockholm University / Department of Applied Environmental Science ITM

Multiple natural and anthropogenic stressors can cause shifts in the oxidative balance of cells. A shift in the balance, either through inducing the production of reactive oxygen species or depletion of the antioxidant defense, can cause damage to biomolecules, such as lipids, proteins and DNA. Changes in antioxidative capacity and oxidative damages are used in ecotoxicological studies as biomarkers of exposure to stressors, such as xenobiotics. Alterations in the antioxidant defense and increased levels of oxidative damages have been connected with organismal fitness and health. However, there are few studies investigating the potential of oxidative biomarkers as indicators of adverse effects at individual or population levels in ecotoxicological studies. Previous studies have shown that oxidative biomarkers in the benthic amphipod *Monoporeia affinis* are affected in response to xenobiotic exposure and hypoxia. In this study we investigated the relationship between alterations in biomarkers associated with oxidative stress, such as antioxidative capacity and lipid peroxidation, and embryo developmental disorders in *M. affinis*. Amphipods in this study were collected from the Baltic Sea, taken in to the lab and exposed to contaminated sediments for 14 weeks. Reproductive success was assessed at the end of the exposure by identifying and quantifying different types of embryo developmental disorders. Alterations in oxidative biomarkers in these organisms could provide a better mechanistic understanding of the observed reproductive effects. Moreover, by establishing a connection between biomarker response and effects at individual and population level, these biomarkers could be used as early indicators of later effects. This is important if we are to increase the value and use of oxidative biomarkers as effect biomarkers in environmental risk assessments.

66

Population growth rate in low- and high density populations

E. Lundström Belleza, Stockholm University / Dept of Applied Environmental Science; M. Breitholtz, Inst för tillämpad miljövetenskap / Department of Applied Environmental Science ITM

Population growth rate is generally thought of as the key intervening variable linking individual level effects to effects on populations (e.g. 1). It integrates effects on survival, development and reproduction, and is therefore by definition a better ecotoxicological endpoint for population responses than any single individual level endpoint (2). The primary aim of the current study was to apply an equation for calculating population growth rate from a life cycle test where *Nitocra spinipes* were exposed to lindane: 0-29 μgL^{-1} (modified from (3)). Effects from stressors at the population level may be severely underestimated when population density is low (4). A secondary aim was therefore to compare population growth rate from a population test (high population density) and a life cycle test (low population density). In the population test, *N. spinipes* were exposed to lindane (in replicates of three): 0-28 μgL^{-1}. Populations were started with three memebers of from each development stage. Population growth rates were calculated and compared, and EC_{10} were calculated. Population growth rates from the life cycle test show that all populations were growing, and all lindane treatments were significantly different from the solvent control. In the population test, population growth rates for the solvent control and the lowest lindane exposure showed growing populations, the intermediate concentration was at the replacement rate for the population. The highest treatment showed a declining population, and was also significantly different to the solvent control. The few significant differences in the population test were a result of high variation. EC_{10} values (22.9 μgL^{-1} in the life cycle test and 11.9 μgL^{-1} in the population test), nevertheless, the population growth rates showed that the population test had stronger effects compared to the life cycle test. If NOEC/LOEC values were to be used, the life cycle test would have resulted in lower NOEC values compared to the population test. This is due to much higher statistical power (i.e. higher number of replicates and thus less variability) and does not reflect the actual effects seen on the population level. Effects of triphenylborane pyridine, tralopyril and capsaicin to marine invertebrates: do novel biocides still pose an environmental risk?

I.B. de Carvalho Benta Santos Oliveira, University of Aveiro CESAM / Biology department; R. Beiras, Universidade de Vigo / Ecology Faculty; K. Thomas, NIVA / Product Metabolism; M.J. Suter, Eawag Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology; C.M. Barroso, CESAM & Department of Biology, Aveiro University

Biofouling results from the settlement of organisms on water-submerged structures causing deterioration of diverse aquatic equipment and raising the fuel consumption by ships due to frictional drag. Antifouling (AF) paints have been used to overcome this problem and throughout history a variety of AF-biocides have been used to boost the paint efficacy. By the turn of the century tributyltin (TBT) was a key biocide in AF paints but its release to the environment resulted in well documented impacts to wildlife, leading to a global ban of TBT-based paints in 2008. Nowadays, the risk assessment of biocides assumes a critical importance for their commercial success. According to the new Biocidal Product Regulation (BPR, Regulation EU No 528/2012), implemented in the European Union in September of 2013, both the active biocidal substance and the commercial formulation have to be approved. This situation is prompting the industry to search for environmentally acceptable alternatives. A good AF performance, rapid transformation to less toxic products, low tendency to bioaccumulate and low toxicity to non-target species are required. The current work investigates the acute toxicity to marine invertebrates of two emergent AF biocides triphenylborane pyridine (TPBP) and tralopyril and a AF biocide candidate, capsaicin. The tested biocides impaired larval development in the mussel *Mytilus galloprovincialis*, inhibited larval growth in the sea urchin *Paracentrotus lividus* and caused mortality to the copepod *Tisbe battagliai* in a dose-dependent manner. Comparisons with TBT were made and the toxicity ranks obtained were TBT = TPBP > tralopyril >> capsaicin for bivalves, TBT > tralopyril > TPBP >> capsaicin for echinoids and tralopyril > TBT ~ TPBP >> capsaicin for copepods. Based on a marine antifoulant model to predict environment concentrations (MAMPEC, Version 3.0; Deltares, Netherlands) and on predicted no effect concentration, TPBP and tralopyril have the potential to harm the environment. Nevertheless, acute toxicity tests are just one of many steps towards the assessment of the environmental risk and therefore further research is essential to better understand their fate and effects.

68

Biomarker responses dependant of pollution source: effects of crude oil contamination through nutrition and water – a laboratory experiment with Baltic Sea blue mussel (Mytilus edulis)

A. Soirinsuo, Finnish Environment Institute SYKE / Marine Research Centre; J. Nuutinen, Finnish Environment Institute / Marine Research Centre; A. Korpela, Finnish Environment Institute; K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre

Oil-derived polycyclic aromatic hydrocarbons (PAH) induce many biomarker responses in organisms. These responses can lead to ecologically relevant effects at higher levels of biological organisation even at low toxin concentrations. In the case of oil-derived PAH bioaccumulation, the nutritional status of mussels can be especially critical since oil and its components can be digested as nutrient by phytoplankton that bivalves use as food A set of different biomarker tests was applied to assess the impacts of crude oil pollution from different sources on Baltic Sea blue mussel (*Mytilus edulis*). An aquarium exposure experiment of 25 days was conducted using water-accumulated fraction (WAF) of Russian crude oil in 1) aquarium water (1:500) or 2) feeding mussels with algae exposed to 1:500 WAF in growth medium. In two reference aquariums mussels were fed with clean algae. The mussels were fed with *Rhodomonas* sp. with final concentrations of either 8000 cells ml^{-1} or 1500 cells ml^{-1}. The algae were grown in T2-media in polluted or in unpolluted conditions, e.g. polluted *Rhodomonas* was grown in T2-medium contaminated with 1:500 WAF of Russian crude oil. The other four aquariums were fed with uncontaminated algae and two of the aquariums were exposed to water contaminated with 1:500 WAF of Russian crude oil. The biomarkers measured included condition index (CI), comet assay (CA), lipid peroxidation (LPO), superoxide dismutase (SOD), protein carbonylation, neutral red retention test (NRR) and lysosomal membrane stability (LMS). The crude oil was deployed as WAF with a concentration of 1:500 (oil/water). The stock solutions as well as mussel tissues were chemically analyzed for confirmation of the pollutant concentrations. Significant changes in comet assay and lysosomal stability occurred within 25 days of the beginning of the experiment, where lysosomal stability measured from histopathological samples produced more reliable results than NRR measured from blood haemocytes. Condition indexes were not correlated with the observed changes in PAH concentration, but in the availability of food. Oxidative stress biomarkers LPO, SOD, TAC and protein carbonylation showed less clear responses on oil pollution from nutrition or water but some responses to differences on nutritional status.

Waste and Wastewater effluents: chemical and ecotoxicological characterisation (II)

69

Toxicity and estrogenicity of aqueous bisphenol A samples treated by advanced oxidation processes

T. Tišler, B. Erjavec, R. Kaplan, A. Pintar, National Institute of Chemistry / Laboratory for Environmental Sciences and Engineering

Bisphenol A (BPA) is an organic pollutant with estrogen-like effects eliciting adverse effects on endocrine systems of humans and wildlife. For this reason an efficient removal of BPA from wastewaters, before discharging them into aquatic environment, is necessary. Several possibilities for endocrine-disrupting chemicals removal from water are available and among them advanced oxidation processes (AOPs), such as catalytic wet air oxidation (CWAO), heterogeneous photocatalysis, ozone-based technologies and ultrasound oxidation seem to be the most promising. However, treatment with these processes sometimes results in by-products that are not eliminated significantly by the same technique and may be more hazardous than the parent compound. In order to detect the presence of possible remaining estrogenic activity and toxicity of aqueous samples treated by AOPs, bioassays should be used in addition to chemical analytical measurements. In the present study, the removal efficiency of toxicity and estrogenic activity of BPA aqueous samples treated by photolytic/photocatalytic oxidation and CWAO processes in the presence of different TiO_2 - based catalysts was investigated. The efficiency of BPA and TOC removal in treated solutions was investigated by HPLC and TOC analyses, respectively, toxicity tests with bacteria *Vibrio fischeri,* green algae *Desmodesmus subspicatus,* water fleas *Daphnia magna,* zebrafish embryos *Danio rerio* and estrogenicity with yeast estrogen screen (YES) assay. In general the presence of catalysts significantly enhanced the removal of BPA from aqueous samples and consequently diminished toxicity and estrogenic activity of BPA samples treated by both catalytic oxidation processes. The obtained results indicated that removal of BPA was not always well correlated with removal of toxicity and estrogenic activity from treated samples, probably due to production of some toxic and estrogenic intermediates during photolytic/photocatalytic oxidation and CWAO processes. Degradation pathways of BPA in aqueous samples depend on the type of catalyst, advanced oxidation process and experimental conditions used to perform oxidation experiments.

70

Efficiency evaluation of a membrane bioreactor to remove emerging pollutants from a hospital effluent based on the combined use of in vitro and in vivo bioassays and targeted chemicals analyses

N. Creusot, INERIS; C. Albasi, Université de Toulouse INPT / UPS Laboratoire de Génie Chimique; N. Manier, INERIS; E. Maillot Marechal, INERIS / ECOT; P. Pandard, J. Porcher, INERIS; C. Martin, LPTC EPOC CNRS; I. Quesada, Université de Toulouse INPT UPS Laboratoire de Génie Chimique / UPS Laboratoire de Génie Chimique; H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC; S. Ait-Aissa, INERIS / Ecotoxicology Unit

Hospital effluents have been identified as an important source of various chemical classes. Because of potential associated risk for humans and wildlife, elimination of such compounds has become an increasing issue of concern. Conventional treatments are often insufficient to eliminate all the active micropollutants. In particular, chemical diversity of endocrine disrupting compounds (EDCs) limits their removal through targeted approaches. Therefore, new processes have emerged, including membrane bioreactor (MBR) to improve removal efficiencies**.** In the present study, we aimed to evaluate the efficiency of an MBR pilot for the elimination of i) EDCs using a battery of *in vitro* bioassays (i.e. reporter cell lines) covering a panel of endocrine activities, ii) various pharmaceuticals classes using LC-MS-MS analysis, in hospital effluents. In parallel, standardized ecotoxicological tests were performed to characterize ecotoxic potency of effluent before and after MBR treatment. All these tools were deployed on several sampling campaigns. In the non-treated effluent, estrogenic and androgenic activities were quite similar to those previously reported in other hospital effluents whereas GR-and PXR-like activities were close to those found in industrial effluents. After MBR treatment, an overall reduction of the endocrine activities was noted.Target chemical analyses revealed the occurrence of a broad range of pharmaceutical classes including cytostatic anticancer drugs and antibiotics but also metabolites in the non-treated effluent. Overall, concentrations were similar to those reported in other studies, except for very high amount of the antibiotic ciprofloxacin (up to 1mg/L). MBR treatment allowed either total, partial or no removal of targeted pharmaceuticals classes, depending on chemical. Finally, ecotoxicological tests showed effects at several trophic levels in the non-treated effluents. MBR treatment significantly reduces this ecotoxicity. Altogether, our results confirm the relevance of the combined use of biological and chemical analyses for an hoslitic characterization of hospital effluent contamination by a broad range of active chemicals. We report also that this complex mixture leads to global toxicity for exposed organisms at different trophic level confirming hazard for aquatic ecosystems. One major outcome is the ability of MBR treatment to reduce both endocrine disrupting activity and global toxicity although some persisted after treatment

71

Aquatic Ecotoxicology: To Assess the Environmental Performance of Sanitation System on Aquatic environment

S. CASAS, VEOLIA Environnement Recherche et Innovation; J. Fabure, Irstea / UR HBAN; C. Cren, Insitut des Sciences Analytiques UMR TRACES Team; K. Seriki, VEOLIA Environnement Recherche et Innovation; J. Garric, Irstea Lyon / Groupement de Lyon; S. Sourisseau, VEOLIA Environnement Recherche et Innovation

The sanitation system focuses on a variety of pollutants from domestic, agricultural and industrial activities that are potentially a source of pollution in the receiving environment. To determine and assess their potential impact on the ecological quality, this collaborative project between IRSTEA & Veolia Environnement Research & Innovation (VERI) has developed a methodology to measure, monitor and define a battery of discriminating bioindicators. A battery of three biological tools has been selected to assess their sensitivity and pertinence in measuring the potential impacts of a wastewater treatment plant. The tools used are mainly based on the measurement of individual responses (survival, growth, reproduction and feeding) which have a direct link with the dynamic of population's. These tools have been developed on model organisms widely present in our freshwater ecosystems, covering several phyla (insect, crustacean and mollusk). In addition several emerging pollutants as pharmaceuticals were analyzed in the organisms to assess chemical impacts of the sanitation system and inform on their relative sensitivity to exposure . Life history traits - biological descriptors - endure the influence of environmental parameters such as temperature and pollutants. Also, their use in a real environment requires a good knowledge of their behavior

according to the variation of these parameters. To avoid the interference of such parameters, a field laboratory will be installed to reproduce the in situ conditions (pollutant pressures) while controlling the influence of confounding factors. The development of a methodology for the application of biological tests for measuring and monitoring the impact of wastewater discharges will provide a better understanding of wastewater treatment plants' contribution to the water quality of receiving systems subject to multiple pressures.

72

Dioxin-like effect potentials and related effects in fish exposed to regular wastewater effluents and effluents with additional wastewater treatment stages

D. Maier, University of Tubingen / Animal Physiological Ecology Group; M. Benisek, Masaryk University Faculty of Science / Faculty of Science RECETOX; M. Scheurer, Water Technology Center TZW Karlsruhe; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology

The removal of micropollutants like pesticides, pharmaceuticals, and other industrial and household chemicals by regular wastewater treatment is often imperfect. In order to overcome this deficiency, additional treatment stages using ozonation, sand- or carbon-filtering have been included into wastewater treatment during the last years. The project SchussenAktiv*plus* aims at an efficiency control of such additional cleaning methods in three wastewater treatment plants (WWTPs) and two stormwater overflow basins (SOBs) in the Lake Constance area. Within the project, chemical and microbiological analyses and various biological *in vitro* and *in vivo* tests are conducted by several co-operating partners. Two of the three WWTPs under investigation are connected to the Schussen River, a tributary of Lake Constance. A model WWTP has been installed at the WWTP Eriskirch which is located at the Schussen estuary. This model includes effluent-treatment with ozonation, a sand filter, and a carbon filter after the final clarifier of the traditional cleaning stages. Two aquaria were placed at the WWTP for rainbow trout exposure, receiving either water of the actual final effluent after sand filter/flocculation, or water of the model installation. The WWTP Langwiese, Ravensburg, has been equipped with an activated carbon filter which is in operation since September 2013. Cage exposure with rainbow trout was conducted directly in the river upstream and downstream of the effluent before and after the upgrade. For control, rainbow trout were kept in climate chambers. Chemical analysis of water, effluent, and fish samples was conducted. Concentrations of the analyzed PCBs were below limit of detection. Dioxin-like effect potentials were measured by a reporter gene assay using rat hepato-carcinoma cells. Higher potentials were measured in the regular effluent of the WWTP Eriskirch compared to the effluent of the model installation. Concerning the WWTP Langwiese, potentials were detected in the effluent prior to the upgrade. EROD activity in samples from the WWTP Eriskirch was significantly lower in fish kept at the effluent of the model installation compared to the regular effluent. Prior to the upgrade of the WWTP Langwiese higher EROD activity was measured in trout exposed in the Schussen River downstream of the WWTP than in those exposed upstream. Sampling after the upgrade will be conducted in March 2014 and results will be presented at the SETAC Europe 2014.

73

Reduction of micropollutants and pathogens in surface waters by improved wastewater and rainwater treatment: What is the benefit for aquatic organisms and human health?

R. Triebskorn, University of Tuebingen / Animal Physiological Ecology; L. Blaha, Masaryk University / Faculty of Science RECETOX; C. gallert, Department Microbiology and Biotechnology University of Applied Sciences Emden Leer; K. Jedele, Jedele und Partner GmbH; B. The joint research project SchussenAktiv*plus* aims to ascertain the efficiency of various wastewater and rainwater cleaning technologies for the reduction of micropollutants and sanitarily relevant pathogens including multi-resistant bacteria in surface waters with regard to the benefit for aquatic organisms and human health. As a model river in a highly populated catchment area, the river Schussen and, as a reference, the river Argen, two tributaries of Lake Constance, Southern Germany, are under investigation in this project. The cleaning technologies include combinations of ozonation with different sand and charcoal filters, a lamella separator connected to a storm water overflow basin, and a retention soil filter. The quality of these technologies installed at three waste water treatment plants (WWTPs) of different size and type, and at two stormwater overflow basins (SOBs) is assessed by means of ample analytical and microbiological exposure analyses and by extended *in vitro* and *in vivo* effect studies which reflect consequences for biota from the molecular to the community level. Toxic and endocrine potentials in water samples from the five test systems as well as in surface water and sediments of five field sites are assessed by laboratory *in vitro* tests which include reporter gene assays based on yeast and vertebrate cell lines, but also by *in vivo* laboratory studies, as the early life stage test with the zebrafish *Danio rerio* or the growth inhibition tests with *Lumbriculus variegatus* or *Lemna minor*. Toxic and endocrine effects, in contrast, are investigated *in vivo* either in feral chub, spirlin, or gammarids sampled from the field, or in fish, gammarids, and snails actively exposed either to effluents in aquaria or cages, or to the river water in flow-through bypass systems. The impact on the health of fish and invertebrates by toxic and endocrine action is assessed by means of different biomarkers (e.g. histopathological changes, genotoxic effects, stress protein, biotransformation enzyme and vitellogenin induction). Exemplarily, results for chemical, microbiological and biological effect analyses will be presented.

74

Ecotoxicological consequences of pharmaceutical facility discharges on wild fish: a french case of study.

O. Cardoso, O. Palluel, INERIS / Unité décotoxicologie in vitro et in vivo; A. Bado-Nilles; C. Turies, E. Chadili, INERIS; S. Paris, Sciences; J. Porcher, INERIS / Ecotoxicology Unit; W. Sanchez, INERIS

Discharges of wastewater treatment plants receiving effluents from pharmaceutical factories represent a non-negligible source of biologically active chemicals in surface waters able to induce ecological/ecotoxicological effects on wildlife and populations. Recently, ecotoxicological effects on teleost fish and tadpoles exposed to dilutions of Indian bulk drug manufactures effluents have been concluded, suggesting that deleterious biological effects could be induced. Furthermore, an *in situ* study has demonstrated a high proportion of intersex in gudgeons (*Gobio gobio*) living downstream from a French bulk drug manufacture discharges which could be explained by the nature of pharmaceutical production. The present work consists of an evaluation of long-term adverse effects induced by another French pharmaceutical manufacture discharges in wild fish (*Gasterosteus aculeatus*) using a multi biomarker approach. Ecotoxicological analysis includes a semi-quantitative evaluation of histopathological lesions in liver and spleen, an analysis of intersexe frequencies, DNA damages on erythrocytes, and biochemical markers related to biotransformation capabilities (EROD, GST, CYP 3A) and neurotoxicity (AchE). Our results highlights a marked hepatotoxic effects mainly characterized by fibrosis, lipoid degradation, confirmed by inductions of biochemical responses, increased densities of splenic melanomacrophages aggregates, and elevated DNA damages in sticklebacks sampled in receiving waters. This works argues for the implementation of monitoring programs, using effect-based tools, and the need to improve our knowledge about possible ecotoxicological disturbances occurring in specific waters which receiving pharmaceutical facilities discharges. *This work was supported by the French Ministry for Ecology and Sustainable Development (MEDDE-Program 181).*

Fate and effects of nanoparticles under environmentally realistic conditions (II)

75

Toxicity of silver nanoparticles on natural microbial freshwater communities in an artificial indoor stream

M. Matzke, Centre for Ecology Hydrology NERC / Molecular Ecotoxicology; A. Arrhenius, University of Gothenburg / Department of Biological and Environmental Sciences; C. Burkart, Technische Universitat Dresden / Institute of Hydrobiology; C.A. van Gestel, Vrije Universiteit Amsterdam / Ecological Science; D. Jungmann, Dresden University of Technology; A. Kroll, Department of Environmental Toxicology; P. Obert-Rauser, GWTTUD GmbH / Institute of Hydrobiology; M. Rybicki, Dresden University of Technology / Institut für Hydrobiologie; C. Svendsen, CEH Wallingford / Pollution and Ecotoxicology; R. Verweij, Department of Ecological Science VU University Amsterdam The Netherlands; T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences

Data on the toxicity of silver nanoparticles (AgNPs) for individual standard microbial test species are well documented in the scientific literature. However, main drawback of single-species methods is their limited ecological relevance, as it is unknown how the sensitivity of the particular test species towards NPs relates to the sensitivities of the plethora of species that are exposed simultaneously in a natural ecosystem. This study used natural microbial freshwater communities from a stream (Gauernitzbach) near Dresden (Germany), settled on ceramic tiles and transferred to controlled test conditions in artificial indoor streams (AIS). The communities were exposed to two concentrations of AgNPs and $AgNO_3$ (2 and 20 µg/L). Two untreated control channels were used as a reference. Exposure was continous for up to 18 days with four subsequent sampling points (day 0 as a reference point for the communities and 4, 11 and 18 days for an effect analysis). Effects on the algal part of the communities were studied through a pigment profile analysis, the bacterial part of the communities was analysed with metabolic profiling (EcoPlates™). Tolerance patterns at the end of the 18 days exposure period were described using MT2 plates, following the concept of a Pollution

Induced Community Tolerance (PICT) approach. The experiment was supported by comprehensive chemical analysis (AAS, ICP-MS for total and dissolved silver concentrations during exposure/stocks, TEM (particle size, homogeneity and quality of the stocks), NTA (particle size distribution of the stocks), CPS (particle size distribution of the stocks)). Analytical results indicate a rapid dissolutin of the AgNPs, a silver accumulation in the biofilms (higher for the AgNPs than the $AgNO_3$) and a silver concentration decrease in the water phase over time. Ecotoxicological results show differences between the AgNP and the $AgNO_3$ exposed communites with more distinct effects for the $AgNO_3$. Experimental data are currently (November 2013) undergoing final evaluation and modeling, in order to describe and quantify the impacts of $AgNO_3$ and AgNPs on the biofilm biocoenoses in detail. Results will be discussed and presented in relation to the analytical data.

76

Long term effects of cerium dioxide nanoparticles (nCeO2) on a simplified food chain of micro-organisms and zebra mussels

M. Garaud, Laboratory LIEC CNRS UMR UdL / CNRS UMR; J. Andreï, CNRS UMR / LIEC CNRS UMR; M. Auffan, iCEINT / International Consortium for the Environmental Implications of Nanotechnology; C. Bertrand, N. Brule, LIEC CNRS Université de Lorraine; S. Devin, Universite de Lorraine; M. Dollard, LIEC CNRS Université de Lorraine; V. Felten, LIEC; F. Guerold, Universite de Lorraine / Laboratoire Interdisciplinaire des Environnements Continentaux; C. Pagnout, LIEC CNRS Université de Lorraine; S. Pain-Devin, Université de Lorraine UL / LIEC CNRS UMR; J. Poinsaint, LIEC CNRS Université de Lorraine; O. Proux, ESRF / Beamline CRG-FAME; F. Rodius, Universite de Lorraine; B. Sohm, P. Rousselle, LIEC CNRS Université de Lorraine; M. Tella, CEREGE; P. Wagner, LIEC CNRS Université de Lorraine; L. Giamberini, Université de Lorraine CNRS UMR

As the field of nanotechnologies is expanding exponentially, more and more nanomaterials of various physico-chemical properties are being developed for new applications and incorporated into commercial products. The release of significant amounts of those nanomaterials in the environment is expected but the ecological consequences are quite unknown. To answer those concerns, the MESONNET project, headed the French GDRi iCEINT and by the US-CEINT, was set up to evaluate the fate and impacts of nanoparticles within terrestrial and aquatic ecosystems. The project included the building of a network of small mesocosms in three French laboratories, working with the same experimental designs on different species to gather complementary data. We first decided to work on cerium dioxide nanoparticles ($nCeO_2$), mostly used in wood stains and as fuel additives. In the experiment conducted in our laboratory, we investigated in 9 mesocosms the effects of two forms of commercial $nCeO_2$, bare nanoparticles (primary size 3 nm), and citrate-coated nanoparticles (primary size 3 nm) used in wood stains, at low concentration (12 injections of 84 μg/L during 4 weeks - 1 mg/L final) on a simplified ecosystem constituted of a natural bacterial consortium, three green algae species, and an invertebrate, the bivalve *Dreissena polymorpha* or zebra mussel. The fate of nanoparticles and biological effects on the organisms were followed for four weeks. Bacterial and algal biomasses and community structures were determined, while a broad set of immunological, biochemical and functional biomarkers were used to evaluate $nCeO_2$ exposure effects on zebra mussel on different biological targets and at different biological levels. Results were synthesized using the Integrated Biomarker Response (IBR) tool. Internal $nCeO_2$ concentrations and speciation of cerium inside the digestive gland were also measured. Results suggested $nCeO_2$ exert no serious toxicity on bacteria, algae and zebra mussels. We did not see any direct impacts of $nCeO_2$ on micro-organism biomasses while bacterial community structures were modulated. For zebra mussels, while $nCeO_2$ accumulated into digestive gland and was reduced from Ce^{4+} to Ce^{3+}, a transient activation of immune system was observed, but gill mRNA and digestive gland biomarker data showed lower expressions and activities of antioxidant enzymes and a decrease in cellular membrane lipoperoxidation, suggesting a potential antioxidant protecting activity of $nCeO_2$.

77

Silver nanoparticles flow in a model aquatic trophic chain

F. Ribeiro, University of Aveiro CESAM / Department of Biology CESAM; J.A. Gallego-Urrea, University of Gothenburg / Chemistry; C.A. van Gestel, Vrije Universiteit Amsterdam / Ecological Science; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; S. Loureiro, Universidade de Aveiro / Biology

Silver nanoparticles (AgNP) are incorporated into a variety of products ranging from personal care products, food packing and medical utilities, serving as an antimicrobial agent (Sotiriou & Pratsinis, 2010). The worldwide estimated production of AgNP is between 250 and 312 tons per year (Hendren, Mesnard, Dröge, & Wiesner, 2011) from which it is still unknown how much silver will end up in the environment. In this study we focused on three species representative of a model aquatic trophic chain, a primary producer (*Pseudokirchneriella subcapitata*), a primary consumer (*Daphnia magna*) and a secondary consumer (*Carassius auratus*), to evaluate the potential food-chain bioaccumulation of AgNP. The final aim of this work was to realize a worse case scenario in which *C. auratus* was exposed to AgNP via water and food. A step-by-step approach was developed in order to find the conditions in which the species of lower trophic levels would concentrate AgNP at a higher rate. *P. subcapitata* was exposed to AgNP and $AgNO_3$ for 48 hours followed by a 48-h elimination period. AgNP accumulation in *D. magna* was studied upon exposure through water, food and both water and dietary exposure. Finally, the worse case scenario of AgNP accumulation in *D. magna* was chosen to produce a model trophic chain in which *C. auratus* was exposed for 10 days to both AgNP and $AgNO_3$ contaminated water and food (*D. magna*) followed by 7 days of elimination. Following exposure of *P. subcapitata* to both AgNP and $AgNO_3$, the algae did not internalize AgNP but did accumulate Ag ions. *D. magna* accumulated higher amounts of Ag when exposed through water and food, and also had higher Ag body burdens when exposed to AgNP than to $AgNO_3$. The pattern of Ag bioaccumulation in *C. auratus* differed between AgNP and $AgNO_3$. In conclusion, our data suggests that AgNP have the potential to bioaccumulate within an aquatic trophic chain, which may be due to their physico-chemical properties and the interaction with biological tissues.

78

Habitat selection of a leaf shredding amphipod affected by photocatalytic properties of nTiO2

A. Feckler, Swedish University of Agricultural Sciences SLU / Department of Aquatic Sciences and Assessment; R.R. Rosenfeldt, Uniersity of KoblenzLandau Institute for Environmental Sciences / Institute for Environmental Sciences; F. Seitz, Inst for Environmental Sciences / Institute for Environmental Sciences; R. Schulz, University of KoblenzLandau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

The increasingly worldwide use of titanium dioxide nanoparticles ($nTiO_2$) raises the concern of potential risks for wildlife when released into the aquatic environment. For this reason, numerousness studies focused on their toxicity towards aquatic wildlife, however, mostly assessing the sole effects of $nTiO_2$. Consequently, there is only limited information about ecotoxicological effects of $nTiO_2$ in combination with environmental parameters. The present study investigated the (in)direct effects of $nTiO_2$ towards the amphipod *Gammarus fossarum* (Crustacea: Amphipoda), considering the photocatalytic properties under environmentally relevant intensities of UV-A and UV-B irradiation. Gammarids' habitat selection was thereby used as a sublethal measure of response, judged by their feeding preference on leaf discs either exposed to or protected from direct UV-irradiation. UV-protected parts of the test vessel were significantly preferred ($p < 0.001$) when gammarids were solely exposed towards UV-irradiation, indicated by approximately 40% less feeding in the part of the test vessel directly exposed to UV-irradiation compared to the UV-protected counterpart. Most likely, an avoidance of the damaging effects of UV-irradiation for amphipods may explain this behavior. The same significant habitat selection pattern ($p < 0.001$) was observed when both $nTiO_2$ and UV-irradiation were applied as stressors, however, with up to 85% less feeding on UV-exposed leaf discs. This two-fold increase in feeding preference may be explained by the photoactivation of $nTiO_2$ since no such pattern was observed for $nTiO_2$ alone: the photocatalytic properties led to the formation of reactive oxygen species (ROS) under UV-irradiation, provoking an active habitat selection of gammarids to diminish deleterious effects (e.g. lipid peroxidation). On the other hand, ROS may have influenced the nutritional value of leaf discs. Gammarids may have thus rather preferred a higher quality food source due to its palatability, explaining the observed habitat selection (=indirect effect). Summing up, results of the present study clearly demonstrated environmental parameters (represented by UV-irradiation) to influence the ecotoxicity of $nTiO_2$. The understanding of interactive effects between nanoparticles and environmental parameters seems therefore fundamental for an accurate prediction of environmental risks posed by nanoparticles, which should be further investigated in the future.

79

Individual and functional impacts of environmentally realistic silver nanoparticle exposures on Gammarus sp (Amphipoda)

J. Andreï, CNRS UMR / LIEC CNRS UMR; S. Pain-Devin, Université de Lorraine UL / LIEC CNRS UMR; G. Francois, LIEC CNRS Université de Lorraine / Campus Bridoux; V. Felten, LIEC; M. Garaud, Laboratory LIEC CNRS UMR UdL / CNRS UMR; P. Jean-Francois, R. Philippe, W. Philippe, LIEC CNRS Université de Lorraine; L. Giamberini, Université de Lorraine CNRS UMR

By means of some antibacterial properties, silver nanoparticles (nAg) are more and more widely used in current consumer products and probably released into aquatic environment. One of the main priorities is now how to perform proper evaluation of risk using environmentally realistic exposure concentrations and media. Gammarids are currently used as test organism in ecotoxicology. They also play a major role in ecosystem functioning by their capacity to breakdown leaf-litter. The fine particulate organic matter (FPOM) released by the shredding activity of *Gammarus* can be in turn incorporated in the aquatic food chain. In this context, the effects of low concentrations (from 0.5 to 50 μg/l) of silver nanoparticles with

different sizes, shapes and coatings were tested on *Gammarus sp*. The first study, conducted in microcosm systems, aimed to assess the individual and functional impacts on three *Gammarus* species during three days. Then, most sensitive species was studied during three weeks in a more complex medium (mesocosms) containing sediment and other freshwater organisms (microorganisms, invertebrates). Our objectives are to use various endpoints at different biological organization levels from individual (physiological, behaviour) to ecosystemic ones. Realistic silver concentrations did not induce mortality of gammarids despite a metal bioaccumulation. All nanoparticle and nitrate silver exposures induced a significant locomotion decrease. These impacts were dependant of the nanoparticle size, shape, concentration, exposure time and medium. The effects were also more important for *Gammarus roeseli* which seemed to be the most sensitive species. For example, leaf litter consumption and FPOMs production were significantly reduced by the 10nm silver nanoparticle at 5 μg/l. On the contrary, the assimilation was really increased. This increase could be interpreted as an indirect effect: exposure may conduct organisms to enhance energy storage in order to be able to face energy cost when detoxification will be needed. For environmentally realistic concentrations, silver nanoparticle contamination has direct effects on organism's behaviour and function. These impacts are dependant of the size and the shape of nanoparticle. Interestingly, we found that low nAg concentrations, through the effects on the energetic metabolism of *G.roeseli* (increased assimilation) may cause indirect effects on the aquatic organic matter cycle.

80

The mesocosm approach to estimate the fate, bioaccumulation and toxicity of silver nanoparticles on two endobenthic species: the bivalve mollusk Scrobicularia plana and the worm Nereis diversicolor

A. Vergnoux, Universite de Nantes; P. Buffet, Universite de Nantes / Ecotoxicology; A. Chatel, Université Catholique de lOuest; B. Berthet, ICES; I. METAIS, MMS UCO / Biology; H. Perrein-Ettajani, Université Catholique de lOuest; l. poirier; H. Thomas-Guyon, Université de La Rochelle; C. Risso de Faverney, M. Guibbolini, Université de Nice; D. Gilliland, Institute for Health and Consumer Protection, European Commission - DG JRC; E. Valsami-Jones, The Natural History Museum; C. Mouneyrac, Université Catholique de lOuest / MMS EA

The widespread use of engineered silver nanoparticles (Ag NPs) will likely lead to their increase into the environment. The aim of this study was to evaluate under environmentally realistic conditions the fate, bioaccumulation and toxicity of maltose-Ag NPs on clams (*Scrobicularia plana*) and worms (*Nereis diversicolor*). Animals were exposed in outdoor mesocosms to Ag (10 μg.L^{-1}) added either in the nanoparticulate or soluble forms in comparison with controls for 21 days. The fraction of Ag under labile forms was determined in water and sediment by using Diffusive Gradient in Thin films (DGT). Bioaccumulation of Ag was quantified in the whole soft tissues of both species. Toxic effects were evaluated using a set of biomarkers at different levels of biological organization: i) sub-individual level (biochemical biomarkers) and ii) individual level (behaviour, feeding rate). Results from DGTs indicate a release of Ag ions from Ag NPs either in seawater as in sediment. Both Ag forms were bioaccumulated in both species but no differences between forms were shown. This result is not surprising since a solubilization of Ag from Ag NPs was observed. At the sub-individual level, GST, CAT and CSP activities were induced in both species exposed to soluble and Ag NPs compared with controls. Greater PO and lysozyme activities were observed in clams and worms respectively, exposed to Ag NPs compared to other treatments. DNA damages in the digestive gland of clams were higher in contaminated Ag NPs mesocosms compared to soluble Ag and controls. These results suggest that dissolved Ag species partly control toxicity effects but cannot alone completely explain them, suggesting a specific nano effect. At the individual level, soluble Ag only induced burrowing impairments in both species compared with Ag NPs and controls. This is the first experiment with endobenthic species exposed to Ag as soluble and NP forms under environmentally realistic conditions. Such a degree of complexity in term of exposure to engineered NPs and of the related impacts is a real challenge for the scientific community, and will provide necessary data for Environmental Risk Assessment. This work has received funding from the European Union Seventh Framework Programme (FP7/2007–2013) under grant agreement No. 214478 (NanoReTox). Key Words: silver nanoparticles, outdoor mesocosms, *Scrobicularia plana*, *Nereis diversicolor*

Human exposure to emerging contaminants: monitoring and modeling (II)

81

Accounting for volatilization losses of dermally applied cosmetic ingredients: How important is the inhalation route?

T. Dudzina, ETH Zurich / Institute for Chemical and Bioengeneering; E. Garcia Hidalgo, N. Von Goetz, ETH Zurich / Institute for Chemical and Bioengineering; C. Bogdal, ETH Zurich; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

Accurate modeling of aggregate consumer exposure to a cosmetic ingredient is essential for its safety assessment. For many personal care products that are applied dermally, exposure to their ingredients is considered to occur mainly via dermal absorption, unless vapor pressure of a substance is above a certain cut-off value. However, the contribution of inhalation to the total systemic dose of a substance may potentially be affected by other factors influencing the substance's evaporation from skin, e.g. interaction with other ingredients contained in a product, also called matrix effect (Jovanovic et al., 2008; Tokarzcyk et al., 2012) or binding to lipids/proteins in viable epidermis. In order to test the effect of the product matrix on the volatilization of a common cosmetic ingredient, decamethylcyclopentasiloxane (D5), which is widely used in personal care formulations, we compared the volatilization of the neat substance and two different commercially available formulations: a deo roll-on and a face cream. Single doses of D5 were applied neat (control) and in formulations on either an aluminum circle or porcine full-thickness skin *in vitro* resting on a modified static diffusion cell at two working temperatures (23°C and 32°C). The masses of D5 remaining on the surface, D5 penetrated into the receptor fluid, D5 captured in the trap and D5 retained in the chamber were measured after 15, 30, 45, 60 and/or 75 minutes of exposure. Quantification of D5 was done based on the internal standard (M4Q) quantification procedure using GC/FID, following D5 extraction/desorption. The evaporation rates were determined as slopes of the regression lines for the volitilized mass over time adjusted for the surface area exposed. The results were analyzed using a one-way blocked analysis of variance. The cosmetic formulation had a significant effect on the evaporation rate of D5 (F-test=27.9, p-value< 5.4e-08). The differences in mean evaporation rates between the groups were all significantly different from zero. The greatest difference was observed for the neat-face cream pair at 32°C. No significant difference in evaporation rates was observed between aluminum and skin surface. Overall, the volatilization of D5 from skin *in vitro* occurred very fast, thus indicating that indirect inhalation exposure to volatilized material is a very important exposure pathway. Other ingredients contained in a cosmetic formulation can substantially lower the evaporation rate of D5.

82

Traffic-Related Metal Emissions and their Bioaccessibility in Urban Atmospheric Dust of Human Health Concern

C.L. Wiseman, University of Toronto / Centre for Environment; F. Zereini, Goethe University of Frankfurt / Institute for Atmospheric and Environmental Sciences Department of Environmental Analytical Chemistry

Metal(loid)s emitted from automotive traffic are suspected contributors to the negative health effects observed among urban populations exposed to respirable fractions of atmospheric dust. While measures of total metal(loid) concentrations in urban particulate matter (PM) are important, more information regarding elemental bioaccessibility is essential to support assessments of risk. This study used artificial lysosomal fluid (ALF) and Gamble's solution to simulate conditions in the human lung to assess metal(loid) solubility in airborne PM_{10}, $PM_{2.5}$ and PM_1 sampled in Frankfurt am Main, Germany. Samples, collected using a high volume sampler between June 2009 and November 2010 at a busy roadside location (n=43), were incubated with the simulated lung fluids at 37ºC. The extracts were analyzed for a range of metal(loid)s, including As, Ce, Co, Cr, Cu, Mn, Ni, Pb, Sb, Ti, Pt, Pd and V using an ICP-Q-MS (Varian 820-MS). Metal(loid) concentrations were also determined for filters digested with aqua regia (HNO_3/HCl ratio: 1:3). The results demonstrate that many traffic-related metal(loid)s are highly soluble in simulated lung fluids. In particular, Cu, As, Pb, V and Sb were observed to be the most soluble. Metal(loid) solubility was observed to be strongly pH dependent, with the highest solubility observed for samples extracted with the acidic ALF. Further, metal(loid) solubility did not always increase with decreases in particle size fraction, as is often predicted. For instance, the solubility of Pb was observed to decrease with increasingly finer PM fractions, with a mean solubility of 96 and 78% in PM_{10} and PM_1, respectively. The results demonstrate that many of the toxic metal(loid)s associated with airborne PM are soluble in lung fluids, increasing the risk of negative health outcomes in exposed individuals. Given the complex mix of airborne PM, risk assessments will ultimately need to examine the combined effects of contaminant exposures.

83

Inverse age-dependent accumulation of decabromodiphenyl ether and other PBDEs in serum from a general adult population

J. Grimalt, Environmental Chemistry; M. Gari, Ins of Environ AssessmentWater Resch IDAEACSIC

Polybromodiphenyl ethers (PBDEs), including the decabromodiphenyl congener (BDE-209), were determined in serum of 731 individuals from a general adult population (18-74 years) collected in 2002 in Catalonia. The BDE-209 was the predominant congener (median 3.7 ng/g lipid) followed by BDE-47 (2.6 ng/g lipid) and BDE-99 (1.2 ng/g lipid). PBDEs in this population (median 15.4 ng/g lipid) ranked among the highest of previously described concentrations in populations in Europe, Asia, New Zealand and Australia, yet they were lower than those found in North America. Age was clearly the socio-demographic factor of highest influence

on the PBDE distributions. However, unlike usual trends of higher accumulation of POPs through age, the higher concentrations were found in young individuals (< 30 years) rather than in adults (≥ 30 years), with differences of 14%, 31% and 46% in the most abundant congeners (i.e. BDE-209, BDE99 and BDE-47, respectively). This age-dependent distribution of PBDEs (including the case for BDE-209, which is shown for the first time in this cohort) is explained by the higher and widespread use of these compounds since the 1980s. In view that these compounds remain highly used, this accumulation pattern is likely to evolve, anticipating an increasing level of PBDE concentrations in future general population surveys, yet probably assuming an age-dependent increase pattern. Socio-economic level was also a determinant of BDE-47 concentrations, but only relevant for the least affluent class, suggesting that lifestyle and environmental conditions in the dwelling place may also contribute to exposure. Nonetheless, gender, body mass index, place of birth, parity and education level did not show any statistically significant influence on the observed PBDE distributions.

84

Determination of DEHP metabolites, PFOS and PFOA in breast milk and cord plasma samples from European birth cohorts

M. Lamoree; J. Koekkoek, VU University, Institute for Environmental Studies; T. Trnovec, Slovenska Zdravotnicka Univerzita v Bratislave; G. Schoeters, Flemish Institute for Technological Research VITO; M. Van de Bor, Institute of Health Sciences VU University; M. Eggesbo, Norwegian Institute of Public Health; J. Legler, VU University / Institute for Environmental Studies

The incidence of childhood obesity has reached epidemic proportions globally. There is accumulating evidence that factors that influence long-term risk of obesity and related disorders begin very early in life. Early life exposure to environmental contaminants has been implicated in altering developmental programming, resulting in possible higher susceptibility to obesity. The OBELIX (OBesogenic Endocrine disrupting chemicals: LInking prenatal eXposure to the development of obesity later in life) project examined the hypothesis that prenatal exposure to endocrine disrupting compounds (EDCs) in food plays a role in the development of obesity later in life. The project focused on assessing prenatal exposure to chemicals from six major classes of EDCs found in food including dioxins and dioxin-like polychlorinated biphenyls (PCBs), non-dioxin-like PCBs, brominated flame retardants (BFRs), organochlorine pesticides, phthalates and perfluorinated alkyl acids (PFAAs), e.g. perfluorooctanoic acid (PFOA) and perfluorooctanesulfonate (PFOS). In this presentation, method development, validation and analytical results of the quantitative trace level analysis of DEHP metabolites, PFOS and PFOA in cord plasma and breast milk samples from different European birth cohorts (FLEHS II, HUMIS, Michalovce, Linc) will be discussed. The levels of PFOS, PFOA and selected secondary DEHP metabolites in cord plasma and breast milk will be compared with those obtained in other cohort studies. However, especially for secondary DEHP metabolites in cord plasma, data are extremely scarce, emphasizing the uniqueness of our study. Other topics to be addressed are e.g. the influence of contamination of the samples and remaining enzymatic activity on the suitability of specific metabolites for exposure assessment

85

Nontarget analysis of organic pollutants in human urine: developing a generic screening method

M. Plassmann, Department of EffectDirected Analysis; W. Brack, M. Krauss, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis

Human biomonitoring programs usually analyse human samples for a limited number of chemicals and biomarkers. However, there might be many more chemicals of concern to human health, which so far are unknown or simply not analysed for so far. The goal of this project is thus to develop screening methods for the detection of new emerging chemicals in human tissues like urine and blood. Here we present the method development for a nontarget screening of human urine. 38 analytes representing different chemical groups with a wide range of properties were chosen for recovery experiments and determination of lowest detectable concentrations. Direct injections of spiked samples into a liquid chromatograph coupled to a high resolution mass spectrometer and sample preparation via QuECheRS (Quick Easy Cheap Rugged and Safe) extraction were tested. Recoveries show that by a combination of both sample preparations all analytes can be detected. Thus this type of sample preparation is suitable for a nontarget screening of human urine samples. The additional application of a deconjugation step makes it possible to detect the original substances and thus have a control for the nontarget detection of metabolites. The nontarget screening of a set of human urine samples will be presented at the conference.

Advancing Adverse Outcome Pathways for Integrated Toxicology and Regulatory Applications (II)

86

SeqAPASS: Sequence alignment to predict across-species susceptibility

C.A. LaLone, US EPA; D.L. Villeneuve, US EPA / Midcontinent Ecology Division; H. Helgen, Computer Sciences Corporation; G.T. Ankley, US EPA / National Health and Environmental Effects Research Laboratory

Efforts to shift the toxicity testing paradigm from whole organism studies to those focused on the initiation of toxicity and relevant pathways have led to increased utilization of in vitro and in silico methods. Hence the emergence of high through-put screening (HTS) programs, such as U.S. EPA ToxCast, and application of the adverse outcome pathway (AOP) framework for identifying and defining biological key events triggered upon perturbation of molecular initiating events and leading to adverse outcomes occuring at a level of organization relevant for risk assessment [1]. With these recent initiatives to harness the power of "the pathway" in describing and evaluating toxicity comes the need to extrapolate data beyond the model species. Sequence alignment to predict across-species susceptibilty (SeqAPASS) is a web-based tool that allows the user to begin to understand how broadly HTS data or AOP constructs may plausibly be extrapolated across species, while describing the relative intrinsic susceptibiltiy of different taxa to chemicals with known modes of action (e.g., pharmaceuticals and pesticides). The tool rapidly and strategically assesses available molecular target information to describe protein sequence similarity at the primary amino acid sequence, conserved domain, and individual amino acid residue levels. This in silico approach to species extrapolation was designed to automate and streamline the relatively complex and time-consuming process of comparing protein sequences in a consistent, logical, and criteria driven manner intended for predicting across species susceptibility to a chemical perturbation. To define the domain of applicability and enhance the utility of the SeqAPASS tool, multiple case studies have been explored, including the derivation of predictions for across species susceptibilty to chemicals that target the human estrogen receptor, bovine androgen receptor, mosquito voltage-gated sodium channel, fungus cytochrome P450 51, and honey bee nicotinic acetylcholine receptor. These examples highlight the utility of the SeqAPASS tool for researchers and regulators alike.

87

Predicting the sensitivity of endangered sturgeons to dioxin-like compounds: Molecular investigation into the aryl hydrocarbon receptor pathway

J.A. Doering, University of Saskatchewan / Toxicology Centre; R. Farmahin, Environment Canada / National Wildlife Research Centre; S.B. Wiseman, University of Saskatchewan / Toxicology Centre; S. Beitel, University of Saskatchewan Toxicology Centre / Toxicology Centre; S.W. Kennedy, Environment Canada; J.P. Giesy, University of Saskatchewan / Toxicology Centre; M. Hecker, University of Saskatchewan / School of the Environment Sustainability and Toxicology Centre

Numerous sturgeon species around the world are endangered, which has rendered these fishes of interest in context with the risk assessment of anthropogenic stressors. However, current risk assessment attempts are hampered by a lack of knowledge about the sensitivity of sturgeons to toxicants of concern, such as dioxin-like compounds (DLCs). DLCs elicit their toxic action through activation of the aryl hydrocarbon receptor (AhR) and are known to cause a variety of adverse effects in vertebrates. In birds, the amino acid sequence of the ligand binding domain of the AhR is known to result in differences in affinity for DLCs and therefore differences in sensitivity among species. In order to incorporate differences in species sensitivity of sturgeons to DLCs into the adverse outcome pathway framework, the objectives of this study were to: 1) characterize the relative differences in sensitivity to DLCs between two species of endangered sturgeon (white sturgeon and lake sturgeon) and 2) develop methods to predict the relative sensitivity to DLCs of other species of sturgeons based upon knowledge of species differences in mechanisms of the molecular initiating event. White sturgeon were found to have 10-fold greater response following exposure to a model DLC, compared to lake sturgeon with regard to up-regulation of hepatic CYP1A transcript abundance. Since effects of exposure to DLCs are known to be driven by activation of the AhR, the AhR1 and AhR2 of white and lake sturgeon were cloned and characterized in an attempt to explain the observed differences in *in vivo* responses between these species. White and lake sturgeon AhR1s had similar sensitivity to 2,3,7,8-TCDD *in vitro* using the luciferase reporter gene assay, while white sturgeon AhR2 had an EC50 10-fold less than lake sturgeon AhR2. Relative differences in response between white and lake sturgeon *in vivo* and with regard to AhR2 activation *in vitro* appear similar indicating that the AhR2 might drive differences in sensitivity to DLCs among these species of sturgeons. Homology modeling will be used to predict whether amino acid differences in the ligand binding domain of the AhR2 drives the observed differences in sensitivity between the AhR2 of white and lake sturgeon and could allow prediction of the sensitivity of other endangered sturgeon species based on their AhR2 amino acid sequence. This research could be essential in the risk assessment of sturgeons, and other endangered fishes, to DLCs.

Application of genome-wide transcript profiling to elucidate the mechanisms of toxicity of environmental chemicals in model and non-model fish species

E.M. Santos, University of Exeter / Biosciences College of Life and Environmental Sciences; T. Uren Webster, C.R. Tyler, Biosciences College of Life and

Environmental Sciences; R. Van Aerle, University of Exeter / Biosciences College of Life and Environmental Sciences
In recent years, advances in sequencing technologies and approaches for transcript profiling in biological samples have allowed the unbiased assessment of the mechanisms of toxicity of environmental chemicals in model organisms, mainly through the use of gene expression microarrays. However, the development of genome wide microarrays for non model organisms required very significant research effort, which precluded their use in the majority of environmentally relevant species. As a result, researchers have investigated mechanisms of chemical toxicity principally in model species and datasets for other species of ecological importance are still scarce. The very recent accelerated development in high throughput sequencing technology has allowed for genome wide transcript quantification to be conducted without previous sequencing information and provided researchers with new opportunities to investigate chemical toxicity in both model and non model organisms of ecological relevance. These datasets provide essential information for the construction of adverse outcome pathways to support risk assessment. We have made use of both gene expression microarrays and high throughput sequencing (RNA-Seq) to conduct transcript profiling in model and non model fish species in order to investigate the mechanisms of chemical toxicity in a range of environmentally relevant chemicals (including oestrogens, metals and pesticides) and determine the molecular pathways most affected by each chemical. We observed conserved molecular pathways of response to a number of environmental chemicals and in particular for oestrogens. In addition, our research identified novel effect pathways for a range of chemicals and most notably a striking down-regulation of the cholesterol biosynthesis pathway following exposure to both copper and linuron. These results provide case studies for the utility of global transcriptomic approaches in the identification of the pathways of effect of environmental chemicals in an unbiased manner. In addition, our data provide critical examples of conserved response pathways across vertebrate species.

89

Development of an in vitro metabolomic approach for enhanced neurotoxic effects by contaminants, with emphasis on neurotransmitter pathways

P. Leonards, VU University Institute for Environmental Studies / Chemistry Biology; S. Tufi, VU University, Institute for Environmental Studies; J. Kamstra, VU University Amsterdam; R.v. Dijk, VU University Institute for Environmental Studies; R.v. Kesteren, VU University CNCR; T. Hamers, VU University / Institute for Environmental Studies
Worldwide, serious concern has arisen about the increased incidence of learning and developmental disorders in children. From a scientific point of view, there is no doubt that exposure to neurotoxic chemicals during early brain development can adversely affect learning and development. Various recent epidemiological studies have indicated that exposure to low doses of environmental biologically active contaminants during human development can have deleterious effects on cognitive development in childhood. The European commission-funded project DENAMIC "Developmental Neurotoxicity Assessment of Mixtures in Children" investigates neurotoxic effects (e.g. learning and developmental disorders) of low-concentration mixtures of pesticides and a number of common environmental pollutants in children. One of the aims is to develop better and sophisticated tools, procedures and testing methods to screen compounds for (developmental) neurotoxicity and to improve assessment of exposures and effects (www.denamic-project.eu). As part of the project, a new alternative assessment strategy based on a combination of in vitro and in vivo assays is under development in order to prioritize compounds for further in vivo testing. To this end, hazard characterization of pesticides and environmental pollutants on a molecular and cellular level is carried out, with emphasis on adverse effects during neuronal development. An array of in vitro assays is used to investigate (developmental) neurotoxic effects, including neuron differentiation in the SH-SY5Y human neuroblastoma cell line, acetylcholinesterase (AChE) inhibition, and transthyretin (TTR) binding. An important aspect is the development of biomarkers for (developmental) neurotoxicity in animal models using (epi-)genomics, proteomics and metabolomics. This paper present the development of a metabolomic and neurotoxicity approach for the SH-SY5Y cell line. The focus is on four neurotransmitter pathways: Dopamine, Serotonin, Gaba, and Acetylcholine. Analytical methods were developed to detect and quantify the precursors, neurotransmitters and metabolites in the SH-SY5Y cells using a 12 well based system and LC-MS/MS. An LC-HRTOF system was used for untargeted analysis. SH-SY5Y cells were exposed to various pesticides, their metabolites and MeHg to investigate the effects on the neurotransmitter pathways.

From Laboratory to assessing efficiency of Water reprocessing plants

H. Munasinghe, T. Williams, University of Birmingham / School of Biosciences; P. Antczak, University of Liverpool / Institute of Integrative Biology; A. Murk, Wageningen Agricultural University / Dept of Toxicology; E. Foekema, Wageningen IMARES; E. Roex, DELTARES; F. Smedes, DELTARES / RECETOX; M. Sebire, J. Prokkola, Cefas; M.R. Viant, K. Chipman, University of Birmingham; R. Van der Oost, Waternet; I. Katsiadaki, Cefas / Environment and Animal Health; F. Falciani,
Anthropogenic contaminants from waste water treatment plants (WWTPs) contribute to the pollution of surface waters. Although conventional WWTPs improve water quality, additional steps such as sedimentation ponds, reed beds and wetland forests can be used before discharge to surface water and have been shown to improve water quality indicators such as dissolved oxygen. The efficiency of the purification process can be assessed by measuring chemical concentrations at different stages of the process. This approach however is limited by its relevance to the biological effect and is limited in scope of chemicals which can be measured. Traditionally ecotoxicology has assessed biological effect through a number of acute or chronic toxicity endpoints and a small number of endocrine disruptor biomarkers. While these have shown to be informative, they suffer from several limitations. They do not for example allow for identification of potential adverse outcome pathways (AOPs) and they do not provide quantitative assessment of risk nor do they allow prediction of exposure effects. To address these limitations we have developed a battery of computational modelling tools and applied these to model a set of control experimental exposures to predict exposure effects in the environment. We analyse an integrated dataset of 1) laboratory exposures to define baseline measurements for 10 different chemicals and 26 complex mixtures and 2) in a mesocosm experiment linked to effluent purification steps at three different WWTPs. Our approach uses and integrated computational biology approach to utilize all available transcriptomic, bioassay and chemistry information on the experiments in a network inference approach linked to predictive modelling methodologies. AOPs defined by this procedure represent inferred networks linking genes and additional measurements and endpoints recorded as part of the experimental design. Here we show its effectiveness in real world applications – assessing the efficiency of WWTPs. While this still only focuses on a relatively small number of compounds we have shown that AOPs can be identified which relate to single and mixture responses and are able to link these in real world applications. Furthermore we show that mixture exposure can lead to additional functions being perturbed.

91

Hepatic vitellogenin induction in fathead minnows is influenced through both soluble estrogen receptors and membrane receptors

N.D. Denslow, S. Jayasinghe, University of Florida / Physiological Sciences; K.J. Kroll, University of Florida / Physiological ScienceVet Med; N. Vinas, Mississippi State University; T. Sabo-Attwood, University of Florida / Department of Environmental Global Health Center for Environmental and Human Toxicology
Adverse outcome pathways are defined by linking the interaction of a toxicant with a molecular initiating event and then to a series of steps at increasingly higher biological relevance that lead to a final adverse consequence for the organism. Important for this concept to work is defining precisely the interactions in the pathway, so that there is a clear consequence of exposure to the toxicant. In the case of estrogens, they are believed to bind directly and specifically to soluble estrogen hormone receptors which are then able to bind to response elements in promoters of susceptible genes. Vitellogenin (Vtg) has emerged as a strong biomarker for estrogenic chemicals, induced through soluble estrogen receptors. Male fathead minnows (*Pimephales promelas)* were exposed to 5 ng ethinylestradiol (EE_2)/L or to a mixture of 5 ng EE_2 and 100 ng ZM189,154/L (a potent antiestrogen, known to block activity of all estrogen receptors) for 48 h. Microarray analysis of hepatic gene expression changes indicated, as expected, that many genes, including the three vitellogenins, were up regulated by the exposure to EE_2. Inclusion of ZM189,154 in the mixture blocked expression changes for some genes, but enhanced expression of others, generating two distinct expression patterns. Among the genes that were blocked by the antiestrogen were Vtg 2 and Vtg3, however the mixture enhanced expression of Vtg1, among other transcripts that appear to be targeted via non-genomic signaling pathways. To verify whether the membrane estrogen receptor GPER could influence expression of Vtg 1, fathead minnows were exposed to 5, 30 and 100 ng G1/L, a specific agonist of GPER that does not agonize soluble ERs. Vtg1 mRNA expression increased in a dose-responsive manner in both females and males, suggesting that non-genomic signaling may indeed be involved in regulating the expression of this transcript. Our results suggest that both genomic and non-genomic pathways influence Vtg expression and that membrane receptor molecular initiating events should be considered when defining adverse outcome pathways resulting from exposures that interrupt Vtg synthesis in fish.

Modelling techniques for future-oriented LCA and forecasting scenarios (II)

92

Accounting for resource functionality in resource use impact assessment

V. De Bruille, CIRAIG École Polytechnique de Montréal / Chemical Engineering; C. Bulle, CIRAIG Polytechnique Montreal / Chemical Engineering; T. Dandres, CIRAIG; O. Jolliet, University of Michigan / School of Public Health; C. Gaudreault, NCASI Canada; R. Samson, Ecole Polytechnique de Montreal / Department of Chemical Engineering
Life Cycle Assessment (LCA) is used increasingly over the past years in decision making, in order to predict environmental impacts of products, processes or services. Hence, LCA is used to asses the environmental benefits of lifestyle changes such as the electrification of the transport sector that is undertaken to diminish the emissions of greenhouse gazes (GHG). Yet, while GHG emissions are diminished, other environmental concerns arise, such as the depletion of the resources needed in electrical cars. Electrifying the transport sector implies an intensive use of resource and questions arise concerning future resource availability: is there enough mineral resources to support a global electrification of transport an all the other human needs given the fact that some of those resources are non substitutable for some functionalities whereas other have easy alternatives. Facing the challenge of linking current LCA with future scenarios is not possible with existing life cycle impact assessment methods. In this study, an approach based on the competition that exists for resources is proposed by accounting for resource availability variation in the future. As variation in a resource's availability affects its end-use users differently, resource is no longer considered for its nature but for the functions it provides. Competition evolves in time depending on the adaptation capacity of its users facing availability decrease. The easier it is to replace a resource or a technology whilst remaining functionally equivalent, the quicker users will adapt and resource competition will decrease accordingly. The consequence of a decreasing availability is a shown by a non-dimensional competition factor, the MAterial Competition Scarcity Index (MACSI), which represents the proportion of the users that will remain unable to fulfil their functionality when the resource is depleted. The moment when depletion occurs is given by the ratio of reserve over current production. The proposed competition factors are obtained for resources used in electrical vehicles batteries and express how fierce competition may be for these resources in the future based on today knowledge. The developed indicator is applied to a case study modelling the potential environmental consequences and benefits that will occur if the province of Quebec reaches its goal of replacing 20% of its current intern combustion engine cars by electrical vehicles.

93

Environmental consequences of stormwater harvesting for flood prevention

A. Petit-Boix, e. sevigne, sostenipra; A.P. Barbassa, B. Teixeira, D. de Lima Nascimento Sirio, L.A. Gutierrez Rojas, Federal University of Sao Carlos / Civil Engineering Department; D. Marin, CETaqua Water Technology Centre; J. Rieradevall, Institute of Environmental Science and Technology ICTA Universitat Autònoma de Barcelona / sostenipra; X. Gabarrell Durany, Universitat Autònoma de Barcelona / Chemical Engineering Department Institut de Ciència i Tecnologia Ambientals
Rainwater has been mostly studied as an opportunity for those regions facing water scarcity problems that will become more severe in the near future. As a result, different strategies were developed in order to reuse rainwater in households, buildings and neighbourhoods. However, it must be taken into account that evacuation systems also play an important role in water and wastewater management, given that intense rainfall might cause flooding events and consequently reversible and irreversible material and human losses. Therefore, the goal of this study is to determine the net environmental benefits of constructing flood prevention systems from a consequential life cycle assessment (CLCA) perspective. Two different scenarios with and without prevention systems are compared and the environmental amortisation of the infrastructure is accounted for considering the production of new cars and new buildings after a flooding event. In addition, the environmental savings deriving from the rainwater reuse will be discounted from the burdens associated to the water supply network. As case study, the city of São Carlos (Brazil) is considered, given the heavy precipitation events that usually take place through the year.

94

CONSEQUENTIAL LCA TO ASSESS ENVIRONMENTAL BENEFITS OF SMART GRIDS

A. Gallice; S. Worbe, VEOLIA Environnement Recherche et Innovation / Health and Environment
Development of smart grids is considered as promising to reduce environmental impacts associated to energy consumption. The introduction of communication and information technologies would ensure an optimal adjustment between means of production (including intermittent means as renewable energies), and electrical consumption, thus stabilizing the balance of the grid and reducing the use of the most pollutant plants. This would result in environmental benefits, which still need to be evaluated. Given the time scale and the underlying decision involved, Consequential-LCA was identified as the most relevant methodology to evaluate environmental benefits associated to a Smart Grids project. The identification of the marginal mean of production is based on a forcasting methodology linked to the Spot market price. This methodology has been tested on several management strategies applied to a stock of commercial buildings and industrial sites, in the PACA region (France) in the Reflexe project. This approach allowed identifying the global environmental consequences of a smart management of different power consumption profiles, implemented at local level.

95

The role of dynamic perspectives to model future scenarios for attributional and consequential life cycle assessments: case of old scrap aluminium

e. sevigne, sostenipra; C. Gasol, Inedit Innovacio sl; J. Rieradevall, Institute of Environmental Science and Technology ICTA Universitat Autònoma de Barcelona / sostenipra; X. Gabarrell Durany, Universitat Autònoma de Barcelona / Chemical Engineering Department Institut de Ciència i Tecnologia Ambientals
Cities have become huge reserves of materials in form of in-use stock and in subsequent years, this in-use stock will be an important source of waste materials to treat. Therefore, in order to project future scenarios for waste management, dynamic perspectives accounting for this in-use stock should be incorporated into the analysis. Besides, these projections are the basis for determining the future potential GHG benefits of recycling. In this regard, two different methodologies are applied to determine the GHG benefits from recycling, which include attributional life cycle assessments (ALCA) and consequential life cycle assessments (CLCA). As the methodologies are based on different assumptions, results between the two differ. The aim of this study is to show the necessity of incorporating dynamic material flow analysis (dMFA) in LCA (ALCA and CLCA) in order to properly project waste generation trends. As case study, the old scrap aluminium generated in Spain is considered. The projection shows a significant increase in old scrap generation with a value of 290,154 tonnes in 2020, equivalent to an increase of over 780% since 1995 and over 146% since 2010. GHG savings conducted with CLCA double results with ALCA. Main differences are due to the energy mixes profiles considered. In this sense, we have used the average energy mix and average technology mixes in the ALCA, independently of the market constraints or conditions. However, demand for primary aluminium has been displaced to Asian countries, as well the demand for old scrap, which leads to different energy mix profiles and technologies. In this sense, with CLCA it is possible to evaluate the primary aluminium traded in the global market and evaluate changes in supply and demand. If LCA studies on waste management are conducted for decision making, projections should consider the past and current consumptions in order to project proper scenarios. Otherwise, the results could be underestimated.

96

Influence of initial conditions of agent-based model simulation for consequential LCA of bioenergy

T. NAVARRETE GUTIERREZ, CRTE CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; S. Rege, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; A. Marvuglia, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTEResource Centre for Environmental Technologies CRTE; E. Benetto, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE
Consequential LCA (C-LCA) aims at identifying the changes (Δ), in terms of potential environmental impacts induced into a system, caused by human driven actions, most often related to policy or strategic decisions. The use of a formal modelling strategy is often advocated to compute Δ more accurately than using simplified scenario-based approaches. In this presentation we deal with the implications of using agent-based modelling (ABM). Our objective is to build an ABM of the consequential effects of possible incentive mechanisms set up to increase the area under maize in Luxembourg to produce biofuels. For this, it is necessary to model farmers' behaviour and market mechanisms of price discovery. Considering behavioural aspects in farming would potentially improve the modelling power. When developing an ABM, one is faced with the problem of initializing parameters. The question we focus on is: what is the sensitivity of simulation results to the initial distribution of agent attributes? This presentation discusses using ABMs for C-LCA and the influence of using different strategies to initialize values of the ABM. In our model, agents have a profit maximizing behaviour. Specification of past prices is known to all farmers and a common forecast of future price of each crop. We have implemented the model in a virtual laboratory programmed in java. Two different approaches were used to initialize parameters. One is to distribute them uniformly around the mean for each farm type. The other is to fit a right-skewed distribution to the entire farming sector with a global average farm size. The resulting values are similar in their means and standard deviations, when compared farm class wise, but the number of farms belonging to each farm class is different. The results achieved so far show that the modelling strategy followed is suitable to address the complexity of the problem at hand for Consequential and future-oriented LCA.

97

Towards comparative short-period time-resolved life cycle assessment of differently charged electric vehicles

B. Zimmermann, Karlsruhe Institute of Technology / Institute for Technology Assessment and Systems Analysis ITAS; M. Baumann, Karlsruhe Institute of Technology KIT / Institute for Technology Assessment and Systems Analysis ITAS; H. Dura, KITITAS / Institute for Technology Assessment and Systems Analysis ITAS; M. Weil, Karlsruhe Institute of Technology KIT / Institute for

Technology Assessment and Systems Analysis ITAS
Local traffic emissions, like noise, particulate matter, ozone or nitrogen oxides are a threat to human health in cities worldwide. Many municipalities try to abate those emissions by restricting vehicle access and promoting electric mobility in the city centers, which can reduce overall emissions or shift emissions to less occupied regions. Not only individual car-traffic is responsible for those emissions. Large vehicles, such as public transit buses, could also be electrified in order to reduce the local traffic emissions. Several energy storage system options for powering such electric vehicles are available on the market, e.g. batteries or supercapacitors. Supercapacitors, which have a smaller energy density but longer service lifetime than lithium-ion batteries, are expected to be frequently recharged while the bus is in operation. Whereas batteries are expected to be recharged when the vehicle is off duty. This means that a supercapacitor-bus is quickly recharged at bus stops and has only a short driving range between two halts, while in contrast a battery is recharged over several hours in the depot and can propel the bus over the full operation range on a single charge. Thus the energy storage type determines the charging timeframe. It is expected that the energy supply varies during the operation and non-operation periods of the vehicle and thus the charged energy of both storage types has different environmental impacts. For example, the supercapacitor-vehicle is expected to be mostly charged during daytime, when more environmentally friendly photovoltaic electricity is available in the power grid. In order to perform a comparative life cycle assessment of both energy storage types, a detailed analysis of the power supply is necessary. In this study the hourly and seasonal variation of the German electricity mix is used in a time-resolved manner in order to calculate the different environmental impacts of on-duty and off-duty charging of electric public transit vehicles. Time-resolved electricity mix data is taken from public sources with minimal use of generic models. For this first comparative approach the vehicle's and storage systems' production, as well as the infrastructure and the end of life are disregarded. The study is meant as a first attempt to sample time-resolved life cycle assessment for comparative analysis on a small timescale and is thus also aiming at pinpointing issues and development potential of the methodology.

How can scientific advances support regulatory risk assessment for pesticides? (II)

98
Re-evaluation of the assessment factor for the earthworm Tier 1 risk assessment of plant protection products
G. Ernst, Bayer CropScience / Ecotoxicology; J. Bendall, Dow AgroSciences LLC; M. Bergtold, BASF SE; M. Coulson, Syngenta; A. Dinter, DuPont / Crop Protection; B. Garlej, Makhteshim Agan Poland; K. Hammel, Bayer CropScience AG / Environmental Safety; P. Kabouw, BASF SE; G. von Mérey, Monsanto / Regulatory; A. Sharples, Cheminova AS; S. Vrbkova, Tier Solutions GmbH; G. Weyman, Makhteshim-Agan; H. Christl, Tier Solutions GmbH
The conservatism in tier 1 earthworm risk assessment for plant protection products (PPP) under the Regulation 1107/2009 is expected to increase due to revision of the PEC_{soil} modeling procedure in the near future. EFSA proposes to use realistic worst case PEC_{soil} values for each European regulatory zone considering a lower soil bulk density, a lower organic carbon content, and a reduced crop interception rate due to consideration of worst case wash-off assumptions. Furthermore, several different soil layers for which PEC_{soil} values could be calculated are under discussion, i.e. 0-1 cm, 0-2.5 cm, 0-5 cm, and 0-20 cm soil depth. PEC_{soil} values based on the new EFSA proposal are estimated to increase up to a factor of 40 which would lead to an overly conservative tier 1 risk assessment in case these PEC_{soil} values are simply plugged into the current risk assessment scheme with an assessment factor of 5. In order to re-calibrate the future earthworm tier 1 risk assessment, under revised PEC_{soil} modeling assumptions, effect levels in the standard laboratory reproduction tests are compared with the effect levels in higher tier studies for a representative set of case studies compiled by ECPA companies (n=59). For re-calibration of the tier 1 risk assessment, the relevant soil layer for the risk assessment and the assessment factor is adjusted in the way that the regulatory acceptable concentration or rate based on the tier 1 laboratory study (no-observed effect level divided by the assessment factor) does not exceed the NOEAEC or NOEAER derived from the corresponding field study. The results of this evaluation give clear evidence that considering a layer for PEC_{soil} modeling of 0-5 cm in combination with the current assessment factor of 5 would lead to an appropriate earthworm tier 1 risk assessment. Whereas, PEC_{soil} values based on a soil depth of 0-1 cm in combination with an assessment factor of 5 would lead to an overly conservative tier 1 risk assessment. This would trigger a large number of additional field studies without any indication for a real-world problem. It is therefore recommended to leave the relevant layer for PEC_{soil} modeling at 0-5 cm in combination with a tier 1 assessment factor of 5 which has been shown, based on a large dataset to be protective overall for a large dataset. This would lead to a meaningful tier 1 earthworm risk assessment avoiding a large number of false positives and minimizing the risk of producing false negatives.

99
A tiered Collembola risk assessment approach under the EU Regulation 1107/2009
G. Ernst, Bayer CropScience / Ecotoxicology; P. Neumann, Bayer CropScience AG
According to the EU Regulation 1107/2009 the toxicity of a plant protection product (PPP) for Collembola is assessed with the standard Collembola reproduction test (OECD 232, *F. candida*). If a potential risk cannot be excluded in the tier 1 risk assessment by comparing no effect level in the OECD test (including an assessment factor) and the predicted environmental concentration in soil (PEC_{soil}) higher tier studies are suggested, i.e. semi-field studies or field studies under realistic use conditions. However, the PEC_{soil} modeling procedure is about being revised in the near future by EFSA. PEC_{soil} are estimated to increase by a factor of up to 40 leading to a strong increase in Tier 1 risk assessment conservatism. In order to buffer an unreasonable increasing number of false positives in an overly conservative tier 1 risk assessment intermediate tiered alternatives are needed. Therefore, a toolbox for a tiered Collembola risk assessment approach is discussed: 1) The standard Collembola reproduction test with *F. candida* (OECD 232) where the PPP is mixed homogenously into artificial soil is a suitable tool to detect the intrinsic toxicity of a PPP to Collembola in a first step. 2) To account for a more realistic exposure in an ´extended` laboratory test system, the PPP can be applied e.g. via treated seeds or granules in the OECD 232 test. 3) A Collembolan two-generation study is developed as an intermediate tiered laboratory test system in order to assess the intrinsic potential for recovery from the treated population itself. 4) In semi-field test systems, e.g. Terrestrial Model Ecosystems (TME), the short- and long-term impact of a PPP on Collembola communities can be tested in soil cores. Comparative measurements with field data indicate that a TME is an intermediate tiered test system. 5) A Collembola field study under realistic use conditions is suggested as highest tier within the tiered Collembola risk assessment approach, including typical crop specific agricultural management practices. Case studies will be presented and demonstrate that the proposed intermediate tiered test systems are conservative and fit well into the tiered risk assessment scheme.

100
Supporting Agrochemical Registration Through Bespoke Multi-Country Data Collection
J. White, ARCADIS UK / Environment; A. Newcombe, ARCADIS US Inc; B. Billson, P. Hamer, ARCADIS UK; D. Wallace, S. Parry, Syngenta Limited
Current regulations governing the registration of plant protection products in the European Union (1107/2009) mandate that an assessment for the potential to reach groundwater is made. This is primarily undertaken using conservative modeling approaches. Registration of plant protection products is becoming increasingly difficult within the EU as the risk assessment framework has evolved to make the parameterization of these models more conservative. At present, however, there is no generally accepted higher tier option that can be used to put conservative modeling estimates in to context. Monitoring presents a potential higher-tier option to demonstrate zero or very low exceedence of groundwater concentration limits when modeling suggest the potential for extensive movement. To support the registration of a pesticide and address EU and member state questions, a very large pan-European groundwater testing programme has been designed and undertaken to establish if this product has the potential to leach to groundwater following commercial use. The methodology of the study will be outlined, alongside how key challenges have been overcome, and initial findings of the study will provided.

Fate of rice herbicide Propanil and its metabolite 3, 4-Dichloroaniline in water-sediment systems from rice paddy with and without flooding simulation
Y. Yuan, P. Zhang, C. Possberg, RWTH Aachen University / Institute for Environmental Research Biology V; M. Romich, RWTH Aachen University / Institute of Sociology; B. Scholz-Starke, RWTH Aachen University Institute for Environmental Research / Institute for Environmental Research BioV; H. Hollert, RWTH Aachen University / Institute for Environmental Research; M. Ross-Nickoll, RWTH Aachen / Institute for Environmental Research; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research
Fate of rice herbicide Propanil and its metabolite 3, 4-Dichloroaniline in water-sediment systems from rice paddy with and without flooding simulation Ye Yuan[1], Peng Zhang[1], Burkhard Schmidt[1], Manfred Romich[2], Bjoern Scholz-Starke[1], Henner Hollert[1], Martina Ross-Nickoll[1], Andreas Schaeffer[1]
[1]Institute for Environmental Research (Biology V), RWTH Aachen University, Aachen, Germany [2]Institute of Sociology, RWTH Aachen University, Eilfschornsteinstr 7, 52062 Aachen, Germany E-mail contact: ye.yuan@bio5.rwth-aachen.de In order to determine the fate and behavior of a model pollutant in Yangtze water sediment systems, we selected the rice herbicide Propanil, which is known to release the priority pollutant 3,4-dichloroaniline (DCA). DCA, which could also be formed by many other pesticides and has been reported to form a toxic metabolite in soil and sediment, i.e., tetrachloro-diazobenzene (TCAB), which we included in our fate studies. We incubated Propanil in water sediment collected from rice agriculturally influenced area of the Three Gorges Reservoir area at Yangtze during dry season and simulated flooding conditions to the system in lab, applying radioactively labeled compounds in order to establish mass balances and to figure out further metabolisms as well. The fate of ^{14}C labeled DCA was also studied similarly in a water-sediment system collected from a rice paddy area in Italy. Besides, qualitative interviews with farmers and pesticide shop owners/ retailers /wholesalers were also carried out in order to figure out the influencing factors of farmers' choices on pesticides/herbicides related products, as well as to know farmer's pesticide usage habits, annual agricultural activities, related knowledge and environmental awareness, and so on, which is a supplementary support for the environmental risk assessment of pesticide use in this area.

102
Environmental quality through science? – Reflecting "the new challenges" for pesticide risk assessment
T. Frische, Federal Environment Agency UBA / Section IV
In March 2013 the three independent European Scientific Committees (SCHER/SCENIHR/SCCS) adopted their opinion "Addressing the New Challenges for Risk Assessment". The opinion was delivered upon request of the European Commission asking for "a comprehensive review of risk assessment procedures and new challenges for risk assessment". Regarding ecological risk assessment of organic chemicals, the opinion concludes: "The approaches in current use for ecological risk assessment are likely to suffice for regulatory purposes as sufficiently protective for ecosystems. However they lack environmental realism. This entails high uncertainty on the actual consequences of environmental contaminations on the ecosystem structure and functions that has to be addressed by the application of uncertainty/safety/default factors. The main challenge for ecological risk assessment is to develop tools that take account of the complexity of the potentially exposed ecosystems and enable assessment of site-specific effects." Several priority areas for improvement are identified by the Committees in view of their "vision of future risk assessment methodology". Focusing on the state-of-the-art in pesticide risk assessment in Europe, the presentation is reflecting the SCHER/SCENIHR/SCCS-opinion against the following questions: What are the basic assumptions of the opinion? What is the evidence in support of these assumptions and the main conclusions of the opinion? What are the mechanism driving the evolution of risk assessment methodology? What are the roles of the main stakeholders (academic science, industry, government) involved in this process? What might be the consequences of the changes envisaged by the opinion (i.e. moving risk assessment methodology further towards increasing complexity)?

Plants and pollutants in the environment (II)

Strategies for enhancing plant survival and remediation potential under metal toxicity
G. Adediran, The University of Edinburg / School of Geosciences; B. Ngwenya, K. Heal, B. Havie, The University of Edinburgh / School of Geosciences; F. Mosselmans, The Diamond Light Source Harwell Sci and Innovation Campus
The natural nutrient mining ability of plants has been widely explored in the quest for evolving sustainable strategies for remediating toxic contaminants in the environment. Some plants have been discovered to possess inherent ability to accumulate high amounts of contaminants and referred to as hyperaccumulators. Apart from simply classifying plants as either phytoremediator or as non-phytoremediator, the mechanism(s) behind the phenomenon remain poorly understood. Moreover, despite the unique contaminant accumulation potentials of these phytoremediatiors, they often suffer from the toxic effects of the contaminants they are to remediate, and remediation efficiency remains poor. We explored the survival and remediation potential of *Brassica juncea* plants (a well-known phytoremediatior) under soil contaminated with zinc sulfate and compared it to that of *Vicia sativa* (a leguminous plant). *B. juncea* plants exposed to 600 mg kg^{-1} Zn over 8 weeks exhibited poor Zn growth with a tolerance index of 5.0% while *V. sativa* under similar conditions significantly survived Zn toxicity better with a tolerance index of 82.0%. A synchrotron based m-XAFS analysis of the plants revealed that *V. sativa* stores Zn in its root in the chelated forms of Zn histidine, Zn carbonates and Zn phytate whereas the roots of *B. juncea* plants were dominated by toxic Zn sulfate and Zn oxalate. Despite the significantly high tolerance index of *V.sativa*, it exhibits poor remediation potential (1.5% Zn removal) compared to the low tolerant *B. juncea* plants (16.3% Zn removal). The possibility of *V.sativa* to confer its tolerance to the better remediating *B. juncea* was investigated under a mixed planting system. This significantly improved the tolerance index of *B. juncea* plants to 72.5% and also enhanced Zn removal to 33.0%. It was hypothesized that the Rhizobia bacterium symbiotic to the leguminous *V. sativa* was responsible for the better plant growth and remediation of the *B. juncea* plant. Evaluation of *B. juncea* plants inoculated with *Rhizobium leguminosarum* supported this hypothesis and the bacteria significantly improved plant tolerance and phytoremediation potential with m-XAFS analysis of plant roots revealing root storage of Zn as Zn Polygalacturonate, Zn phytate and Zn cycteine. This work therefore suggests bacteria induced changes in Zn speciation in plant is a key mechanism for plant survival under metal toxicity.

Modelling air-vegetation distribution of BaP in the Iberian Peninsula using biomonitoring data
N. Ratola, LEPAE University of Porto / Physics of the Earth; P. Jimenez-Guerrero, University of Murcia / Physics
In this study, an extensive database on levels of atmospheric PAHs in pine needles from biomonitoring schemes in the Iberian Peninsula fuelled the establishment of the first models of behaviour for PAHs, using the example of benzo[α]pyrene (BaP). The modelling system WRF+CHIMERE was implemented with high spatial and temporal resolution to the Iberian Peninsula (9 km, 1 hour), using BaP atmospheric levels collected over a year-long sampling scheme comprising 4 campaigns (one per season) in over 30 sites in Portugal and a single sampling campaign in the NE of Spain, also in over 30 sites. Information on meteorological parameters was collected from the weather stations closest to the sampling sites. Climatology of the levels and transport patterns (e.g. dispersion) established for air by the model and the estimated values in vegetation were validated with the concentrations in pine needles, whereas the estimated levels in air from the values in pine needles were obtained by 5 different approaches. The justification for this study is the gaps still existing in the awareness of the life cycles of SVOCs, particularly the partition processes between air and vegetation. The comparison of the levels on a regional scale will enable the strong enhancement of the knowledge available in the current scientific literature for studies of atmospheric chemistry and transport of trans-boundary pollutants, which is scarce (and even more if we consider its model validation against experimental data). The WRF+CHIMERE modeling system accurately reproduces the spatio-temporal patterns of concentrations of BaP over the vegetation in the Iberian Peninsula (errors lower than 50% for all stations and seasons). Several methods have been tested to convert vegetation concentration (pine needles) to atmospheric concentrations; therefore they have been used as biomonitors of BaP over the IP. The results indicate that, from the several methods tested, the St. Amand approach reveals the most accurate results when compared both to modeling results and observations from the EMEP data network. Acknowledgements: This work has been partially funded by the European Union Seventh Framework Programme-Marie Curie COFUND (FP7/2007-2013) under UMU Incoming Mobility Programme ACTion (U-IMPACT) Grant Agreement 267143.

Bioaccumulation of ionized and neutral emerging contaminants: Exposure of edible crops via solid and liquid effluent streams
K.C. Hyland, Colorado School of Mines / Civil and Environmental Engineering; A.C. Blaine, Colorado School of Mines / Civil Environmental Engineering; C. Rich; C.P. Higgins, Colorado School of Mines / Civil Environmental Engineering
Many wastewater- derived anthropogenic organic contaminants persist through treatment processes either dissolved in the aqueous stream or sequestered by sorption to sludge solids. These contaminants of emerging concern (CECs) represent a diverse chemical suite and include but are not limited to pharmaceuticals, flame retardants, corrosion inhibitors, surfactants, and plasticizers. Concerns arise when reclaimed water becomes a viable resource for agricultural irrigation, or when wasted sewage sludge solids (biosolids) are applied to agricultural lands as a soil amendment. This study examined strawberry and lettuce plants grown under greenhouse conditions with reclaimed water fortified at eight levels of increasing contaminant doses. The accumulation in the edible portion was found to correlate with dose for many of the selected target contaminants in lettuce leaf tissues, while the strawberry was found to accumulate two chlorinated organophosphate flame retardants (TCEP, TCPP) in a dose-dependent manner. Further investigation involved the examination of CEC accumulation in other tissues of the plant including roots (both crops) and stems/leaves (strawberry). Root concentration factor (RCF) and translocation factor (TF) values were calculated to improve understanding and possible predictive capability of how CECs will be transported and accumulated in plant tissues that may be consumed. Additionally, lettuce crops were grown in control and biosolids-amended soils, and the edible leaf portions examined for uptake of CECs from the solid phase. Results from this study have important implications with respect to the potential exposure of humans to contaminants in fresh produce. The ultimate goal of this ongoing project is to improve mechanistic understanding of plant uptake of CECs from both reclaimed water and amended soil pathways, thereby allowing for advancement of models intended to predict human exposure.

106
Phytoxicity of Azoles from Personal Care Products and Pharmaceuticals in the Absence and Presence of Biosolids
E. Richter, ECT Oekotoxikologie GmbH / Aquatic Ecotoxicology Goethe University FrankfurtMain; E. Roller, A. Coors, ECT Oekotoxicologie GmbH
Sewage sludge may be a valuable agricultural fertiliser. However, it also represents

a sink for poorly degradable and highly adsorptive wastewater-born pollutants. One group of agents frequently detected in sewage sludge are fungicides from the structural group of azoles. They are applied in plant protection products but also in cosmetics and pharmaceuticals. Climbazole, ketoconazole and fluconazole are contained in anti-dandruff shampoos, systemic antimycotics and skin creams, respectively, and have been measured in sewage sludge at concentrations between 50 and 4450 μg/kg. Despite their high efficacy against fungi and the recent indication for specific toxicity toward plants, their possible impact on the terrestrial environment has so far only poorly been studied. The aim of this work was therefore to characterise their phytotoxicity and its dependance on biosolids amendment since the environmental exposure route will be through sewage sludge application. To this end, plant growth inhibition tests were conducted according to the OECD guideline 208 using *Brassica napus* with and without addition of biosolids to the test soil at a realistic application rate of 3.8 g biosolids d.w./kg soil d.w.. For fluconazole, the lowest EC_{50} was determined with 9.3 mg/kg soil d.w. for shoot biomass. The presence of biosolids had no impact on its toxicity when comparing the effective concentrations with and without biosolid amendment. This is in agreement with the expectation because fluconazole is water soluble and ionic at environmentally relevant soil pH and thus not likely to be bound by sewage sludge. First results for climbazole and ketoconazole indicate that they are less phytotoxic than fluconazole with an EC_{50} of 30 mg/kg soil d.w. and 666 mg/kg soil d.w., respectively, in the absence of biosolids. We assume that in contrast to fluconazole, for climbazole and ketoconazole the bioavailability, and hence the phytotoxicity, will be reduced in the presence of biosolids.

Impact of deposition produced during the static testing of solid rocket motors on corn and alfalfa
W.J. Doucette, S.J. Mendenhall, L. McNeill, Utah State University / Utah Water Research Laboratory; J. Heavilin, Utah State University
Tests of horizontally restrained rocket motors at the ATK facility in Promontory, Utah, USA, result in the deposition of an estimated 1.5 million kg of entrained soil and combustion products (mainly aluminum oxide, gaseous hydrogen chloride and water) on the surrounding area. The deposition is referred to as test fire soil (TFS). Farmers observing TFS deposited on their crops expressed concerns regarding the impact of this material. To address these concerns, we exposed corn and alfalfa to TFS collected during a September 2009 test. The impact was evaluated by comparing the growth and tissue composition of controls relative to the treatments. Exposure to TFS, containing elevated levels of chloride (1000 times) and aluminum (2 times) relative to native soils, affected the germination, growth, and tissue concentrations of various elements, depending on the type and level of exposure. Germination was inhibited by high concentrations of TFS in soil, but the impact was reduced if the TFS was pre-leached with water. Biomass production was reduced in the TFS amended soils and corn grown in TFS soils amended did not develop kernels. Chloride concentrations in corn and alfalfa grown in TFS amended soils were two orders of magnitude greater than controls. TFS exposed plants contained higher concentrations of several cations, although the concentrations were well below livestock feed recommendations. Foliar applications of TFS had no impact on biomass but some differences in the elemental composition of leaves relative to controls were observed. Washing the TFS off the leaves lessened the impact. Results indicate that the TFS deposition could have an effect, depending on the amount and growth stage of the crops, but the impact could be mitigated with rainfall or the application of additional irrigation water. The high level of chloride associated with the TFS is the main cause of the observed impacts.

108
Genotoxicity of Contaminated Drinking Water Sources Detected by a Plant Bioassay
O.P. Olorunfemi, University of Benin / Animal and Environmental Biology; M.I. Chigozie, University of Benin / Department of Plant Biology Biotechnology; D.I. OLORUNFEMI, University of Benin / Plant Biology Biotechnology
Climatic conditions are important factors that influence the level of contaminants present in water sources and the extent of their toxic effects on plant and animal life. In this study, water samples from a borehole and a man-made lake used for domestic and human consumption in Ozomu, a rural community in Edo State, Nigeria were obtained in the dry and wet seasons and subjected to macroscopic and microscopic evaluations using the *Allium cepa* root test. Compared to the control (tap water), all the water samples induced significant ($p< 0.05$) inhibition of root growth and increased frequency of chromosomal abnormalities in a season-dependent relationship. Our monitoring approach with the plant bioassay was able to detect contamination related to the drinking water sources. In particular, the results indicate that seasonal variation has influence on the level of toxic and genotoxic contaminants in the lake water which may be of health risk to the inhabitants who use it without prior proper purification treatments. *Key words: Allium cepa*, genotoxicity, lake water, public health.

REACH after the second registration deadline:

Environmental challenges (II)

109
Data availability, data requirements and opportunities for improvements in the hazard assessment under REACH
M. Scheringer, ETH Zuerich / Institute for Chemical and Bioengineering

110
Systematic analysis of REACH data and their use in screening and prioritisation
P. Karamertzanis, ECHA; T. Netzeva; J. Provoost; T. Sobanski, European Chemical Agency; A. Aparicio; B. DILHAC, ECHA; T. Alasuvanto; A. Gissi; M. Rasenberg,
ECHA has so far received approximately 38 500 new registrations under REACH (excluding notifications to Member State Competent Authorities under the previous European chemicals legislation - Directive 67/548/EEC), out of which 31 000 full registrations, covering approximately 7500 distinct substances. For 5000 of these substances not registered exclusively as an isolated-intermediate, industry has submitted one or more technical dossier with one or more study summary for each of the REACH endpoints required for the corresponding tonnage band according to the REACH Regulation. Overall, ECHA has received over 900 000 endpoint study records and approximately 15 000 chemical safety reports. At the same time, the Classification and Labelling Inventory (C&L) has been populated with more than 3 million notifications for over 120 000 substances according to the requirements of the CLP Regulation. These submitted dossiers and notifications are the most important sources of information for carrying out the activities of all REACH and CLP processes, including Compliance Check, Substance Evaluation and Risk Management. The large amount and complexity of information in ECHA's registration database and the C&L Inventory presents opportunities for a more effective regulation of chemicals but also a number of challenges. In addition to disseminating these data in a comprehensible and useful form to the general public, Member State Authorities and ECHA need to use the data for verifying safe use and impose risk management measures when needed. At the same time, it is necessary to ensure high quality of the standard information as required by the REACH Regulation, particularly when the submission of hazard and exposure data that do not meet the standard information requirements can lead to different hazard and risk conclusions. The REACH processes to increase dossier quality and identify substances that require risk management are clearly distinct. However, they allow the use of similar methods and thus provide opportunities for synchronisation and coordination for maximum efficiency. Given these challenges, ECHA has made significant steps towards developing methodologies and tools to allow the systematic analysis of registration and notification data. This presentation will describe the underlying machinery behind these tools and will exemplify their recent applications in screening and prioritisation activities in ECHA.

R&D needs and knowledge gaps
D. KNIGHT, ECHA
ECHA administers the REACH, CLP and Biocidal Products Regulations, and therefore we have a good understanding of the limitations of current regulatory science and where there are needs for fundamental scientific research and applied R&D. The research we suggest will also be useful in other regulatory schemes covering chemicals and chemical products. In addition to long-term fundamental research, we suggest R&D leading to results of practical use in the medium term, e.g. to be of benefit for 2018 REACH registration. R&D should as far as possible build on and incorporate current methods, with targeted development when appropriate, to produce 'toolkits' with methodologies to combine the data into an overall prediction (e.g. as IATAs). The aim would be to produce generally-accepted and scientifically-valid, 'fit for purpose' techniques that are fairly standardised yet still flexible. To support such combined approaches further fundamental research will be needed into the biological mechanisms that underpin (eco)toxicity effects (e.g. AOPs). There are two needs for assessing the hazardous properties of chemical substances: To screen a large set of substances to select groups with particular characteristics for further action. To assess a specific substance for a defined purpose, e.g. to fill a 'data gap' and establish safe use from a risk assessment.

Therefore combined-approach assessment techniques should be fit for the purpose the prediction is to be used for and also flexible enough to allow substance specific adjustments. The degree of uncertainty tolerated in the prediction depends on the regulatory purpose: therefore assessing and communicating uncertainty is a key element. In general, higher certainty is needed to assess specific individual substances than for screening sets of chemicals for priority setting. Regulators generally set standards for the information on the properties of chemicals, whether from standard tests or non-standard approaches; hence if the prediction does not meet the standard it is not fit for purpose.

Ecotoxicology in tropical and polar regions (III)

115
An Antarctic research station as a local source of perfluorinated organic pollutants
S.J. Wild, Griffith University; R. Bossi; D. Hawker, Griffith University / School of Environment; R. Cropp, Griffith University; J. Stark, C.K. King, Australian Antarctic Division; S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program SOPOPP
Persistent organic pollutants (POPs) are industrial chemicals and ubiquitous global contaminants. With an increasing number of chemicals fulfilling the classification criteria of POPs, and increasing human activity in Polar Regions, the potential for direct introduction of pollutants to high latitude environments is enhanced. Many consumer products, including textiles and furnishings contain perfluorinated compounds (PFCs), including PFOS recently annexed under the Stockholm Convention. As people visit and work in Antarctica these products are just as likely to be used there as they would be in other parts of the world. Although highly stable, these compounds can leach out of products and be released into the surrounding environment. In this study we investigate Australia's Casey Station as a local source of PFCs to the environment and evaluate accumulation in various biological matrices as evidence of human activity introducing recently listed POPs directly into the Antarctic environment. Samples of five different abiotic and biotic matrices were collected from Casey Station and its immediate marine and terrestrial environment, namely; indoor dust, secondary treated wastewater, lichen, moss, and marine amphipods. Of the 16 PFCs analysed for, 15 were detected in the indoor dust collected. PFOS was detected at the highest concentration, more than 10 times higher than any other compound. PFOA was also found at notable concentrations. The levels of PFOS and PFOA detected in this study mirror the levels typically seen in houses and other buildings from Australia and other developed countries. More recently constructed parts of the station had lower levels of PFOS than older areas perhaps indicating a decrease in usage of PFOS since its restriction. Secondary treated wastewater samples were dominated, in both the dissolved and particulate phases, by PFOS, with PFOA and PFDS also present. The concentrations of PFCs were 2 – 6 times higher in the dissolved phase than in the particulate phase. The levels of PFCs found in wastewater from Casey Station are similar to those seen in treated wastewater from Australia and other developed countries. Only negligible or below detection limit concentrations of PFCs were detected in moss, lichen and amphipod samples. These results indicate that Antarctic research stations such as Casey are acting as local sources of PFCs into the Antarctic environment, increasing the continents level of pollution.

116
Mobilisation of Persistent Organochlorine Burdens in Migrating Southern Hemisphere Humpback Whales
S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program SOPOPP; C.A. Waugh, Queensland University of Technology / Institute for Health and Biomedical Innovation IHBI; M. Schlabach, Norwegian Institute for Air Research
The dependence of polar species on lipid rich diets to sustain the temperature and productivity extremes of high latitude environments, makes them particularly susceptible to bioaccumulation of lipophilic persistent organic pollutants. Marine mammals are at the greatest risk of accumulating toxic levels of these chemicals due to their trophic level, longevity and high proportion of body fat. Southern hemisphere humpback whales (*Megaptera novaeangliae*), feed in the Southern Ocean and overwinter in tropical breeding grounds, seasonally undergoing the longest migration and fasting events known in any mammal. The extreme life history behavior of these populations provide a unique opportunity to study the toxicokinetics of POPs during a period of chronic energy deficit. Medical research has previously evidenced the toxic effects associated with rapid weight loss and concomitant mobilization of POP burdens. This study targeted free-swimming males humpback whales at two time points on their annual migration along the east coast of Australia (breeding stock E1). Biopsies were collected from 58 individuals and analysis of superficial blubber yielded a comprehensive overview of contaminant accumulation in Southern Ocean foraging baleen whales. Further, significant differences between northward migrating (early migration, post-summer feeding) and southward migrating (late migration; fasted) cohorts was observed. The concentration indece (CI), defined as the average compound concentration in southward versus northward migrating cohorts, were consistently greater than 1. The average CI of compounds detected in ≤50% of both early and late cohort animals was 5.1. The results of this study emphasize the importance of considering prolonged periods of food deprivation when assessing chemical risks posed to wildlife. This is of particular importance for Polar biota adapted to extremes in ecosystem productivity.

117
Persistent organic pollutants and trace elements in blood of the wandering albatross: influence of individual traits and foraging ecology
a. carravieri; P. Bustamante, Université de La Rochelle / LIENSs; S. Tartu, Ecophysiology; A. Meillere, Centre dEtudes Biologiques de Chizé CEBC CNRS UPR; P. Labadie, H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC; H. Weimerskirch, O. Chastel, Y. Cherel, Centre dEtudes Biologiques de Chizé CEBC CNRS UPR
Marine Antarctic and subantarctic environments are contaminated by persistent organic pollutants (POPs) and trace elements through atmospheric transport and wet and dry deposition processes. Seabirds are regarded as cost-effective bioindicators of environmental contamination, because they integrate biomagnifying pollutants *via* food intake. Several intrinsic and extrinsic factors may drive intra-specific variation in seabird contamination, but this has rarely been studied. Here we measured POPs (10 organochlorine pesticides, OCPs, and 7 polychlorinated biphenyls, PCBs) and trace elements (Ag, As, Cd, Co, Cr, Cu, Fe, Hg, Mn, Ni, Pb, Se, V and Zn) in blood of 169 individuals of wandering albatross *Diomedea exulans*, a long-lived (50+ years) and wide-ranging top predator, sampled at the Crozet Islands, southern Indian Ocean. Thanks to an exceptional long-term dataset, the effect of individual traits (sex, age and breeding status) and foraging ecology on contamination could be assessed. Wandering albatrosses carried remarkably high loads of contaminants in their blood, with strong between-individual differences. In several cases, contamination differed between sexes, which could be due to sexual-specific physiological dynamics of contaminants. For instance, females had lower levels of OCPs, as they can excrete organic lipophilic pollutants into eggs. Breeding status affected blood levels of some contaminants. For example non-breeding birds had lower Hg levels than breeding ones. Age was not expected to influence contaminant levels, since blood reflects recent exposure (i.e. days to several weeks), rather than accumulation through time. Yet, blood Hg levels decreased with age in males, but not in females. As aging male wandering albatrosses were shown to change their foraging habitats, old individuals could be exposed to lower Hg levels through their diet. Feeding habitat (inferred from carbon stable isotope ratios) had indeed a strong effect on blood Hg levels, with individuals feeding in warmer subtropical waters being more contaminated than those feeding in colder subantarctic waters. The opposite relationship was shown for the sum of OCPs, potentially translating their enhanced deposition at higher latitudes. In conclusion, this work provides new insights into the contribution of different intrinsic and extrinsic factors on intra-specific variations of contaminant levels in seabirds, stressing the critical role of individual foraging specialisation.

118
Temporal trends of persistent organic pollutants in arctic foxes from Svalbard in the light of a changing climate
M. Andersen; E. Fuglei, The Norwegian Polar Institute; A. Polder, The Norwegian School of Veterinary Sciences; N. Yoccoz, University of Tromsø; A. Pedersen, M. Koenig, H. Routti, The Norwegian Polar Institute
The present study investigates concentrations and temporal trends of persistent organic pollutants (POPs) in arctic foxes (*Vulpes lagopus*) from Svalbard, Norway, considering changes in food availability and feeding habits. We analysed liver of 100 arctic foxes, collected in 1997/98, 1998/99, 1999/00, 2001/02, 2002/03, 2003/04 and 2010/11 for concentrations of polychlorinated biphenyls (PCBs; PCB -28, -52, -101, -118, -138, -153 and -180), chlordanes (*cis*-chlordane, trans-nonachlor and oxychlordane), *p-p'*-DDT, *p-p'*-DDE, HCB, mirex and β-HCH. Number of reindeer carcasses in Adventdalen and sea ice coverage of Isfjorden in the spring preceding the trapping season were used as indexes for climate influenced food availability between years. Stable isotope analyses were performed to assess feeding habits in the last months before trapping. The POPs found in highest concentrations were oxychlordane, PCB-180 and PCB-153. Concentrations of ∑PCBs (PCB -118, -138, -153, -180) and ∑chlordanes (trans-nonachlor and oxychlordane) decreased over time when controlling for possible confounding variables. We also found evidence for an effect of body condition and $\delta^{13}C$ on the POP concentrations, as thinner foxes and foxes feeding from the marine food web had significantly higher levels of POPs. There was no effect of reindeer mortality and sea ice coverage on the concentrations of POPs, although increased reindeer mortality had a non-significant negative effect on all

the POPs analysed.

119

The endocrine disruption properties of an adipose contaminant mixture extracted from East Greenland polar bears studied in the H295R cell line

R. Hjorth; R.J. Letcher, Environment Canada / Ecotoxicology and Wildlife Health Division; D. Blair, Environment Canada; R. Dietz, C. Sonne, Aarhus University / Department of Arctic Environment; B. Styrishave, Dep of Pharmaceutics Analytical Chemistry

In recent years there has been much debate on the potential risk of chemicals that have been classified as endocrine disruption compounds (EDCs). Human and environmental risk assessment of EDCs is a challenge since the exposure to humans and wildlife is a complex mixture of many known and unknown compounds, where some can be in the parts-per-billion (ppb) concentration range. However, most reported studies on endocrine disruption effects have been on single compounds at concentrations higher than environmentally relevant. The presence of persistent organic pollutants (POPs) in arctic wildlife has been well described and especially the polar bear (*Ursus maritimus*) is recognized as being one of the most contaminated species in the Arctic. The present study investigated the *in vitro* endocrine disruptive effects of the POP mixture found in adipose tissue from 10 East Greenland polar bears collected in 2011. Specifically, the tissue extracts were tested for steroidogenic activity in the human adrenocortical carcinoma cell line H295R. These extracts contained a complex mixture of measured polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs) and brominated flame retardants (BFRs). GC-MS/MS analysis showed that all 10 adipose extracts caused significant changes to the hormone levels in H295R compared to solvent controls. Levels of progestagens expressed upstream of the enzyme CYP17 (pregnenolone and progesterone) increased with a corresponding decrease in androgens expressed downstream (dehydroepiandrosterone and androstenedione). These results demonstrated comprehensive *in vitro* effects of POPs extracted from polar bear adipose tissue on key elements in the steroidogenesis, and identifies disruption of CYP17 activity as a mode of action. A POP-induced interference with CYP17 can potentially explain previously observed hormone levels in polar bears and could pose a risk to their reproductive health.

120

Mercury and persistent organic pollutants as endocrine disruptors in polar seabirds

S. Tartu, Ecophysiology; A. Goutte, F. Angelier, Centre d études biologiques de Chizé CNRS; P. Bustamante, Université de La Rochelle / LIENSs; J. Bustnes, Norwegian Institute for Nature Research; G. Gabrielsen, The Norwegian Polar Institute; B. Moe, Norwegian Institute for Nature Research; J. Wingfield, University of California Davis; P. Labadie, H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC; O. Chastel, Centre dEtudes Biologiques de Chizé CEBC CNRS UPR

Added to climate change, Polar Regions are also subjected to high levels of environmental pollutants such as persistent organic pollutants (POPs: PCBs and pesticides) and heavy metals, as mercury. This additional input in the environment represents a supplementary challenge for top predators such as seabirds which accumulate high levels of these contaminants. However the precise impact of mercury and POPs as endocrine disruptors has been poorly investigated in free-living organisms. Using field studies on 2 polar seabirds (Black-legged kittiwakes in the Arctic and snow petrels in Antarctica) we investigate the specific roles of mercury and POPs on several major endocrine mechanisms (Luteinizing hormone and prolactin, 2 key pituitary hormones for the onset of reproduction and parental behavior; and corticosterone, the stress hormone, which mediate major reproductive decisions). In both species, increasing levels of mercury were clearly related to decreasing levels of Luteinizing hormone and to a greater probability of non-breeding. In snow petrels, high blood mercury levels were associated with low prolactin secretion and most contaminated individuals were less committed into incubation behavior. Corticosterone secretion was clearly affected by POPs in both species: the most polluted birds had a stronger stress response and would maintain high levels of corticosterone post-stress. Those findings underline two different pathways used by pollutants to impair breeding, as mercury would rather affect pituitary hormones and POPs the hypothalamo–pituitary–adrenal (HPA) axis. We will then discuss the possible mechanisms disrupted and the potential long-term demographic impacts of contaminant exposure in polar seabirds.

Marine and coastal ecotoxicology and risk assessment (III)

121

Harmful Algal Blooms and associated toxins: mussel larvae at risk?

M. De Rijcke, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology; M.B. Vandegehuchte, Ghent University / Applied Ecology Environment Bio; N. Nevejan, Ghent University / Laboratory of Aquaculture and ARC; J. Vanden Bussche, L. Vanhaecke, Ghent University / Laboratory of Chemical Analysis; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology

Due to the combined effect of overfishing, climate change, eutrophication and the dispersal of invasive species in the marine environment, harmful algal blooms (HABs) are steadily increasing in frequency, intensity and geographical scale. Yet to date, our understanding of the effects of HABs on the recruitment of marine organisms is limited. As shellfish farming is expected to play a crucial role in the fulfilment of the future global protein demand, a better understanding of the risks that HABs pose to the reproduction and development of bivalves is needed. This research therefore aimed to investigate the acute toxic effects of harmful algae and marine toxins on the larval viability, development and innate immune response of bivalves. To this end, embryos of the model species *Mytilus edulis* (blue mussel) were exposed for 48 hours to a concentration series of the marine toxins domoic acid (DA) and okadaic acid (OA) as well as their respective toxin-producing algae *Pseudo-nitzschia multiseries* and *Prorocentrum lima*. We found that neither bloom concentrations of domoic acid, nor bloom densities of *P. multiseries* displayed acute toxic effects on the viability and development of *M. edulis* larvae. Okadaic acid on the other hand significantly reduced the viability of veliger larvae at concentrations as low as 37.8 $\mu g.l^{-1}$, which is a concentration range likely to occur during dense blooms of OA producing algae. This effect may be related to a significant inhibition of larval protein phosphatases by OA as observed *in vitro*. *P. lima* was not found to affect the larval development or viability but induced an increase in the phenoloxidase innate immune activity which could not be attributed to the occurence of OA in the algae. A similar increase in PO activity was detected for *P. multiseries*. This effect was strain dependent and could partially be attributed to the presence of DA. As this is the first study to investigate and detect the activation of the phenoloxidase innate immune activity by harmful algae and marine toxins, the consequences of these increases for the larval resilience to other stressors are unknown. Yet the change of the immune activity combined with the reduced viability associated with OA warrants closer investigation as HABs could possibly influence natural recruitment as well as the hatchery-cultured production of bivalves.

122

The use of eco-toxicological tests for characterization of contaminated soil from boat activities

B. Eklund, L. Johansson, E. Ytreberg, Stockholm University

The object of this study was to study a boat maintenance facility by investigating the degree of contamination and assessing how leachate water from soil affects organisms from three trophic levels. Surface and subsurface (20 cm depth) soil samples were collected in a typical boatyard (200 boats, 12000 m^2) at a 70 m (station A), 90 m (station B), 120 m (station C), and 160 m (station D) distance from the shoreline. Three replicate samples, ca 10 m apart, were taken at stations A, B and C, respectively, and one replicate was taken at station D, (i.e. altogether 20 samples with 10 at surface and subsurface, respectively. The total copper (Cu), lead (Pb), tin (Sn) and zinc (Zn) concentrations were determined for all replicates. Pooled samples from the respective stations were used for analysis of organotin compounds, irgarol and polyaromatic hydrocarbons. Leachate waters were produced from the pooled samples and used for toxicity testing with the bacterium *Vibrio fischeri*, the macroalga *Ceramium tenuicorne,* the macrophyte *Myriophyllum spicatum* and the crustacean *Nitocra spinipes*. Very high concentrations of Cu, Pb, Zn were detected, with maximum values of 16 300, 6 430 and 18 600 mg/kg dw, respectively. Organic hazardous compounds were found in high concentrations with maximum values of 37, 27 and 16 mg/kg dw for tributytin (TBT), dibutyltin (DBT) and triphenyltin (TPhT), respectively. All pollutants exceeded existing guidance values for both sensitive land use and less sensitive land use by several factors, in both surface and subsurface soil. The least and worst cases of total amount of TBT (12 000 m^2 and 0.2 m depth) were estimated to be 10 and 122 kg of TBT. Leachates were shown to be toxic in all three test organisms. Several known hazardous pollutants were found in boatyard maintenance areas and they exceeded recommended guidance values by several factors. Leachates were shown to be toxic to test organisms of several trophic orders. This underlines that boat maintenance facilities in general should be better regulated to minimize further exposure to humans and spread of contaminants in the environment. The amounts of contaminants accumulated in these areas calls for investigations of how remediation should be performed.

123

Physiological responses of Mytilus galloprovincialis under multiple stressors: nutritive stress and PAHs

C. González-Fernández, Spanish Institute of Oceanography / Marine ecosystems; M. Albentosa, J. Campillo, Instituto Español de Oceanografia; L. Vinas, Spanish Institute of Oceanography; J. Bellas, Centro Oceanografico de Vigo / IEO (Instituto Espa?ol de Oceanografia)

Large spatial scale mussel monitoring programs are characterized by a great variability of environmental conditions which cause important differences in the physiology of the animals that inhabit them. One of main differences encountered is the trophic condition which is highly variable when different habitats are

monitored. Moreover, a low availability or even the total absence of food during variable periods is a normal feature in marine ecosystems. Mussels, such as *Mytilus galloprovincialis*, are extensively used as sentinel species of pollution in marine coastal monitoring programs. Natural food availability in the studies areas could be inferred from mussel condition index, whose high variability has been repeatedly evidenced in the N-NW Spanish Marine Pollution Monitoring Program [1][2]. From such studies, it has been stated that biological responses caused by pollutants seem to be masked by biological variables as mussel condition. In this context, a laboratory experiment was designed to determine the relative importance of two stressors: low food availability and the presence of toxicants on some physiological biomarkers. Two experimental trophic conditions were simulated by regulating daily food ration: low and high food availability which promote negative and positive mussel energy balances, respectively. In both cases, mussels were exposed to a concentration range of the polycyclic aromatic hydrocarbon (PAH) fluoranthene (FLU).

124

Health status of cod (Gadus morhua) at dumpsites for chemical warfare agents in the Baltic Sea

T. Lang, N. Fricke, Thünen Institute; K. Broeg, Bundesamt für Seeschifffahrt und Hydrographie; R. Baude, Alfred Wegener Institute; M. Brenner, Alfred Wegener Institute / Biosciences; K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre; R. Turja, Finnish Environment Institute SYKE / Marine Research Centre; J. Barsiene, University of Vilnius

After World War II, large amounts of chemical weapons stored on German territory were dumped in the Baltic Sea by order of the allied forces . In addition of being a cheap method of disposal, the belief was that the vast amounts of waters in the oceans would neutralize and absorb the dangerous substances. At least 40.000 tonnes of chemical munitions containing an estimated 13.000 tonnes of chemical warfare agents were dumped in the Baltic Sea, primarily in the Bornholm Basin. Other official dumping sites were the Little Belt area and the Gotland Deep. There is evidence, however, that also other areas besides the offical CWA dumpsides are contaminated by chemical warfare agents (CWA). CWA were dumped as artillery shells, aircraft bombs or in containers; partly entire ships loaded with munitions were sunk. Today, munitions are in different stages of decomposition. Metal shells are corroding and contents are leaking into the environment at a rate that has not been measured so far, posing a possible risk for the Baltic Sea ecosystem. In previous studies, several CWAs of major concern for biota, such as inorganic arsenic and organo-arsenic compounds, have been found in the sediments within and around dumpsites (Missiaen & Paka 2007). Unaware of this risk, human sea-bottom activities, such as bottom trawling, constructions of pipelines and cables as well as windfarms are increasingly claiming space within the contaminated areas. The aim of the present study was to increase knowledge on the bioavailability and biological effects of CWAs on fish, using a suite of biomarkers in an integrated approach.

125

Hazard and risk of herbicide contamination for marine microalgae: a field relevant approach

S. Sjollema, H. van der Geest, University of Amsterdam; P. Booij, Institute for Environmental Studies; R. Laane, D. Vethaak, DELTARES; W. Admiraal, University of Amsterdam

Coastal waters are among the most productive ecosystems on the planet. Yet, they also receive a high contaminant load due to riverine inputs, land run-off and shipping activities, resulting in high concentrations of contaminants. Exposure of microalgal communities to these contaminants can potentially result in shifts of microalgal species which can, as they form the basis of marine food webs, ultimately affect the carrying capacity of marine and estuarine ecosystems. However, a comprehensive understanding of the actual hazard and risk of contaminants towards the microalgal community in coastal and estuarine waters is currently lacking. Therefore, a series of field relevant experiments was performed which included: 1. single species tests with different microalgal species and herbicides; 2. a multi-stress experiment with field relevant light conditions and 3. an outdoor multi-species experiment with a natural phytoplankton community. The hazard of the herbicides atrazine, Irgarol®1051, diuron and isoproturon was determined for three different microalgal species and a clear compound and species specific effect was demonstrated. Although the risk at current field concentrations was low, occasional harmful peak concentrations reaching potential effect levels do occur. Additionally, a risk for microalgae under the current environmental legislation (MAC-EQS) of several compounds was demonstrated. In a multi-stress experiment in which different seasonal light conditions were mimicked, herbicide toxicity was demonstrated to be significantly ($p< 0.05$) higher under spring light conditions compared to autumn light conditions. This observed season specific toxicity suggest that standard test conditions might under or overestimate the hazard of a compound in the field. In an outdoor multi-species experiment, the photosynthetic efficiency as well as the community composition of a natural phytoplankton community were significantly ($p< 0.05$) affected at the MAC-EQS concentration of the herbicide diuron. This study provides information on the hazard and risk of herbicide contamination under environmentally relevant conditions. It can be concluded that in coastal and estuarine areas, the presence of anthropogenic contaminants might result in changes in species composition in natural phytoplankton communities and therefore might be a threat to marine ecosystems.

Periphyton as bioindicator and community model – critical review, work in progress, future perspectives

126

Direct and indirect effects of triclosan on periphyton under grazing pressure

H. Guasch, University of Girona / Institute of Aquatic Ecology

The influence of grazing in the algal triclosan toxicity was evaluated in fluvial biofilm communities. Biofilms were exposed to grazers and triclosan individually, as well as to their interaction. As expected, grazers heavily influenced the biofilm community, reducing algal biomass and keeping the biofilm in a young state of development, which resulted in higher P-uptake capacity and less efficient defence towards oxidative stress. Although triclosan has been described as a bactericide, both algae and snails were clearly affected. Toxic effects of triclosan (22µg/L) on biofilms were noticeable at both structure and functional level. The diatom mortality increased and the community changed its composition, growth forms and richness. Moreover, the bactericide addition had negative consequences for biofilm function, which lost P-uptake and detoxification capacity. Snail mortality was also enhanced by triclosan addition. The presence of grazers modulated triclosan toxicity by enhancing the structural membrane damage provoked by grazers with their scraping mouthparts, resulting in a cascade of contaminant effects from producers to higher trophic levels.

127

Community diversity and 3D structure of periphyton exposed to silver nanoparticles and silver nitrate

A. Kroll, L. Sgier, Department of Environmental Toxicology; A. Arrhenius, T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; C. Burkart, Technische Universitat Dresden / Institute of Hydrobiology; D. Jungmann, Dresden University of Technology; M. Matzke, Centre for Ecology Hydrology NERC / Molecular Ecotoxicology; P. Obert-Rauser, GWTTUD GmbH / Institute of Hydrobiology; M. Rybicki, Dresden University of Technology / Institut für Hydrobiologie; R. Verweij, Department of Ecological Science VU University Amsterdam The Netherlands; C. Svendsen, CEH Wallingford / Pollution and Ecotoxicology

Periphyton provides essential ecosystem services by primary production and release of O_2. Its sensitivity to environmental conditions make it an important bioindicator and small-scale community model. It is a potential receiving compartment for engineered NP. The highest number of NP containing consumer products involve Ag NP due to their bactericidal properties. These have been attributed to both NP and Ag^+ released in aqueous media. Most toxicity studies are based on short-term exposure of single species. The possible chronic effects on complex communities such as periphyton are unknown. We thus used periphyton exposed to Ag as a community model to study changes in diversity and structure. Ag was applied as PVP-stabilized AgNP or as $AgNO_3$ over 18 d under controlled conditions, to understand effects dependent on the Ag species as well as on concentration and time. Periphyton was analysed regarding genetic diversity (Automated Ribosomal Intergenic Spacer Analysi (ARISA), Terminal Restriction Fragment Length Polymorphism), composition of extracellular polymeric substances (EPS), and 3D structure. These data were complemented with species/genera identification. Dissolved, total, and periphyton-associated Ag was measured at each sampling point. Algal diversity decreased in biofilms treated with 20 μg/L Ag over time. Preliminary results acquired by ARISA of diatoms show a decrease in diatom genetic diversity after 18 d of exposure to 20 µg/L Ag NP. EPS size distribution was not influenced by 18 d of exposure to different Ag species and concentrations. Biofilms exposed to 2 µg/L $AgNO_3$ or Ag NP had a significantly lower C/N ratio in the polymer fraction indicating a lower amount of polysaccharides and a higher amount of proteins. The relative concentration of low molecular weight acids was decreased in EPS from periphyton exposed to 20 µg/L Ag. The porosity of the biofilms decreased significantly in the presence of 20 µg/L $AgNO_3$. It remained at control levels in AgNP exposed biofilms. Biofilm roughness increased in $AgNO_3$ treated periphyton but was less heterogeneous in the presence of AgNP. Based on the preliminary evaluation of our data we conclude that both AgNP and $AgNO_3$ induce changes in periphyton relative to exposure time, concentration, Ag species, and the endpoint assessed. A range of characterization methods is thus necessary to capture effects caused by Ag. There seem to be Ag species dependent and independent effects.

128

Combined ionic and toxic stress induces community tolerance in periphyton

M. Schmitt-Jansen, UFZ Helmholz Ctre Environm Research / Dept Bioanalytical Ecotoxicology; L. Bley, M. Krumbiegel, UFZ Helmholtz Centre for

Environmental Research
Taxonomy-based approaches like diatom indices are not flexible enough to diagnose causes of ecological impairment. Approaches combining functional and structural assessments may support a better mechanistic understanding of stressor interactions in multiple stressed environments. In aquatic communities stressors exert a selection pressure, increasing community tolerance. A suitable approach for evidencing these processes is the "pollution-induced community tolerance" (PICT) concept. PICT can be detected in short-term tests by appropriate metabolic responses. The PICT concept was developed to determine the effects of toxicants to communities and for autotrophic communities photosynthesis inhibition was mainly used as an endpoint so far. For analyzing effects of different stressor qualities on community tolerance, further metabolic tests need to be developed. High ionic loads and herbicides often co-occur in aquatic systems. Rotter et al (2013) found joint effects of high ionic loads and the herbicide prometryn on periphyton tolerance to the herbicide. However, combined effects on salt tolerance were not quantified, yet. The aim of this study was the quantification of salt tolerance of freshwater periphyton and the determination of potential combined effects from salt and toxic stress on community tolerance. Therefore, we established a metabolic test to quantify salt tolerance by using the amino-acid proline as an indicator. This test was applied in a microcosm study using periphyton as a model community. In a factorial design two different concentrations of NaCl were used as a single stressor and were combined with prometryn. Over a growth period of 4 weeks community parameters such as photosynthesis and community tolerance were measured. Proline proved to be a suitable metabolic test for detecting induced salt tolerance in periphyton. Combined stress of prometryn and NaCl caused a higher tolerance of periphyton to the toxicant (analysed by inhibition of photosynthesis) than expected from the sum of single stressors. Salt tolerance of periphyton to combined stress of prometryn and NaCl (analyzed as induced proline) was clearly higher than tolerance from periphyton exposed to the toxic stressor but in the range of the salt stressed communities indicating no interaction of these stressors in terms of salt tolerance. These functional changes will be discussed in view of the structural changes observed in the diatom community.

129
Seasonal variability of natural river biofilm tolerance and diversity in an urban contamination gradient
A. Autret, M. Dufour, Irstea / UR HBAN; L. Fechner, UR HBAN
The aim of this study was to investigate the seasonal variability of the biological response of periphytic communities (river biofilms) chronically exposed to multi-metallic pressure. Biofilms were grown on immersed plastic membranes at three sites on the Seine river along an urban pollution gradient upstream (site 1) and downstream (sites 2 and 3) from Paris (France). They were collected in September 2011, March 2012, July 2012 and December 2012 after a 3 to 5 weeks colonization period. We measured biofilm tolerance to Cu, Ni, Pb and Zn, using a PICT (Pollution-Induced Community Tolerance) approach with a previously developed short-term toxicity test based on bacterial β-glucosidase activity (the tolerance of the heterotrophic community was investigated). In order to reliably compare metal tolerance among biofilms, the EC_{50} values derived from the toxicity tests were normalized by the corresponding total suspended solids concentration of the biofilm suspensions used for the test. Bacterial and eukaryotic diversity was also assessed on biofilm samples collected in summer (July 2012) and winter (December 2012) using high-throuput 16S and 18S DNA sequencing. Normalized EC_{50} values globally increased from site 1 to site 3 reflecting the metallic pollution gradient measured in the river water collected at the three sites and confirming a previous study on biofilm metal tolerance with biofilms collected at the same sites in 2009. Cu tolerance levels appeared to be positively correlated to water temperature but no clear seasonal tendency could be found for Ni, Pb and Zn tolerance levels. Partial Least Squares Regression (PLS) was performed on biological data (Y variables) and metallic contamination and physico-chemical data (X variables). Temperature appeared as one of the most important variables in the PLS regression. This study shows that chronic *in situ* exposure to environmental concentrations of metals has a significant impact on natural biofilms. Biofilm tolerance to metals reflects metallic exposure levels. Yet temperature appears as an important environmental variable shaping community structure and response to toxic exposure which shows that the sampling date is an important parameter to consider when using natural river biofilms to assess the impacts of urban pressure.

Metagenomic sequencing of periphyton: Taxonomic and functional insights into marine biofilm communities
K. Sanli, Department of Biological and Environmental Sciences; J. Bengtsson-Palme, University of Gothenburg / Department of Infectious Diseases; H. Nilsson, University of Gothenburg / Department of Biological and Environmental Sciences; E. Kristiansson, Chalmers University of Technology / Department of Mathematical Statistics; M. Rosenblad, University of Gothenburg / Department of Chemistry and Molecular Biology; H. Blanck, Goteborg University / Department of Biological and Environmental Sciences; M.M. Eriksson, Chalmers Technical University / Department of Shipping and Marie Technology
The majority of metagenomic studies have so far focused on the free-living microorganisms in the human gut, soil or in the aquatic environment. An important form of microbial life, *the biofilm*, has been considerably overlooked in the metagenomics literature as such; only five percent of the publicly available metagenome data in the mg-RAST server is associated with microbial biofilms. Periphyton communities are complex multispecies biofilms harbouring a great diversity of organisms attached to inorganic, organic, living or dead substrata. In this study, we used metagenomics to identify periphyton organisms in the coastal marine environment of western Sweden, and assessed the major molecular mechanisms that predispose these communities for an attached life-style. We identified highly abundant phototrophic groups including macro- and micro-algae as well as *Cyanobacteria* and *Roseobacter*. Heterotrophic organisms are found to be dominating periphyton such as those bacterial groups belonging to the phyla *Proteobacteria* and *Bacteroidetes*. Large number of sequences mapping to marine invertebrate genomes is one of the intriguing results of our study where a clearer picture of periphyton diversity in terms of micro and macro inhabitants could be drawn. However, we also point out special concerns related to metagenome sequencing of environments involving communities of prokaryal and eukaryal species together. Functional repertoire of periphytic organisms comprises protein and enzymes related to biofilm's extracellular matrix, surface attachment strategies of primary invader species and various transporter systems, highly relevant for the biofilm mode of microbial life. Since metagenomics incorporates all organisms, regardless of size or metabolic capabilities, it can be a powerful tool in bioindicator research. However, the sequencing effort needed, and the associated bioinformatics analysis, is challenging. Still, we expect metagenomics to have an important role in the future of environmental monitoring.

Waste and Wastewater effluents: chemical and ecotoxicological characterisation (III)

131
Coupling in vitro and in vivo neurochemical-based assessments of wastewater effluents from the Maumee River Area of Concern (AOC)
A. Arini, McGill University / Department of Natural ressources science; J.E. Cavallin, US EPA; J.P. Berninger, US EPA / Toxic Effects Characterization Research Branch; R. Marfil-Vega, American Water / ORISE Research Participant to the National Risk Management; M.A. Mills, US EPA; D. Villeneuve, U.S. EPA / Mid-Continent Ecology Division; N. Basu, McGill University / Department of Environmental Health Sciences
In this study we utilize *in vivo* and *in vitro* approaches to study whether wastes water treatment plant effluents released in the Maumee River (Toledo, OH) Area of Concern (AOC) contain neuroactive substances that may impair fish reproduction and behavior. Our approaches help extend the concept of endocrine disruption beyond routine bioassays (ER, AR, TH) under the premise that toxicants may also interact with and disrupt the function of neurotransmitter receptors and enzymes that play critical roles in vertebrate reproduction and behavior. Cell-free methods were used to study such interactions, and to also compare the *in vivo* and *in vitro* responses. First, 288 fish (fathead minnow) were exposed in cages to river water at 8 different sites along the Maumee River, including several in close proximity to wastewater treatment plant (WWTP) discharges. After 4 d of *in situ* exposure, brains were sampled and analyzed for N-methyl-D-aspartate (NMDA) receptor binding, and monoamine oxidase (MAO) and glutamine synthetase enzyme activity. The preliminary work shows that fish caged downstream of a major WWTP had increased MAO activity (66% and 35% in males and females respectively), and that NMDA receptor binding was also significantly changed (30% decrease in females). Second, *in vitro* studies were performed on river water extracts (final concentration 5x) to see if they interfere with the aforementioned neurochemicals studied *in vivo*. The initial *in vitro* results suggest that extracts optimized for recovery of alkylphenols significantly impacted the NMDA receptor binding (15% decrease), whereas those optimized for recovery of steroid hormones induced binding (up to 34%) in fish. Our work thus far suggests that wastewater effluents discharged to the Maumee River AOC contain chemicals that may directly interact (and possibly interfere) with neurochemicals that are important in fish reproduction and behavior. In addition, the work here (via a US EPA STAR grant) is taking next steps to identify key neurochemical indicators, resolve *in vitro* and *in vivo* responses, and compare responses across taxa.

132
Biomarkers of stress and effect evaluated on caged clams exposed to the Bay of Cádiz, SW Spain
G.V. Aguirre-Martinez, Universidad de Cadiz / Chemical Physical; T. DelValls, University of Cadiz / Department of Physical Chemistry; M. Martin-Diaz, University of Cádiz Center for Marine Science and Technology CACYTMAR / Chemical Physical
Effluents from waste water treatment plants (WWTP) constitute a continuous source of pollutants to the aquatic environment. Mussels are at high risk of exposure to such contamination because they can filter high volumes of water. The purpose

of this study was to examine sublethal responses and general stress on *Ruditapes philippinarum* after 14 days of exposure to field conditions in areas close to WWTP in the Bay of Cádiz, SW Spain. *In situ* experiments were performed with caged clams (duplicate) in Playa Chorrillos (reference site), La Puntilla and Trocadero located in the Bay of Cádiz. Subletal effects were evaluated *in vivo* in clam's haemolymph applying the lysosomal membrane stability test (LMS) by the neutral red retention time assay (NRRT). Enzymatic responses were studied in digestive gland tissues including biomarkers from Phase I: Ethoxyresorufin O-deethylaseenzyme activity (EROD) and dibenzylflourescein dealkylase enzyme (DBF); Phase II: glutathione S-transferase enzyme (GST); oxidative stress enzymes glutathione peroxidase (GPX) and glutathione reductase (GR), injurious effects were evaluated by lipid peroxidation (LPO) and DNA damage. After 14 day bioassay the mean NRRT (n = 10) in haemocytes from clams exposed to reference site P. Chorrillos was 128 ± 9 min, NRRT in clams exposed to El Trocadero was 50 ± 8 min indicating general stress syndrome, NRRT of clams exposed to La Puntilla was 33 ± 18 min, these clams were considered to present diminished health status. EROD and DBF enzymatic activities were significantly induced in EL Tocadero ($p < 0.05$); induction of DBF enzymatic activity might suggest the presence of pharmaceuticals in this area. GST enzymatic activity and antioxidant enzymes were significantly induced in clams exposed to La Puntilla and El Trocadero compared to reference site indicating oxidative stress. Injurious effects were observed in clams from EL Tocadero as LPO and DNA damage significantly differ from the response observed in clams from reference site ($p < 0.01$). Contaminants present in studied areas may affect the health status of *R. philippinarum* as well as other aquatic organisms. Finally, the data reported in this study including general stress and metabolic responses from Phase I and II represent important ecotoxicological information and provide useful reference for assessment of areas adjacent to WWTP and the effect their effluents might have in marine organisms, using as bioindicator species *R. philippinarum*

133
Characterisation of a sewage treatment plant effluent using biomarkers in brown trout (Salmo trutta fario) as tools in active monitoring
K. Vincze, Animal Physiological Ecology; V. Scheil, Tübingen University; H. Köhler, University of Tubingen / Animal Physiological Ecology; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology
The Neckar River (Southern Germany) represents an aquatic habitat which is strongly affected by numerous anthropogenic activities, thus it is an excellent system for ecotoxicological investigations. The present work is a model field survey for the assessment of the impact of sewage treatment plant (STP) effluents on fish health using active monitoring and biomarker techniques as suitable tools. During active monitoring, brown trout *(Salmo trutta fario)* from an uncontaminated fish farm were exposed in swimming steel cages up- and downstream of a Neckar River STP for 10 and 30 days respectively. Unexposed fish from the same hatchery served as negative control. The application of biomarker offered a possibility to investigate histopathological, geno-, proteo- and neurotoxic effects in various fish organs. Biological results were also complemented with chemical analysis data of tissues in order to provide a better understanding on exposure-effect relationships. Our results highlighted several histopathological abnormalities and an elevated stress protein level (proteotoxicity) in gills, liver, and kidney of brown trout at both monitoring sites. However, downstream fish always revealed stronger effects and also a higher mortality than the upstream ones. There were organ-specific reactions observed as well: gills showed a more rapid response to environmental contaminants when compared to liver and kidney, but neither toxic nor endocrine effects could be seen in the gonads. Our study did not reveal any genotoxic impact; the neurotoxic investigations are still ongoing. There were various organic compounds (PAHs, DDE) detected in brown trout tissue at both sampling sites in the low μg/kg range. Interestingly, an up to 4-fold concentration of disinfectant and synthetic musk derivates were found in the tissues of downstream-exposed fish, suggesting a considerable toxic input through the STP effluent. Our survey shed a light on an evident pollutant burden in the Neckar River; furthermore, it demonstrated the effectiveness of cage-exposure studies and biomarker methods in ecotoxicological effect characterisation.

134
Effect-Assessment of wastewater effluents by molecular biomarkers in brown trout (Salmo trutta)
S. Fischer, R. Beer, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology; K.J. Groh, Eawag / UTOX Environmental Toxicology; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; K. Schirmer, Eawag / Environmental Toxicology
The identification and monitoring of chemical effects in organisms exposed in the environment is based on an array of approaches and specific endpoints. However, many of the existing tests have been established for only a few model organisms. Accounting for the variety of species and their different responses to environmental stressors is still a big challenge for ecotoxicological risk assessment. mRNA expression analysis of selected biomarker genes is a promising approach for field monitoring of non-model organisms because it can capture a wide spectrum of responses of organisms to chemical exposure.We established a biomarker gene set for brown trout (*Salmo trutta*) to assess the effects of micropollutants released by wastewater effluents. The biomarker set consisted of 20 genes which reflect different cellular stress responses like general stress (e.g. *Hsp70*), oxidative stress (*NrF2*) or biotransformation (*Cyp3a*). The transcriptional regulation of these genes was measured, using quantitative polymerase chain reaction (qPCR), in liver and kidney tissue samples of wild brown trout caught downstream and upstream of a wastewater treatment plant (WWTP) (St. Gallen, Switzerland) and from a reference river. qPCR results showed that mRNA levels of the selected genes were differentially regulated depending on the sampling site. Fish taken downstream generally had higher mRNA transcript abundances compared to fish from the upstream and reference sites, indicating that fish downstream are exposed to a higher level of environmental stressors. For example, the metal (*metallothionein B*) *or* endocrine disruption (*estrogen receptor alpha*) sensitive geneswere found to be significantly up-regulated in fish from downstream location compared to the other two sites. Results implicated a higher content of metals and potential estrogen-mimics downstream of the WWTP. Indeed, chemical analysis confirmed high concentrations of such compounds in the water from this site compared to the others. Partially, concentrations were above the threshold value for surface water. Our data demonstrate that the expression patterns of only ten fish per site already reflect the presence of certain contaminants. Therefore, transcript analysis of the biomarker set is a promising screening assay for assessing surface water quality. Moreover, based on the selected set of genes, predicting potential adverse effects may be possible, in particular for exposure to micropollutants.

135
Can Daphnia behavioral endpoints be used as tool for ecotoxicological assessment of wastewater effluents?
J. Chevalier, EDF RD / National Hydraulics and Environment Laboratory; J. Cachot, Université Bordeaux / EPOC; P. Pandard, INERIS; M. Grote, EDF RD / National Hydraulics and Environment Laboratory
Toxic stress can induce rapid behavioural changes in exposed organisms at concentration below acutely toxic levels. Analysis of behavioural parameters has therefore been proposed as tool for detection of potential toxicity in wastewater effluents. However, it is currently unclear how to derive robust ecotoxicological endpoints from observation of organism behaviour and how to quantify the sensitivity of these endpoints. The aim of the study is (i) to assess how behavioural responses can be used as ecotoxicological endpoints and (ii) to compare the sensitivity of standard versus behaviour endpoints in order to assess their usefulness for ecotoxicological assessment of wastewater effluents. As daphnid behavior shows a natural variability, different exposure concentrations and replicate testing is required in order to allow an appropriate statistical analysis of the behaviour parameters. However, commercially available image analysis systems have a limited test capacity (small number of measuring cells). A new image analysis system has been designed allowing the simultaneous tracking of up to 200 *Daphnia magna* distributed in 20 exposure chambers (10 daphnids per chamber). Twelve substances covering a wide range of different modes of action were tested at different concentrations with replicates. Two behavioural parameters (swimming speed and number of active organisms) were continuously recorded during 48 hours. Time courses of the two parameters were compared to control responses. Overall, significant behaviour responses are observed in the first hours of the experiment well below the acute EC50 (based on immobility at 48h) for most tested compounds. The behaviour endpoint "swimming speed" shows higher sensitivity than the number of active organisms. Differences between tested compounds are observed in the time of effect onset, duration and intensity of effects on swimming speed depending of their mode of action. Narcotics shows an intense increase peak of the swimming speed from the first hour of the experiment followed by a gradual decreased while neurotoxic chemicals induced a slightly but significant increase at different times depending on their mode of action. The exposition in the new image analysis system provides early and sensitive information compared to standard test endpoints and may be a great contribution to wastewater and effluent quality assessment

136
Evolution of stormwater quality between 2002 and 2010 for the city of Toulouse, France
S. DEFFONTIS, INPENSIACET LCA Laboratoire de Chimie Agro industrielle INRA UMR CAI; C. Vialle, Université de Toulouse / INPENSIACET LCA Laboratoire de Chimie Agro industrielle INRA UMR CAI; C. Sablayrolles, ENSIACET / INPENSIACET LCA Laboratoire de Chimie Agro industrielle INRA UMR CAI; A. Breton, CatarCritt Agroressources / LCA Laboratoire de Chimie AgroIndustrielle UMR INRA INPT; C. Vignoles, Veolia Eau / Direction Régionale SudOuest; M. Montrejaud-Vignoles, Université de Toulouse / INPENSIACET LCA Laboratoire de Chimie Agro industrielle INRA UMR CAI
The city of Toulouse with its separate storm sewer system is ideal for studying stormwater. That is why since 2002, three stormwater sampling campaigns were conducted. Samples were taken from the outlets of two storm drains located in

heavily and moderately urbanized areas. Sampling was undertaken during wet weather and dry weather during the year 2002 for the first campaign, during the year 2007 for the second one and during the year 2010 for the last one. The overall pollution parameters were analyzed (chemical oxygen demand, biological oxygen demand, total nitrogen, ammonium, nitrate, total phosphorus, suspended solid matter, volatile suspended matter, pH, conductivity, turbidity). Results showed an evolution of stormwater quality between the three campaigns. They indicated also that dry weather had an impact on annual pollution load from separate storm sewer and that level of urbanization was also a factor.

Personal care products in the environment: strengthening science to support regulation

137

Occurrence, Distribution and Risk Assessment of Organic UV Filters in the Aquatic Environment in Hong Kong and Other Countries

T. Mei Po Mirabelle, City University of Hong Kong / Biology and Chemistry; H. Leung, State Key Laboratory in Marine Pollution and Department of Biology and Chemistry City University of Hong Kong; N. Yamashita, National Institute of Advanced Industrial Science / Emtech; S. Taniyasu, AIST / Institute for Environmental Mngt Technology; W. Liu, Marine Biology Institute Science Center Shantou University; P. LAM, City University of Hong Kong; M.B. Murphy, University of Hong Kong / Dept of Biology Chemistry

Organic ultraviolet (UV) filters protect skin against sunburn by absorbing UV radiation and are important ingredients in personal care products such as sunscreens, cosmetic make-up and lip care products. They can enter the aquatic environment through recreational activities and wastewater treatment plants (WWTPs). The increasing incorporation of organic UV filters into products has raised concern about their potential environmental impacts as some of these chemicals have the potential to bioaccumulate and have been shown to act as environmental estrogens. The occurrence and risks of these compounds in the aquatic environment (especially the marine environment) are not well known. The objectives of this study are to (1) develop quantitative analytical methods for the simultaneous multiclass determination of 12 commonly-used UV filters (4-MBC, BMDM, BP-1, BP-3, BP-4, BP-8, EHS, HMS, IAMC, OMC, OC and OD-PADA) in surface water, (2) determine their occurrence and distribution in samples collected in the United States (New York and Los Angeles), China (Hong Kong, Shantou and Chaozhou), Japan (Tokyo) and Thailand (Bangkok), and (3) conduct a preliminary environmental risk assessment of these compounds in the aquatic environment. Analytical methods for the extraction and quantification of the 12 UV filters were optimized based on solid phase extraction (SPE) and liquid chromatography-tandem mass spectrometry (LC-MS/MS). All of the target compounds were detected in Hong Kong seawater throughout the sampling period (July 2012 – June 2013) and were found to be widely distributed in the marine environment, with median concentrations less than 200 ng/L. BMDM, BP-3, HMS, OMC, OC, BP-1 and BP-8 were frequently detected (>75% of samples). The number of compounds detected was Hong Kong (12) > Tokyo (9) = Bangkok (9) > New York (8) = Los Angeles (8) > Shantou (5) = Chaozhou (5). The number of compounds detected generally increased with population density. Preliminary risk assessment showed that two frequently detected compounds (BP-3 and OMC) could pose high risk to egg development in fish and cause growth inhibition to algae.

Parabens in water and sediment: occurrence in river and lakes in different rural and urban environments

F. Botta, INERIS; F. Alliot, ecole pratique des hautes etudes UMR SISYPHE; V. DULIO, F. Lestremau, INERIS; M. Chevreuil, ecole pratique des hautes etudes UMR SISYPHE

Parabens are a group of alkyl esters of the p-hydroxybenzoic acid that are widely used as preservatives in pharmaceutical and personal care products. In order to gain knowledge about presence (or not) of parabens in different water categories, a screening study was performed in France and in 5 overseas territories in 2012. More than 1700 occurrence data were obtained in water and sediment samples for 3 parabens (methylparaben, ethylparaben and propylparaben). Samples were collected on more than 160 sites during 3 sampling campaigns (spring/summer/fall). Sampling sites representing different types of landcover were chosen. This screening study has been conducted on a larger datasets compared to previous reported literature data. For methylparaben and propylparaben, concentrations are similar in all samples, and no obvious effect could be identified associated to the type of anthropogenic sources. The occurrence of parabens as ubiquitous contaminats in almost 100% of the analysed samples can represent a risk. At the measured levels, acute and chronic toxicity is not expected with any of these compounds tested individually. However, currently available PNEC values do not take into account non-standard endpoints, such as endocrine disrupting effects which need to be considered in assessing the potential risksassociated to occurrence of parabens in the aquatic environment. Parabens are common hygiene product ingredients and special care must be considered for sampling.

139

Field dissipation and risk assessment of typical personal care products in biosolid-amended soils

G. Ying, Chinese Academy of Sciences / State Key Laboratory of Organic Geochemistry; F. Chen, Z. Chen, Chinese Academy of Sciences Guangzhou Institute of Geochemistry; Y. Ma, Chinese Academy of Agricultural Sciences

Antibacterial agents triclocarban (TCC) and triclosan (TCS), and synthetic musks AHTN (Tonalide) and HHCB (Galaxolide), and antifungal agents climbazole, clotrimazole and miconazole are extensively used in many household and personal care products. After use, they enter wastewter treatment plants and finally reach the receiving environment via discharge of effluent and disposal of sewage sludge. Due to their hydrophobic nature, these compounds have been detected in biosolids. Land application of biosolids has become a common practice throughout the world. However, concerns continue to be raised about the potential risks of this practice to the soil environment and public health. The aims of this study were to evaluate contamination levels of four typical personal care products (TCC, TCS, AHTN and HHCB as well as three antifungals) in biosolids and biosolid-amended soils of three field trial sites (Zhejiang, Hunan and Shandong), investigate their dissipation patterns in the biosolid-amended soils under different treatments (T1: single application; T2: repeated applications), and assess their potential risks to terrestrial organisms. The seven target compounds (TCC, TCS, AHTN and HHCB, as well as three antifungals) were detected in all biosolid-amended soils from the three trial sites (HN, SD and ZJ) in October 2010. The concentration levels for the seven compounds of both T1 and T2 in the biosolid-amended soils of the three sites were found to have the following order: TCC > TCS > AHTN > HHCB > miconazole > clotrimazole > climbazole. TCC was found to have concentrations ranging from 111 (ZJ) to 365 (SD) mg/kg for T1, and from 454 (ZJ) to1584 (HN) mg/kg for T2. The presence of these personal care products in the soils applied with biosolid indicates the persistence of these compounds in the soils. One-year field monitoring at the SD site showed dissipation of these chemicals with their half-lives of 51-1000 days. Preliminary risk assessment suggests that TCC and TCS might pose high risks to soil organisms based on the limited toxicity data, while AHTN and HHCB showed low to medium ecological risks. The results from this study will help evaluate the environmental impacts of these personal care products associated with biosolid application on agricultural land.

140

Determination of toxicity data of ultraviolet filters toward selected aquatic organisms for a preliminary environmental risk assessment

D. Molins Delgado, Environmental Chemistry; P. Gago, CSIC / Environmental Chemistry; S. Diaz-Cruz, IDAEACSIC / Environmental Chemistry; D. Barcelo, IIQABCSIC / Environmental Chemistry

UV Filters (UV-F) constitute a heterogeneous group of chemicals used as a protection against the harmful effects of the UV solar radiation. We can find them in a wide range of compounds such as personal care products or as additives in polymeric materials that need protection against sunlight. Nowadays, these emerging pollutants are considered persistent due to their continuous release into the environment [1]. Some studies performed mostly *in vitro* but also in *in vivo* have shown that many of these compounds can produce adverse effects on reproduction, interfering the normal development on fishes and rodents [2,3]. For instance, 4MBC has similar estrogenic effects than those of 17-b-estradiol in mammals and amphibious species [4]. Despite that, the knowledge on the potential chronic or acute toxicity to biota of these compounds is still very scarce [5,6]. In order to fill the knowledge gap on the ecotoxicity of UV-F, this study aims to i) determine the EC_{10},EC_{30},EC_{50} values of the target UV-F through a series of toxicological assays on three aquatic species i.e. *Daphnia Magna*, *Selenastrum Capricornutum* and *Vibrio Fischeri*, and ii) explore the potential synergetic effects in UV-F mixtures. Besides that, the ecotoxicological risks associated to UV-F and some of their known transformation products in selected case studies will be presented. **References** [1] Gago-Ferrero P., Mastroianni N., Díaz-Cruz M.S., Barceló D., J. Do insect repellents induce drift behaviour in aquatic non-target organisms?

P. Fink, University of Cologne / Aquatic Chemical Ecology; K. Vasters, University of Cologne / Workgroup Aquatic Chemical Ecology; E. von Elert, University of Cologne / Biology

Synthetic insect repellents are substances applied to surfaces to discourage insects, mainly mosquitoes from landing on these surfaces. As some of these repellents have been detected in surface waters, they may also exert repellent effects on aquatic non-target organisms. In running water systems, aquatic invertebrates actively enter the drift in order to move out of locally malign environments. We thus tested the hypothesis that the widely used insect repellents DEET (N,N-Diethyl-m-toluaminide) and EBAAP (3-(n-n-butyl-n-acetyl-amino)-propionic acid ethyl ester) induce drift behaviour in the aquatic invertebrates *Gammarus pulex* (Crustacea, Amphipoda) and *Cloeon dipterum* (Insecta, Ephemeroptera), using a laboratory-scale drift assay. If the insect repellents cause drift behaviour in such non-target organisms at environmentally relevant concentrations, the resulting changes in resource consumption, but also in prey availability for predators, may influence ecosystem functioning in streams. Further, the effects of insect repellents on the behaviour of non-target organisms may also interfere with these organisms' natural behavioural responses to predator infochemicals with resulting detrimental effect of repellents in surface waters.

Screening human health risk of environmental and direct exposure to personal care products

A. Ernstoff, University of Michigan / Environmental Health Science; S.A. Csiszar, University of Toronto / Dept of Chemical Engineering and Applied Chemistry; P. Fantke, Technical University of Denmark / IER; O. Jolliet, University of Michigan / School of Public Health

No existing assessment framework evaluates the uptake of product ingredients via both product use and via environmental exposure. To address this issue, this work presents a framework to flag potential risk and compare use and environmental exposures of chemicals within personal care products. The framework is based on the novel concept of the *product intake fraction* (*PiF*) defined as: the chemical mass of substance *i* within a product *x* taken in by humans via both use-phase and environmentally related emissions, per unit of chemical mass within that product. Chemical mass within products may be taken in by individuals via several use-phase pathways including direct dermal contact, and via several environmentally related pathways, such as food chain bioaccumulation. Applying the *PiF* conceptto evaluate all relevant exposure pathways for 25 chemicals within personal care products, we found use-phase *PiFs* ranged from 0.02 to 1 (kg intake/kg applied) and were mostly dominated by dermal intake, and environmental *PiFs* were generally several orders of magnitude lower and mostly dominated by intake of lipophilic chemicals with high bioaccumulation. *PiFs* may also be converted into daily population-scale intakes using production volume data. We demonstrated this framework using a paraben case-study with available NHANEs biomarker data for US women, and found model predictions generally in-line with observed *in vivo* paraben concentrations. To flag potential risk, the *PiF is* combined with Oral Equivalency Doses (OED) back-calculated from e.g. ToxCast *in vitro* bioactivity assays to estimate a maximum allowable fraction of chemical within a product. Evaluating the maximum allowable fraction for 25 chemicals within personal care products and to known product concentration data for 11 of the compounds (documented by the Household Product Database), we find 4 out of 11 potential chemical/product combinations with known chemical fractions within products exceeding the maximum allowable chemical fractions and 9 out of 10 with margins of exposure lower than 100. Evaluating both use-phase and environmentally related intakes of chemicals due to consumer products, suggests risk evaluation of dermal application of products must be held in high priority due to intakes that may exceed oral equivalency dose estimates for bioactivity and use-phase intakes generally dominating over environmentally associated intakes.

Fate and effects of nanoparticles under environmentally realistic conditions (III)

143

Sulphidation kinetics of silver nanoparticles reacted with metal sulphides

B.A. Thalmann, Eawag; A. Voegelin, Eawag Swiss Federal Institute of Aquatic Science and Technology; E. Morgenroth, ETH Zurich; R. Kaegi,

Silver nanoparticles (Ag-NP) are used in many consumer products, most importantly textiles and cosmetics, due to the well-known antimicrobial properties of Ag^+. Eventually, these particles will be released from products and either reach surface waters or a wastewater treatment plant through the municipal sewer system. Ag-NP undergo either dissolution or other transformations, most importantly they react with sulphide to form Ag_2S. Because Ag as Ag_2S is several orders of magnitudes less toxic than ionic Ag^+, the sulphidation of Ag-NP is of prime interest. Thermodynamically Ag_2S is not the stable form of Ag in aerobic waters but it has been shown to be rather resistant towards oxidation with dissolved O_2, due to the formation of extraordinarily strong sulphide bonds. Therefore, the speciation of Ag-NP in aerobic surface waters is determined by the kinetic rate laws rather than by the thermodynamic stabilities. However, little is known about the sulphidation kinetics of silver nanoparticles under conditions typical for surface and waste waters. Although sulphide is dominantly present as bisulphide (HS^-, pH >7) in anaerobic environments, it is not stable under oxidizing conditions. Metal sulphides such as ZnS and CuS that resist rapid oxidation by O_2 may serve as sulphide sources for the sulphidation of Ag-NP under aerobic conditions. The goal of this study was, therefore, to assess the sulphidation kinetics of Ag-NP (10, 20, 40, 70 and 100 nm) reacting with ZnS and CuS. We measured the sulphidation kinetics of Ag-NP in oxygen saturated DI water buffered to a pH of 7.5. The reactions exhibited pseudo-first-order kinetics, with rate coefficients depending on the Ag-NP size and initial metal sulphide concentration. Analytical electron microscopy analysis revealed Ag-Ag_2S core-shell formation of Ag-NP. Reported concentrations of ZnS in aerobic surface waters range from 1.5 and 127 nM with corresponding half-life times of 5 days. By material-flow analysis predicted Ag-NP concentrations are 6.7 pM in combination with now experimentally determined half-life times of the Ag-NP ranging from 2 h to 2.4 days, therefore suggest a complete sulphidation of the Ag-NP also in aerobic surface waters.

Co-tolerance of microbial litter decomposers to silver nanoparticles and antibiotics

A. Tlili, Eawag / Environmental Toxicology; M. Kuburic, Leibniz Institute of Freshwater Ecology and Inland Fisheries / Experimental Limnology; C. Canhoto, IMAR-CMA and Department of Life Sciences, University of Coimbra; R. Behra, Eawag / Department of Environmental Toxicology; M. Gessner, Leibniz Institute of Freshwater Ecology and Inland Fisheries

With the accelerated production and use of silver nanoparticles (AgNP) in commercial products, freshwater ecosystems will most likely serve as recipients of, and repositories for, these nanomaterials. In addition to their potential environmental toxicity, there is a growing concern that AgNP act as a selective agent in antibiotic resistance. The aim of this study was therefore to evaluate the consequences of a long-term exposure to silver nanoparticles (AgNP), $AgNO_3$ (as a source of Ag^+) or a mixture of 5 antibiotics on the pollution-induced community tolerance (PICT) of microbial decomposers associated to leaf litter in freshwaters. Moreover, specificity of PICT was assessed by evaluating the co-tolerance between these toxicants. Bacterial production by ^{14}C-leucine incorporation and fungal sporulation rate by microscopy were used in short-term inhibition bioassays with antibiotics, AgNP and $AgNO_3$ to assess sensitivities of pre-exposed microbial decomposers. Diversity profiles of the bacterial and fungal communities following the different treatments were determined by DNA fingerprint technique. The results demonstrated that chronic exposure to AgNP, $AgNO_3$ or ATB induced structural shifts in the community and led to tolerance enhancements in the bacterial communities. On the other hand, communities exposed to AgNP also increased their tolerance to Ag^+ and ATB. Similarly, communities exposed to Ag^+ showed an increase of their tolerance to AgNP and ATB. Finally, bacterial community exposed to ATB displayed higher tolerances to AgNP and Ag^+. Overall, our findings support the fact that exposure to toxicants as diverse as ATB and metal-based nanoparticles may lead to similar effects when considering complex biological systems such as microbial litter decomposers raising a direct environmental and public health implications.

145

Fate and heteroaggregation of titanium dioxide nanoparticles in natural surface waters

D.L. Slomberg, CNRSAixMarseille Université / CNRSAixMarseille Université; P. Ollivier, BRGM; J. Labille, CNRS

Despite continual progress in the development of engineered nanoparticles (ENPs), their fate and impact on the natural environment remain largely unknown due to challenges in detection and quantification. New strategies are necessary to more accurately assess ENP hazard and exposure. Titanium dioxide (TiO_2) NPs are of specific interest due to their use in a wide range of commercial products. The fate of TiO_2 NPs in aqueous environments depends on pH, ionic strength, and natural organic matter (NOM) concentration, however a lack of understanding regarding the behaviour of these NPs in natural systems remains, especially at relevant concentrations (μg/L range) where homoaggregation is less likely.[1] The heteroaggregation of TiO_2 NPs with natural suspended particulate matter (SPM) in the aqueous environment is also an important process in transport and fate.[2] Herein, we present the fate of TiO_2 NPs in natural waters from a lake with high NOM and low mineral SPM (Cholet, France), and a main river with high SPM and low NOM (Rhône River at Arles and Jons, France). The holistic approach presented here studies the fate of TiO_2 NPs under relevant concentrations in natural lake and river waters by characterization of their physical-chemical interactions and heteroaggregation with natural suspended matter (NSM). Homo- and hetero-aggregation kinetics were measured using light scattering, nanoparticle tracking analysis, and laser diffraction. The natural waters were evaluated for pH, ionic strength, NOM content, colloidal composition, and major and trace elements to elucidate the key contributors to NP fate. The kinetics of NP–NP and NP–NSM interactions were evaluated and the respective sticking efficiencies for homo- and hetero-aggregation were determined. They were influenced by the pH, ionic strength, and NSM composition of the waters. Nanoparticle concentration also

played a role in the heteroaggregation mechanism, assuming binding between neighbour mineral colloids. Heteroaggregation of the TiO_2 NPs varied significantly in the lake and river waters, thus suggesting different implications for NP fate. Increased mineral SPM in the river water favoured TiO_2 NP–NSM heteroaggregation and sedimentation. However, heteroaggregation was less evident in the NOM-rich lake water. Overall, this holistic approach details TiO_2 NP–NSM interactions pertinent to effective ENP risk assessment within natural surface waters.

146

Environmental fate models for engineered nanoparticles – simulating realistic conditions in a complex natural river system

N. Sani-Kast, ETH Zurich; A. Praetorius, ETH Zurich / Institute for Chemical and Bioengineering; J. Labille, CNRS; P. Ollivier, BRGM; M. Scheringer, ETH Zuerich / Institute for Chemical and Bioengineering; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

An increasing concern regarding engineered nanoparticles' (ENPs) environmental impact is derived from their increasing production, unconventional properties and mostly unknown behaviour in the environment. As of now, environmental concentrations of ENPs cannot be measured by in-situ quantification due to analytical challenges. Consequently, the design of meaningful toxicity tests and ENP risk assessment have to rely on rational estimations of ENP environmental concentrations. In this study we present the design and evaluation of an ENP fate model capable of incorporating environmental complexity to predict realistic environmental concentrations of ENPs. This model is based on a designated fate model for ENPs in surface waters first developed by Praetorius et al. in 2012. As in the original model, heteroaggregation between the ENPs and suspended particulate matter (SPM) is assumed to be a key process determining ENP transport. Realistic conditions were introduced by defining variable SPM composition and concentration along the river and time dependent emissions. We evaluated our model by investigating the predicted fate of nano-TiO_2 in the lower Rhône River (France) since this river is characterized by a unique SPM variability. In order to constrain our model with a realistic SPM composition, the SPM parameters employed were derived from a recent sampling campaign of that river. Since the attachment efficiency - α_{hetero}, a fundamental parameter governing the heteroaggregation process, is not easily measured, we evaluated our model's predictions for all possible α_{hetero} values between the measured SPM and nano-TiO_2. Our model results provide spatially resolved concentration values for the free nano-TiO_2 particles as well as the nano-TiO_2 bound to SPM, both in the water and sediment compartments along the course of the river. The combination of all results was then analysed to obtain the most probable transport profile of nano-TiO_2 in the lower Rhône This novel approach provides a powerful tool for predicting realistic ENP concentrations in surface waters, thereby enabling the design of rational toxicity tests and supporting the risk assessment process of ENPs.

147

Assessing the fate and effect of engineered nanomaterials in reference and wastewater derived organic matter

P.A. Neale, The University of Queensland / National Research Centre for Environmental Toxicology Entox; E. O\Malley, National Research Center for Environmental Toxicology / National Research Center for Environmental Toxicology; A.K. Jamting, Nanometrology Section; J. Herrmann, National Measurement Institute Australia; B.I. Escher, Helmholtz Centre for Environmental Research GmbH UFZ / Cell Toxicology

While concern about the fate and effect of engineered nanomaterials (ENMs) in the aquatic environment is growing, few studies have assessed this under environmentally relevant conditions. Since a major pathway of ENMs to the environment is via wastewater treatment plants, this study assessed ENM behaviour and toxicity towards algae in the presence of secondary treated wastewater effluent. The studied ENM was widely used titanium dioxide (TiO_2), and its fate and toxicity in secondary treated effluent was compared to that in reference organic matter, specifically Suwannee River humic acid. Characterisation by laser diffraction indicated increased agglomeration of TiO_2 in the presence of the secondary treated effluent compared to the humic acid. Inductively coupled plasma-mass spectrometry confirmed the increased agglomeration leading to significant sedimentation by showing that titanium (Ti) concentration dropped to background levels after 24 hours in the wastewater, while only 25 % loss of Ti was observed over the duration of the algal toxicity test (72 hours) in humic acid. The algae toxicity tests showed that TiO_2 did not adversely affect growth, cell viability or photosynthesis ability at the studied concentration (1 mgL^{-1}). This was the case for both the humic acid and the secondary treated effluent, despite the difference in TiO_2 fate in the two types of organic matter. The studied concentration of TiO_2 was around 50 times higher than observed in secondary treated effluent, suggesting that at present TiO_2 from wastewater effluent does not pose a risk for algae. This study also highlights the importance of conducting ENM tests in environmentally relevant media, given the large difference in agglomeration and stability observed. Similar fate and toxicity experiments with zinc oxide are currently being undertaken.

148

Looking beyond standard testing of titanium dioxide nanomaterials – Consideration of relevant exposure scenarios

A.J. Wyrwoll, P. Lautenschlaeger, R. Lothmann, A. Bach, RWTH Aachen University / Institute for Environmental Research; M. Gruber, RWTH Aachen University / Institute for Environmental Science; A. Meister-Werner, R. Petto, IBACON GmbH; H. Hollert, RWTH Aachen University / Institute for Environmental Research; H.M. Maes, RWTH Aachen / Institute for Environmental Research; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research

Although several studies have investigated the effects of nanomaterials to different organisms, it is still unclear, if the test set up and endpoints of standard test guidelines are sufficient to describe the potential environmental implications of nanomaterials. Therefore, relevant exposure scenarios as e.g. the conduction of tests with solar radiation, mixture experiments of nano-TiO_2 and potential co-contaminants and the testing of embryonic development stages were considered during the conduction of OECD test guidelines with two nanoscale (NM 101, 7-10 nm and NM 102, 15-25 nm) and one non-nano scale TiO_2 materials (NM 100, 200-220 nm). *Daphnia* sp. acute immobilization tests (OECD 202, 10 fold diluted ISO medium) and activated sludge respiration inhibition tests (OECD 209) were performed under laboratory light (LL) and simulated solar radiation (SSR). Ti concentrations were measured in test vessels containing the EC50 concentration of the different TiO_2 materials (*Daphnia* tests). Acute and chronic mixture experiments with nano-TiO_2 and an organic biocide (triclocarban, TCC) were conducted with earthworms, activated sludge, daphnids and fish embryos (OECD 207, 222, 209, 202, 236). TCC concentrations were measured in soil samples of the chronic earthworm tests. In all tests single substances and untreated media (control) were additionally tested. Except for NM 101 (EC50 79.5 mg/L) in the *Daphnia* tests, the TiO_2 materials induced no toxic effects to any of the tested organisms when exposed to LL conditions. SSR enhanced the toxicity of NM 101, NM 102 and NM 100 (nominal/measured EC50 0.53/0.09, 1.28/0.24 mg/L, 3.88/0.33 mg/L). The measured EC50 of NM 102 is close to the predicted environmental aquatic nano-TiO_2 concentration in the μg/L range. Therefore, NM 102 may have environmental implications. Mixture experiments reveal that in most cases the presence of TiO_2 materials lowers the toxicity of TCC e.g. by 20 and 50% for fish embryos (NM 101, NM 102 at 1 mg/L) or 30 and 60% for earthworms (reproduction, NM 101 at 400 and 1000 mg/kg). The present study shows that SSR enhances the toxicity of TiO_2 materials, the presence of TiO_2 materials in most cases lowers the toxicity of the tested organic compound and the embryonic development of fish was not affected by TiO_2 materials. Summing up, to properly assess the potential environmental risk of TiO_2 materials it is necessary to consider relevant exposure scenarios, especially exposure to solar radiation.

Delving into the social and monetarised environmental impacts during the evaluation process of the Life Cycle of products in order to be able to take all three pillars of sustainability into account

149

Application of monetary valuation in Life Cycle Assessment: literature review and survey among practitioners

B. Weidema, The ecoinvent centre; M. Pizzol, Aalborg University / Development and Planning; M. Brandao, European Commission / Joint Research Centre; J. GARCIA, SCORE LCA; P. Osset, Solinnen SAS

Monetary valuation, or monetarisation, is the determination of the economic value of non-market goods, i.e. goods for which no market exists. Although monetary valuation has a great potential to be applied in Life Cycle Assessment (LCA), in particular in the weighting phase, several challenges limit its diffusion in the field, which resulted in only a few applications so far. This study evaluated different methods for monetary valuation with respect to their relevance in LCA. The specific objectives were: (i) to review systematically, analyse critically, and evaluate existing monetary valuation methods, as well as existing LCA-applications of these methods for converting (LCA) results quantified in physical units into monetary units; and (ii) to assess to what extent monetary valuation is used by the LCA community and what barriers limit its diffusion. After identifying and classifying monetary valuation approaches, methods, and LCA applications via a keyword-based literature review, their key features, strengths, and weaknesses were determined. Monetary valuation methods and their LCA applications were then evaluated according to a comprehensive set of criteria including: *Scientific foundation; Documentation; Completeness; Uncertainty; Complexity; LCA relevance & compatibility.* Two web-facilitated surveys were performed to collect primary information on: (i) the extent of monetary valuation use in LCA; (ii) which monetary valuation methods are used; and (iii) the opinions of the practitioners and decision makers. LCA practitioners and consultants were identified by using publicly available lists of practitioners, via scientific associations, the network of the project participants, and popular LCA forums. The critical review encompassed 8 monetary valuation methods and 12 applications for LCA. For the two surveys, the total number of respondents was 209. The critial review showed that observed- and revealed-preference methods and the abatement cost method have limited applicability in LCA, whereas the conjoint analysis method and the budget constraint method are the best options for monetary valuation in LCA. The web-based survey among LCA practitioners showed a large interest in and support for monetarisation in LCA, but also a smaller group of respondents with legitimate objections to monetarisation. The surveys revealed a need for education and information about what monetarisation is and does.

External costs of air pollution from energy supply: Reviewing methodologies from ExternE to NEEDS

J. van der Kamp, T.M. Bachmann, EIFER / Urban Systems

European air quality policies are regularly supported by scientific impact assessments, including the monetary valuation of environmental and health damages, also referred to as environmental damage costs (EDC). Since the early 1990s, related methodological developments have taken place in the Externalities of Energy (ExternE) project series and follow-up activities. This study aims at looking back on more than 15 years of external cost quantification in Europe and discusses the main methodological evolutions from the 1990s until recently. The focus here is on the variability of human health costs caused by classical air pollutants (mainly NO_x, SO_2, particulate matter). Using a case from the energy sector, major influencing parameters are identified: exposure modelling is shown to lead to variations in results of up to 30% between different assessment frameworks. Concerning risk functions and monetary valuation, changes in assessing mortality risks due to long term exposure together with assumptions on particle toxicity explain most of the observed variability. This variability and an increasing use in policy making require continued scientifc efforts for a further improvement of the underlying methodology. As regards the integration of EDC into Life Cycle Sustainability Assessment, the Impact Pathway Approach as implemented in the EcoSenseWeb model provides indicators at the endpoint/damage level and this in a monetary and non-monetary way (i.e. physical). However, the physical indicators would benefit from an aggregation, e.g. in terms of DALYs, for integration into environmental LCAs, while the monetised damages could be directly integrated in societal Life Cycle Costing.

151

The external cost of air pollution in the canton of Zurich and the cities Zurich and Winterthur

D. Montanari, econcept AG; S. Bade; W. Ott, econcept AG

In order to justify and allocate public spending on the reduction of air pollution, policymakers are interested in the external cost of air pollution in total as well as per source of pollution. Therefore, we were given the mandate to estimate these external costs in the canton of Zurich and the cities of Zurich and Winterthur. Using existing knowledge of concentration-response relationships, we firstly assessed the effects of primary fine dust, nitrogen oxide, ozone, and ammonia on human health, maintenance of buildings, biodiversity, forests and crop. Secondly, we estimated the monetary value of these damages, hence external cost of air pollution in total. In the last step, the external costs of air pollution were attributed to their respective sources, which are traffic, agriculture, industry as well as households and services. We find that the external cost of air pollution in the canton of Zurich was 882 Mio. CHF in 2010. Between 2000 and 2010 air pollution could be reduced. If this had not been the case, the external cost of air pollution would have been 146 Mio. CHF higher in 2010 than it actually was.

152

Assessing effects of life cycle on income distribution and infant mortality at national level

I. Bocoum, IRSTEA Montpellier / UMR ITAP ELSA; C. Macombe, Irstea / UMR ITAP ELSA; J. Reveret, UQAM

We propose a method to anticipate the effect of the monetary flows generated by a life cycle's production step on income distribution and infant mortality at the national level. The method builds on a cause-consequence relationship identified as an impact pathway. Implementing it requires a two-stage process. The first to which most attention is given here, consists in measuring the change in the income distribution within the country due to the change in monetary flows induced by the production step. The second consists in using an elasticity coefficient estimated econometrically to predict the potential variation in infant mortality due to the variation of income distribution (in Bocoum et al., 2013, SETAC Glasgow). A way of assessing the monetary flows created by the changes in the life cycle is to use Input-Output (IO) analysis, which is based on interdependencies between economic branches and sectors. In this case study, we consider the project of substituting 40 million hectolitres of locally produced table wine to the same imported volume in country A, a theoretical OECD country. We use a national IO table (fictional but that represents a certain economic structure) to infer the variations at the production step and translate them into numbers of extra employees in different sectors, using productivity ratios. After passing out the new employees in the different classes of salaries, we compare the new income distribution in the different classes to the previous one, and calculate the Gini index. This index usually serves as a measure of income concentration. In the case study, we find that the envisioned change decreases income inequality from 0.39 to 0.37, in country A. The effect on infant mortality is inferred from the variation of income distribution and from the above mentioned elasticity coefficient. The 0.02 point decrease of income inequality decreases infant mortality from 11 per 1000 to 10.3 per 1000, fourteen years later. We set many hypotheses. We therefore suggest comparing only effects that are obtained using the same procedure. The pathway is only suitable for life cycles generating large-scale income flows. Development of other impact pathways highlighting other socioeconomic mechanisms is required. Paying more attention to activities downstream of production in future researches is also essential. **Key words:** Life cycle – income distribution – population health – impact pathway

153

Anticipating the psychosocial factors effects in social LCA

F. Silveri; C. Macombe, Irstea / UMR ITAP ELSA; C. GASNIER, S. Grimbhuler, Irstea

The public and private decision-makers are showing an increasing interest in the environmental and social consequences. However, in the social field, a method equivalent environmental LCA remains largely to be built. The purpose of the work is to set up a new theoretical model, and an assessment grid, to allow us to anticipate damage to health of workers (involved in the life cycle) caused by psychosocial risk factors at work. We will take into account improvements caused by the positive psychosocial factors too. However, we do not study the effects of pollutants, radiations and other dangerous items, because they have been dealt with in environmental LCA (for some models) in order to account for the "Human health" impact. We study frequent risk factors that are linked with the organisation of work itself. There is a "human cost of stress in the workplace", which is different between the various sectors and the different ways of organizing work. The work is based on an unconventional approach. In fact, traditionally, health is considered ex post and based on personal risk factors of individuals. The anticipatory approach of the work, on the other hand, identifies groups of workers considered to be at risk because of psychosocial risk factors to which they are exposed. The outputs of the work will contribute to anticipate damages to health. They will help decision makers to choose the best scenario for the production organisation as far as possible. The expected results from the work also will strengthen the research program in the social life cycle assessment in order to provide a new "method of evaluation" (or "pathway") between psychosocial factors of the work and health of workers engaged in the life cycle of the company.

Using simplified S-LCA to identify socially responsible purchasing criteria

J. Couture, Groupe AGÉCO / Corporate social responsibility; J. Parent, J. Reveret, UQAM

Introduction\nSustainable purchasing is a growing global trend. Increasingly organizations from both private and public sectors are integrating social and environmental criteria into the purchasing process as a means to reduce their environmental footprint, leverage social benefits and foster a sustainable economy, throughout a product's life cycle. But as "a management process used to acquire goods and services in a way that gives preference to suppliers [and products] that generate positive social and environmental outcomes" (Sustainability Purchasing Network 2007), sustainable purchasing must, to be effective, rely on sound sourcing criteria – for each dimension of sustainability.\nOn the environmental side, organizations have today access to a vast array of resources, such as fact sheets, to help them selecting the products and/or suppliers with the highest performance in a life cycle perspective. Based on LCA results, hotspots are identified and specific purchasing criteria, such as certifications, can be proposed to manage risks or reduce potential impacts. To date, tools and resources are, however, much more limited to cover the socioeconomic dimension of sustainable purchasing. Consequently, most organizations rely either on detailed supply chains analysis, adopt generic tools such as suppliers' codes of conduct or require indifferently social certifications such as SA8000 from their suppliers. While useful, these tools are time and resources consuming or non-specific and hence, less effective.\nTo overcome this limitation, ECPAR (Espace québécois de concertation sur les pratiques d'approvisionnement responsable) has commissioned Groupe AGECO to develop a method to integrate in a structured and rigorous way the socioeconomic dimension to technical sheets for sustainable sourcing. Based on a simplified Social LCA (S-LCA) methodology, this method has been developed and implemented in the specific case of paper products. The objective of this communication is to describe this methodology, present the results and discuss the opportunity of using simplified S-LCA as a tool to identify sound sourcing criteria in a sustainable purchasing strategy. Bibliography\nSustainability Purchasing Network. 2007. Sustainability Purchasing Trends and Drivers. 64 pages. Key words\nSustainable sourcing; Simplified S-LCA; Social purchasing criteria.

Current Developments and Challenges on Sediment toxicology in Scientific and Regulatory Contexts

155

Advances in setting principles for regulatory sediment risk assessment

A. Karjalainen, ECHAEuropean Chemicals Agency; F. Pellizzato, European Chemicals Agency; A. Kapanen, European Chemicals Agency ECHA; B. DILHAC, ECHA; B. Versonnen, European Chemicals Agency ECHA / Evaluation; J.V. Tarazona, European Food Safety Authority / Pesticides Unit

The European Chemicals Agency (ECHA) hosted a Topical Scientific Workshop on Risk Assessment of the Sediment Compartment in May 2013. Key areas of sediment risk assessment in a broader regulatory context were discussed. The Workshop aimed at updating scientific principles and guidelines for sediment risk assessment by facilitating dialogue between academia, regulators, the regulated industry and other stakeholders. Experts agreed that there has been a significant development regarding the scientific principles and basic methodologies applicable to prospective and retrospective assessments. These developments and new paradigms should be considered for updating guidelines for assessing ecological risks of chemical substances for freshwater and marine sediments. In order to understand the state of the art of the sediment risk assessment in the field of industrial chemicals, ECHA has carried out a critical analysis of the sediment information submitted under REACH. For the substances registered under the 2010 registrations deadline long-term sediment toxicity testing is a standard information requirement according to Annex X section 9.5.1. Of the 2010 dossiers less than 10 % include a sediment toxicity study whereas an adaptation of the standard information requirement is given in the majority, circa 90 %, of the dossiers. For dossiers submitted in 2013 sediment toxicity is not a normal standard information requirement and only 4 % have submitted experimental sediment toxicity information. Overall the data shows that the sediment information submitted under REACH is a compilation of available information generated for two main purposes: 1) pollution control, mostly for the marine environment, and 2) generic (e.g. (pre)-marketing) assessments), based on standardised, mostly fresh-water, species, with limited number of species and functional traits. Based on the Workshop outcome and the analysis of the sediment information in REACH registration dossiers, it was possible to identify the most critical areas where information is needed for the scientifically-justified and consistent assessment of risks in the sediment compartment. The clear need for a more complete coverage of the complex sediment environment for a better quality sediment risk assessment will be discussed.

156

Nickel toxicity in freshwater sediments: Developing an integrated effects assessment to comply with challenges posed by REACH and the Water Framework Directive

M. van Gheluwe, ARCHE; L.T. Nguyen, Ghent University / Applied Ecology and Environmental Biology; J.M. Besser, USGS Biological Resources Division / Columbia Environmental Research Center; B.G. Brumbaugh, C.G. Ingersoll, US Geological Survey / Columbia Environmental Research Center; E.R. Garman, NiPERA / Ecotoxicologist; C. Schlekat, NiPERA Inc

The protection of the sediment ecosystem is embedded in regulatory frameworks such as the European Union regulatory initiative for the Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) and the EU Water framework Directive (WFD). In general the limited availability of appropriate sediment toxicity data and the lack of understanding of how certain sediment characteristics may modify contaminant bioavailability hamper the process of determining risk to the sediment compartment. This study presents a comprehensive effort to develop predictive, mechanistically based sediment effects guidelines for nickel that can be applied across broad ranges of sediment chemistry. A robust database of chronic toxicity tests was generated using a total of 11 field collected sediments spiked with 5 concentrations of nickel and tested with a suite of 9 benthic organisms representing a variety of feeding strategies and taxonomic groups. The data were used to populate a species sensitivity distribution (SSD) and to derive a realistic worst case Predicted No Effect Concentration (RWC-PNEC) for nickel. In a second phase 6 invertebrate taxa were used to characterize relationships between nickel toxicity and sediment characteristics. Bioavailability models were derived based in EC20 values for selected low-variation endpoints. Most of the obtained toxicity thresholds for nickel in sediment were predominantly correlated with acid volatile sulfides (AVS). The strength of the correlations (indicated by the slope) was less pronounced for those organisms with a subsurface feeding/burrower behaviour (slope: 0.12-0.20) if compared to those species which can be considered surface deposit feeders/swimmers (slope: 0.36-0.49). The bioavailability models were subsequently used to establish a SSD for a RWC sediment low in AVS concentration (0.8 μmol/g dry wt.). The results of support the basis of the SEM-AVS concept for nickel as no toxicity was observed at SEM-AV S < 0 for all species. Furthermore, at increasing AVS concentrations nickel toxicity was mitigated for all species, but the extent of this effect was dependent on the living /feeding strategy of the organism. An HC5-50 of 136 mg Ni/kg dry wt. was estimated from the log-normal function calculated with ETX. This value was deemed appropriate for a RWC PNEC or sediment quality guideline (SQG) because it reflects conditions that represent the 10th percentile of parameters controlling nickel bioavailability.

157

AVS based bioavailability models are inadequate for predicting risk in oxic sediments

G.A. Burton, University of Michigan / School of Natural Resources Environment; D. Costello, Kent State University / Biological Sciences; A. Harrison, University of Michigan / School of Natural Resources & Environment; C.R. Hammerschmidt, Wright State University / Department of Earth Environmental Sciences

The partitioning of metals to solid-phases can reduce the bioavailable fraction of metal. Under anoxic conditions, reduced sulfur and organic carbon are the primary binding fractions for metals; however, these fractions are not as important under oxic conditions. Our research aims to improve metal bioavailability models for stream ecosystems by assessing the role of oxic sediments in sequestering metals. Sediments were spiked with Cu or Ni and equilibrated under anoxic conditions. These sediments were aged in a flow-through mesocosm (100+ days) while concurrently exposing Hyalella azteca to measure changes in toxicity. Temporal sampling produced a fine-scale understanding of geochemical and toxicological dynamics in the sediment as surface sediments oxidized. As sediments aged, oxygen penetration depth increased. Through time, total metal pools remained stable but porewater metals declined as metal speciation changed. Further, sediment toxicity decreased through time until it did not differ from controls. Declines in toxicity occurred concurrently with increased pools of metal (particularly for Cu) associated with crystalline Fe and Mn oxides. These data suggest that the current bioavailability models may be inadequate for sediments with oxidized surface sediments and future research should focus on developing bioavailability models that incorporate Fe and Mn oxides.

Bioaccumulation assessment by battery testing allows read across among marine benthic invertebrate species

N. Diepens, Wageningen University / Department of Aquatic Ecology and Water Quality Management; M. Van den Heuvel-Greve, Wageningen IMARES / Marine Coastal Systems; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group Department of Environmental Sciences

In ecological risk assessment schemes, empirical tests are crucial but not sufficient because regulatory context also requires mechanistic understanding of chemical exposure pathways and effects. Relatively few studies address read across of chemical exposure between benthic invertebrates. The main objective of the present work was to improve understanding of uptake mechanisms for a range of species with different traits, and to model these processes. A secondary objective was to test a novel whole-sediment test set up, which combines test species in one aquarium separated by gauze. Using this set up, bioaccumulation tests with PCBs and chlorpyrifos were performed with the following marine benthic invertebrate species: *Arenicola marina*, *Corophium volutator*, *Macoma balthica*,and *Nereis virens*. Exposure conditions were varied using spiked standard OECD sediment with low, medium, or high organic matter content. Biota sediment accumulation factors for PCBs were *N. virens* < *A. marina* ≤ *M. balthica*< *C. volutator*. The relative importances of uptake by either pore water or sediment ingestion were estimated by modelling. Multispecies test designs performed better than individual test designs due to better water quality.

Considering cohesive sediments for the chemical and ecologi-cal status of aquatic ecosystems – New lines of evidence for a WoE approach based on nematodes

S. Höss, Ecossa; M. Brinke, Federal Institute of Hydrology / Biochemistry and Ecotoxicology; K. Ristau, University of Bielefeld; E. Claus, Federal Institute of Hydrology BfG; C. Moehlenkamp, Federal Institute of Hydrology; G. Reifferscheid, Biochemistry and Ecotoxicology; P. Heininger, Federal Institute of Hydrology; W. Traunspurger, University of Bielefeld

Toxicants accumulated in cohesive sediments impair the functioning of the benthic community that holds the fundamental ecosystem service of closing the nutrient cycle by metabolizing the deposited substrate. Moreover, contaminated sediments represent a permanent source of pollutants for the water phase. Thus, polluted cohesive sediments can impede the achievement of a good chemical and ecological status of the ecosystem and should therefore be considered for the quality assessment of waterbodies. However, most of the monitoring tools and pollution indicators cannot be applied to cohesive sediments, as they are based on macro-invertebrates that do not represent the dominant group in these substrates. Therefore, indices were developed to assess the chemical and ecological status of cohesive sediments that are based on the *in-situ* nematode fauna inhabiting these sediments: (1) Effect-based Sediment Quality Guidelines (SQG) providing thresholds for sediment concentrations of contaminants protecting the nematode fauna in cohesive sediments (SQG_{Nema}, Brinke et al., 2013, SETAC EU Meeting, Glasgow, UK, Abstract No. 502), (2) the NemaSPEAR[%]-index evaluating the ecological status by assessing the abundance of Nematode SPEcies At Risk (Höss et al., 2011, Environ Int 37: 940-949). Both indicator tools can be used as lines of evidence (LoE) in a nematode-based Weight-of-Evidence (WoE) approach for sediment quality assessment. In the presented study, these new indices were validated by defining a NemaSPEAR[%] threshold value to draw a line between a good and moderate ecological status and by testing this threshold with contaminated field samples and comparing the NemaSPEAR[%] with SQG_{Nema} and SQGs based on macro-invertebrate data (SQG_{Makro}). Moreover, microcosm experiments were conducted to reveal responses of the NemaSPEAR[%] to single chemicals. The results showed that a NemaSPEAR[%]-threshold of 30% was able to identify sites with polluted sediments, while the NemaSPEAR[%] correlated well with mean TEC-Q values using SQG_{Nema}. The microcosm study showed a dose-dependent response of the NemaSPEAR[%] to Zn confirming the indicative power of this index for chemical pollution. Finally, a WoE approach combining these two LoEs was applied to a large data set of fine river sediments. This allowed prioritization of sites concerning management actions and confirmed the value of these nematode-based indices for quality assessments of potentially polluted waterbodies.

Assessing the environmental quality of estuarine and coastal sediments from the Atlantic and Mediterranean regions using different in-vitro bioassays

D. Fernandes; E. Perez-Albaladejo, IDAEACSIC; M. Bebianno, University of Algarve; C. Porte, CSIC IIQAB / Environmental Chemistry

Sediment contamination poses a potential risk for both ecosystems and human health. Approaches to biomonitor sediment quality are essential in order to characterize the health status of aquatic environments and, ultimately minimize threats and prevent the adverse effects to aquatic wildlife. However, risk assessment remains a challenge as sediments contain complex mixtures of toxicants, and traditional chemical analyses can neither provide information about potential hazards to organisms nor identify and measure all present contaminants. This work deals with the combined use of (a) the fish hepatoma cell line (PLHC-1) and (b) gonad subcellular fractions from sea bass (*Dicentrarchus labrax*) for the screening of cyto-, repro- and genotoxicity as well as the presence of CYP1A and oxidative stress inducting agents in sediment organic extracts from estuarine and coastal areas (Atlantic and Mediterranean regions). Extracts of those sediments collected near harbours, industrial effluents and untreated sewage showed significant cytotoxicity (Alamar Blue and CFDA-AM assays) and genotoxicity (micronuclei induction) in PLHC-1 cells. This was often associated with a higher presence of CYP1A inducing agents (induction of EROD activity after 6- and 24 h-exposure) and generation of oxyradicals in PLHC-1 cells. Furthermore, the incubation of sediment extracts with sea bass gonad subcellular fractions (mitochondria and microsomes isolated from testes and ovaries) allowed the detection of those extracts that significantly inhibited the synthesis of androgens (CYP17, CYP11b) and/or estrogens (CYP19) in sea bass, indicating the presence of endocrine disrupters. Overall this approach based on the combination of different in-vitro bioassays provides useful information to discriminate between polluted and less impacted areas, and highlights those sediments that could pose risk to benthic organisms and that require further action to improve their environmental quality. Moreover, the differential response of the applied assays to the different extracts emphasized the importance of employing multiple endpoints for the determination of specific modes of action of complex mixtures of contaminants.

Novel approaches to incorporate in vitro bioassays in risk assessment

Conceptual Framework to Derive Effect-based Trigger Values for Cell-based In-vitro Bioassays

B.I. Escher, Helmholtz Centre for Environmental Research GmbH UFZ / Cell Toxicology; P.A. Neale, The University of Queensland / National Research Centre for Environmental Toxicology Entox; J.Y. Tang, The University of Queensland / ENTOX; F.D. Leusch, Griffith University Smart Water Research Centre / School of Environment and Smart Water Research Centre

Bioanalytical tools have been applied for monitoring of water quality as well as assessing treatment efficacy of wastewater and advanced water treatment for many years. Cell-based assays either assess general cytotoxicity or target a specific mode of toxic action or step on the toxicity pathway. Comprehensive risk assessment thus requires a battery of bioassays to cover a range of modes of toxic action and/or toxicity pathways relevant to the water sample to be tested. Lack of trigger values and interpretation guidelines have hampered greater adoption in (regulatory) monitoring applications. In this paper we present a conceptual framework for the derivation of effect-based trigger (EBT) values. We propose to translate existing chemical guideline values to EBT values. It must be noted that there is no single EBT value but an individual EBT value must be defined for each bioassay and each set of guideline values. Depending on the biological endpoint, we differentiate between two approaches to define EBT values: (1) For receptor-mediated effects, where a reference chemical can be defined with clear maximum and minimum potency, the corresponding bioanalytical equivalent concentrations (BEQ) can be used to define effect-based trigger BEQ (EBT-BEQ). (2) For non-specific toxicity and adaptive stress responses, where the BEQ concept does not apply, mixture toxicity concepts can be applied to derive effect concentrations of the sample in units of relative enrichment factors that equate to the triggers, i.e., effect-based trigger effect concentrations (EBT-EC). Per definition the EBT-EC must include considerations of the chemicals' interaction in mixtures. The proposed approach was tested with the Australian Drinking Water Guidelines and the Guidelines for Water Recycling and applied to a set of samples collected at Australian wastewater, water reclamation and drinking water treatment plants. EBT-BEQs were derived for a number of endocrine endpoints and in case of estrogenicity also for several bioassays covering the same mode of action. EBT-ECs were derived for non-specific cytotoxicity and for oxidative stress response. All reclaimed and drinking water samples were compliant with the proposed trigger values. The proposed framework is an initial step towards the development of effect-based trigger values. As a next step, the research outcomes must be discussed with competent authorities in order to implement them in practise.

Applicability of in vitro assays for assessment of estrogenicity in case studies – advantages and uncertainties

B. Jarosova, Z. Rabova, Masaryk University / Faculty of Science RECETOX; B. Vrana, Masaryk University Faculty of Science RECETOX / RECETOX Research Centre for Toxic Compounds in the Environment; A. Ersekova, Masaryk University; L. Blaha, Masaryk University / Faculty of Science RECETOX; K. Hilscherova, Masaryk University Faculty of Science RECETOX / Faculty of Science

In vitro bioassays assessing potential of compounds to activate estrogenic receptor are one of the most commonly used and studied type of bioassays. Main aim of this presentation is to show the positive examples of utilization of estrogenic bioassays in monitoring of waste and surface waters as well as to discuss uncertainties regarding their utilization as risk assessment tools such as possible contribution of various types of compounds to estrogenicity of surface waters. An interlaboratory study comparing concentrations of polar organic compounds in passive samplers placed in one sewage treatment effluent showed high variability of concentrations of steroid estrogens determined by chemical analysis in different laboratories and demonstrated usefulness of utilized estrogenic in vitro assay. Estrogenicity and steroid estrogens were also monitored in samples from 75 different European WWTPs. Steroid estrogens were not detected by instrumental analysis above LOQ 10 ng/L in any sample whereas in vitro assay was more sensitive and showed estrogenicity above 0.5 ng/L in 27 samples. Results of the in vitro assay also allowed comparison of estrogenicity of WWTPs of different capacities and wastewater sources. The third study demostrated estrogenicity in all 7 tested headwaters flowing through areas of the Czech Republic with minimal anthropogenic pollution. Increased estrogenicity was detected in all samples from locations downstream of the first towns with WWTPs compared to samples collected at upstream locations. In case of municipal WWTPs, steroid estrogens seem to be mostly responsible for detected estrogenicity and therefore the authors think that trigger values can be derived from in vivo PNECs and in vitro relative potencies of these compounds in the bioassays. However, information about compounds responsible for estrogenicity as well as for other specific modes of actions in rivers is limited compared to what is available for WWTP effluents or rivers close to their discharges. The potential contribution of some less studied compounds occuring in surface waters to estrogenic activity detected in vitro as well as the uncertainties and limitations in interpretation of in vitro data in will be disscussed. Contribution of dyes on the mutagenicity found in Brazilian surface water: the Piracicaba River case

F.I. Vacchi, Faculty of Pharmaceutical Sciences; J.A. Vendemiatti, University of Campinas; B. Silva, UFSCar / Chemistry; M.B. Zanoni, Paulista Júlio de Mesquita Filho State University; G.d. Umbuzeiro, FACULTY OF TECHNOLOGY UNICAMP / LEAL

Dyes are used in the coloration of different substrates, but the largest use is on textiles industries. Dyes are emergent contaminants and have being found in the environment, especially in Brazil, India and China. Recently mutagenic dyes and aromatic amines were detected in samples of Carioba Wastewater Treatment Plant (WWTP) effluent and Piracicaba river at Americana, SP, Brazil. This region has the largest textile center of Brazil and Carioba WWTP receives effluents from various textile industries. But some industries discharge their effluents directly into the Quilombo river, which is a tributary of Piracicaba river. The aim of this study was to analyze the occurrence of dyes in surface water under the influence of textile industries discharges and in treated effluent from a Waste Water Treatment Plant that receives textiles effluents; and evaluate the mutagenicity of these samples and

the contribution of dyes in the mutagenicity found. Samples were collected in Piracicaba river before WWTP discharge, Quilombo river, Carioba WWTP treated effluent, and Piracicaba river after WWTP. Samples were organically extracted by liquid-liquid using dichloromethane/methanol (2.5:1 v/v) and analyzed by a Linear Ion Trap Quadrupole LC-MS/MS. Extracts were tested in the Salmonella/microsome assay using microsuspension method with strains TA98 and YG1041, in the absence and presence of exogenous metabolic activation (S9). Ten different disperse dyes were detected in surface water and effluent samples of Americana city, SP State, Brazil. The most frequent dyes were Disperse Red 1, Disperse Red 60, Disperse Blue 60, Disperse Blue 291, Disperse Blue 373, and Disperse Violet 93. Samples were mutagenic in Salmonella/microsome assay and the highest potencies were found after the discharge (Quilombo river and treated effluent) with YG1041 in the presence of metabolic activation. The dyes Disperse Blue 373, Disperse Blue 291, Disperse Red 1 and Disperse Violet 93 are contributing to the mutagenicity found in Quilombo and Piracicaba River. But the dyes Disperse Blue 373 and Disperse Violet 93 are the major contributors corresponding almost to 40% in Quilombo river and 30% in Piracicaba river after the discharge, both cases with YG1041 with S9 in the second sampling. Other dyes and aromatic amines were found in the samples and studies to evaluate their contribution on mutagenicity are being conducted. Acknowledgement: Fapesp (2008/10449-7 and 2012/13344-7)

Bioluminescence as a tool for studying mechanisms of toxic effects

N.S. Kudryasheva, Institute of Biophysics SB RAS

Bioluminescence (BL) is glowing of living organisms; it is based on chemiluminescent enzymatic reactions. Marine luminous bacteria are widely used as bioassays for monitoring environmental toxicity. Main testing physiological parameter here is BL intensity. The BL assay systems are based on biological objects of different levels of organization – bacteria-based or enzyme-based bioassays, providing for a study of the effects of toxic compounds on cells or enzymes, respectively. Basing on a broad investigation of effects of model toxic exogenous compounds on BL assay systems, classification of the effects on the BL enzyme reaction was suggested. The effects were classified as physical, chemical and/or biochemical ones. Five mechanisms are discussed: (1) change in electron-excited states' population and energy transfer, (2) change in the efficiency of the S-T conversion in the presence of an external heavy atom, (3) change of rates of coupled reactions, (4) interactions with enzymes and variation of the enzymatic activity, (5) nonspecific effects of electron acceptors. The broad experience in investigation of effects of exogenous compounds makes the BL assay systems to be a very convenient tool for studying toxicity mechanisms. The BL assays were found to be sensitive to alpha- and beta-radionuclides. The role of peroxides and electron transfer in hormesis and toxic effects of radionuclides was studied. Changes in protein secondary structure in bacterial cells exposed to radionuclides was discussed in terms of a stress response of the bacterial cells to the low-dose chronic radioactivity. The mutagenic effect of tritium was studied using restriction analysis of marker amplicons. Detoxification of solutions of metallic salts and organic oxidizers by humic substances (HS), products of natural transformation of organic matter in soils and bottom sediments, was studied. Detoxification mechanisms were revealed to be complex, with chemical, biochemical, and cellular aspects conditioning those. The detoxifying effects were explained by: (i) decrease of free toxic compound' content in water solutions under binding and redox neutralization by HS, (ii) increase of rates of biochemical processes in the bioassay system under HS influence, (iii) enhancement of mucous layers on cell surface as a cellular response to unfavorable impact of toxicants. Mechanisms (ii) and (iii) revealed an active role of the bioassay systems in the detoxification processes.

Flagging health risks of chemicals by combining in vitro bioactivity data with environmental and consumer product exposure modeling

A.S. Ernstoff, Quantitative Sustainability Assessment; H. Shin, University of California Davis; D.H. Bennett, Public Health Sciences; J.A. Arnot, ARC Arnot Research Consulting / Department of Physical Environmental Science; S.A. Csiszar, University of Toronto / Dept of Chemical Engineering and Applied Chemistry; P. Fantke, Technical University of Denmark / IER; B.A. Wetmore, The Hamner Institutes for Health Sciences / Institute for Chemical Safety Sciences; O. Jolliet, University of Michigan / School of Public Health

Combining *in vitro* bioactivity data with exposure models is essential to predict potential public health risks. We present a tier 1 framework to flag chemical exposures of potential risk based on *in vitro* bioactivity data for 229 chemicals from the US EPA. To understand chemical-specific exposure, we refined thousands of chemical categories in the US EPA ACToR/CpCat product database to harmonize with exposure modeling. Most chemicals matched several of the following exposure categories: direct intakes (e.g. food), dermal application (e.g. cosmetics), pesticides (e.g. ingestion of residues), and indoor and environmental emissions. Results were also cross-checked with the Household Product Database and FDA-approved food additives. We independently estimated population-scale chemical intake fractions due to environmental and indoor emissions and product intake fractions using three multi-media models (USEtox, CalTox, RAIDAR). Model results predicted similar trends within two orders of magnitude for most chemicals. Intake fractions were multiplied by emission estimates or production volumes to extrapolate daily intake of chemical per unit bodyweight (mg/kg/day). Modeled intake doses per category varied greatly across chemicals due to physicochemical properties and emission estimates - the main source of uncertainty. We found using conservative approaches, that chemical intake due to consumer product use generally exceeds intakes due to environmental exposures, with the greatest intake being 2,600mg/kg/day for phenol in a personal care product. Population-scale average intake doses due to environmental exposures were always less than 0.34 (mg/kg/day). When comparing intake estimates with the bioactivity data, we found 66 chemicals with a maximum intake that exceeds the minimum oral dose equivalents for observed biological activity. For these 66 chemicals there were several chemical/exposure classification combination that exceeded min oral dose equivalents: 12 cases due to environmental exposure, 20 cases due to product use within home, 41 cases due to personal care product, and 47 cases due to food ingestion. These chemical exposures are flagged as needing to be further evaluated in order to understand possible public health threats.

Pollinator risk assessment: past, present and future

166

Second tier options in the EFSA Guidance Document on Risk Assessment of Plant protection products on bees (Apis mellifera, Bombus spp. and solitary bees)

C. Szentes, EFSA; F. Streissl, EFSA / Pesticide Unit; D. Auteri, Auteri; R. Sharp, EFSA European Food Safety Authority

Pesticides are considered as one factor among others that are contributing to the decline of pollinators. Moreover, the current risk assessment schemes for pesticides are not considered to be able to address the risk to pollinators in a comprehensive way. This indicated the need to review the current risk assessment schemes and to develop new, more sophisticated ones. As a response to this regulatory challenge, the European Commission tasked EFSA to develop guidance for pesticide risk assessment for bees. The new guidance document was issued on July, 2013, but has not yet been adopted for use in regulatory risk assessments. The guidance document suggests the implementation of a tiered risk assessment scheme with a simple and cost-effective first tier moving to more complex higher tiers (e.g. using field studies). Each tier of the risk assessment ensures that the appropriate level of protection is achieved. However, the guidance document was heavily criticised by different stakeholders including the industry and some European regulatory bodies. One of the main concerns raised by the industry was the severity of the first tier together with the unfeasibility of the highest tier options. However, there has been very little discussion regarding the 2nd tier options, which is between the 1st tier and highest tier level. A number of 2nd tier options are suggested by the guidance document which can be used to refine the estimation of the exposure of pollinators to pesticides when foraging on the treated plants. These options can also be used to provide a more realistic oral exposure estimate for larvae. Crop or compound specific data are needed at this tier, with which a low risk may be achieved. Consequently, there will be no need to perform the more complex and expensive field studies. As an example, it is expected that using compound specific information on residue levels in pollen and nectar will provide a solution in many cases. For other cases data on the sugar content of the nectar will be sufficient. The presentation will deliver an overview of the most important 2nd tier options that are included in the guidance document. Also, a case study will be presented explaining how some of these options can be applied in practice.

167

Development of a Toxicokinetic-Model of the Bee Hive.

K. Szonn, RWTH Aachen University / Institute for Environmental Research; C.D. Maus; H. Ratte, Research Institute for Ecosystem Analysis and Assessment – gaiac; M. Ross-Nickoll, RWTH Aachen / Institute for Environmental Research; W. Schmitt, Bayer CropScience AG / Environmental Modelling; T.G. Preuss, Bayer CropScience / Institute for Environmental Research

Pollination is an important factor of the food economy and the honey bee *Apis mellifera* is the most important commercial pollinator. Over the last few years, potential effects of insecticides on bee colonies have been discussed. There is largely consensus that the risk assessment for bees will benefit from a deeper understanding of mechanisms of bee exposure to pesticides. To understand the effects of toxicants in the bee hive it is important to fully understand their fate within bee colonies. Literature data were analysed to determine the relevant toxicokinetic processes in the bee colony and how these processes influence the fate of chemical substances in the bee hive. To realistically estimate the quantity of chemical substances bees are exposed to within the hive, the whole process of resource collection and processing has to be taken into account. We assume bee-to-bee-contact as the most important factor for the distribution of chemical substances in the hive; physicochemical properties of the materials in the hive have to be considered, as well. A conceptual model, which is inspired by PBTK-models, was developed; it comprises all relevant processes. It is the basis for a model simulating bee hive toxicokinetics. This model is implemented in R. To solve the differential equations (DE) the model uses the package deSolve, that is developed for solving ordinary DEs. The model will provide a deeper understanding about toxicokinetics and exposure in the bee hive.

168

Weeds in the treated field – a realistic scenario for pollinator risk assessment?

S.K. Maynard, R. Albuquerque, Syngenta / Environmental Safety; C. Weber, Syngenta / Product Biology

In July 2013 the European Food Safety Authority (EFSA) released its final guidance on the risk assessment of plant protection products (PPPs) to bees (EFSA, 2013). One objective of the guidance was to produce a simple and cost effective first tier risk assessment scheme to ensure that the appropriate level of protection is achieved (EFSA, 2013). However, recent impact analyses have indicated that the first tier of this risk assessment does not act effectively as a screen for compounds of low risk to bees. An example of a non-toxic herbicide (honey bee acute oral and contact LD_{50} >85 & >200 μg a.s./bee respectively) is presented here and screened through the first tiers of the EFSA risk assessment. In this example a worst-case exposure to flowering weeds inside the treated field is highlighted. If realistic farming practices (e.g. tillage) are considered weeds are not usually prevalent in fields before and shortly after sowing, in addition to this the application of the example herbicide will likely remove any weeds which remain shortly after application. It is therefore suggested that the scenarios in the guidance could be considered overly conservative and in some instances unrealistic. The EFSA guidance suggests that if < 10% of the area of use is flowering weeds then the exposure route is not relevant in the 90th%ile case. However, despite this, the option to generate data or refine based on available data is questioned as no guidance for the assessment of the abundance of weeds is available (EFSA, 2013). We present and discuss the use of empirical evidence (e.g. occurrence and growth stage of weeds in control and herbicide treated plots from efficacy field trials conducted for regulatory submission) to illustrate that the scenarios in the guidance document could be modified using currently available data to create a more effective screening step and still ensure that the appropriate level of protection is achieved.

Glyphosate: evaluation of exposure and effects on honey bee brood (Apis mellifera) development

G. von Mérey, Monsanto / Regulatory; S.L. Levine, Monsanto Company / REgulatory Sciences; J. Doering, Feinchemie Schwebda GmbH / Registration; S. Norman, RidgewayEco; P. Manson, Cheminova AS European Regulatory Office / Global Regulatory Science; P. Sutton, Syngenta; H. Thompson, Syngenta Ltd / Environmental Safety

To address new European Union (EU) data requirements for plant protection products, honey bee risk assessments are required where exposure of adults and larvae via direct contact or from residues in nectar and pollencannot be excluded. Acute oral/contact toxicity studies are performed on adult bees and registrants may also be required to conduct Tier 1 larval chronic toxicity studies for which an OECD guidance is still under development or Tier 2 colony-level brood effects studies. For EU re-registration of glyphosate, potential exposure and effects, on honey bee brood/colonies were assessed in separate studies. To quantify exposure, a greenhouse study involved a spray application of a glyphosate formulation to flowering *Phacelia tanacetifolia* during peak bee foraging. Glyphosate concentrations over time in forager-collected pollen and nectar were analysed. Mean glyphosate levels in nectar were >10X lower than in pollen and declined rapidly with DT_{50} values of 1-2 days. Pollen and nectar residue values were used as inputs to a bioenergetics-based exposure model to establish realistic worst case dose levels. To quantify effects on brood/colonies, a Tier 2 bee brood feeding study was performed using the Oomen test design. Colonies were tested at four dose levels including the control. Colonies were assessed 1 week prior and weeks 1, 2 and 3 after dosing. Assessments tracked development of individual larvae and emergence, and the health of the colony as a whole with exposure confirmed by residue analysis of larvae collected from within the colony. No effects at any dose level consequently the No Observed Effect Level for brood development and adult survival was the highest dose tested, providing a sufficient margin of safety on the risk of glyphosate to honey bees. This conclusion is consistent with results of independently performed semi-field and field bee brood studies using a glyphosate-based formulation.

170

A four year field program investigating long term effects of repeated exposure of honey bee colonies to flowering crops treated with thiamethoxam

M. Coulson, Syngenta; P. Campbell, Syngenta / INRSETE; N. Ruddle, Syngenta; E. Pilling, JSCI; I. Tornier, Eurofins Agroscience Services

Neonicotinoid residues in nectar and pollen from crop plants have been implicated as one of the potential factors causing the declines of honey bee populations. Indeed the European Commission has introduced a 2 year moratorium for several uses of imidacloprid, thiamethoxam and clothianidin on bee attractive crops. However, much of the data that has implicated neonicotinoids in the decline of honey bee health have been generated either under laboratory conditions or using unrealistic exposure conditions. Field studies are a credible methodology to assess any effects under real world conditions. In this field study the long-term risk to honey bee colonies was investigated following four years consecutive single treatment crop exposures to flowering maize and oilseed rape grown from thiamethoxam treated seeds at rates recommended for insect control. During the study honey bee mortality, foraging behavior, colony strength, colony weight, brood development, food storage levels and over wintering success were monitored and reported. The results confirmed a low risk to honey bees from systemic residues in nectar and pollen following the use of thiamethoxam as a seed treatment on oilseed rape and maize. These results contribute towards reducing the gap in our understanding of exposure and risk to honey bees from the use of neonicotinoids as seed treatments under field conditions.

171

Uptake and translocation of imidacloprid to nectar and pollen in sunflower and raspberry

T. Eggen, S.R. Odenmarck, T. Torp, Bioforsk; M. Randall, Norwegian Food Safety Authority / Pesticides Section

Imidacloprid, a neonicotinoid insecticide known to be highly toxic to bees, is allowed for use in greenhouse production. Recently, imidacloprid was found in nearly all samples from waste (up to 7 μg/g dry weight) and in leachating from waste (up to 48 ug/L) from greenhouse flower production (Roseth 2012, Roseth pers. communication 2013). The Norwegian Food Safety Authority initiated a project to investigate if bee-attractive plants grown in waste with imidacloprid-residues, e.g. waste from greenhouses production, can take up and translocate imidacloprid to nectar and pollen. Sunflower and raspberry were selected as relevant bee-attractive plants for this study. The study was performed in greenhouse in six growth tubes (each 6 m) with drainage pipe, leca and peat. Confidor (active substance imidacloprid) solved in water was prayed to the growth media in two layer; one in the midle and one top surface. Imidacloprid was found in all nectar and pollen samples from both plant species grown in peat with and initial concentration around 28 μg/g dry weight. The project was financed by the Norwegian Ministry of Agriculture and Food's 'National Action plan for reducing risk from the use of pesticides'.

Fish model species in environmental toxicology (I)

Comparison of experimental versus predicted acute toxicity data of four polar narcotic analogues in the zebrafish embryo

A. Hagenaars, Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences; L. Vergauwen, University of Antwerp / Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences; A. Filby, The University of Exeter; N. Dom, University of Antwerp / Biology; C.R. Tyler, Biosciences College of Life and Environmental Sciences; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; D. Knapen, University of Antwerp / Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences

In line with the 3R principles, several modelling methods use physico-chemical properties of chemicals to categorize them into different mode of action (MOA) categories and to predict their toxic potency. Despite the benefits of these modelling methods, several studies have demonstrated inconsistencies between predicted and experimental toxicity. Transcriptomics offers opportunities to elucidate the underlying biological mechanisms of toxicity which can result in more detailed chemical classification and subsequent toxicity prediction. As zebrafish embryos are not considered test animals until 120 hours post fertilization (hpf) according to European legislation, they can be used in alternative testing strategies and offer great potential in biological MOA classification. In this study, QSAR modelling, and morphological and microarray analysis of zebrafish embryos were used to evaluate the predicted toxicity and the mode of action of four aniline analogues which only differ in their degree of chloro-substitution: aniline; 4-chloroaniline (4CA); 3,5-dichloroaniline (3,5DCA) and 2,3,4-trichloroaniline (2,3,4TCA). Results demonstrate a positive relation between the toxicity and the log K_{ow}(increasing chlorination) which is in accordance to the ECOSAR QSAR prediction.The toxicity of aniline with a low log K_{ow} value, however, was overestimated resulting in a wrong categorization. Since chlorinated anilines are structural analogues with a designated polar narcotic mode of action, similar toxicity responses are assumed by modelling tools. Both morphological data (recorded at 24 and 48 hpf) as well as transcriptomics data (custom made Agilent 15k microarray at 48 hpf) demonstrated that the tested chlorinated aniline analogues have a similar mode of action. Overall, oedema, the absence of blood circulation and abnormal pigmentation were detected for all tested chemicals. The mode of action involved alterations in heme biosynthesis, electron transport chain, structural integrity and cell transport, with more specific toxic mechanisms being observed when chlorosubstitution increases. This study demonstrates that the

toxicity of chemicals can be predicted for zebrafish embryos by QSAR models showing greater toxicity with increasing chlorosubstitution. However, biological data at the morphological and molecular level provide more insight in the general mode of action as well as more specific effects associated with the different structural analogues.

173

Effect of an herbicide, ethofumesate, on aerobic metabolism in roach (Rutilus rutilus) at two temperatures

V. Maes, Unersité de Reims Champagne Ardenne / UFR Sciences Exactes et Naturelles; A. Vettier, Université de Reims Champagne Ardenne / Unité de Recherche Interactions Animal Environnement EA; O. Dedourge-Geffard, University of Reims ChampagneArdenne / Unité de Recherche Interactions Animal Environnement EA; A. Geffard, Université de Reims Champagne Ardenne / Interactions Animal-Environnement (IAE); O. Palluel, INERIS / Unité décotoxicologie in vitro et in vivo; W. Sanchez, INERIS; S. Paris, Sciences; S. Betoulle, Université de Reims; E. David, Université de Reims Champagne Ardenne / UFR Sciences Exactes et Naturelles

Ethofumesate is a benzofuran herbicide commonly used to control weeds of sugar beet. Its mechanism of action in plants is to inhibit the synthesis of very long chain fatty acids. The aim of this study was to determine the effect of ethofumesate on aerobic metabolism in juvenile roach at different (biochemical, molecular and cellular) regulation levels. Studying the energy metabolism constitutes an appropriate approach to detect physiological disturbances of organisms linked to their exposure to pollutants. Indeed animal survival depends on the availability of energy necessary to ensure physiological functions as maintenance, growth and reproduction. Among biological processes involved in cellular energy synthesis, we focused on glycolysis and respiratory chain pathways. Two temperatures were tested to assess potential effects of this parameter on energy metabolism responses to chemicals. During exposure, fish were exposed to 0.5; 5 or 50 $\mu g.L^{-1}$ of ethofumesate during seven days, at 10°C for the first experiments and at 17°C for the second. For each experiments, fish were sacrified and white muscle sampled at 0,1 and 7 days. Glycolysis fluxes, gene expression, electron transport system, anti-oxydant responses and mitochondria ultrastructure were analyzed. Concerning glycolysis pathway, aerobic flux seemed to be affected at T_1 when individuals exposed to ethofumesate at 10°C presented a lower aerobic flux than control. Expression of HK gene decreased significantly at T_1 in fish exposed to ethofumesate at 10°C. As HK is the only aerobic enzyme of the glycolysis pathway, we can hypothesize that such an under-expression of this gene could be related to an effect on aerobic flux. Focusing on respiratory chain, this pathway was differently affected depending on temperature. Ethofumesate seems to have more effects at 17 than 10°C, what seems consistent, as energy metabolism is known to be more active with increasing temperature. This temperature effect was observable in electron transport system and antioxidant activity essentially. Indeed, ETS decreased in muscle of contaminated fish at 17°C only. In conclusion, this study revealed a disturbance on aerobic metabolism due to ethofumesate exposure on juvenile roaches, especially in glycolysis pathway with an effect of exposure temperature. This study provides potential new biomarkers related to the energy metabolism, but further analyses are required to understand the action mechanisms.

174

A novel method for measuring disruption of energy metabolism in vivo in the zebrafish

J. Legradi, M. van Pomeren, P. Cenijn, VU University Amsterdam / Institute for Environmental Studies; A. Dahlberg, L. Asplund, Stockholm University / Department of Materials and Environmental Chemistry; A. Bergman, Stockholm University; J. Legler, VU University / Institute for Environmental Studies

In recent years halogenated phenolic compounds (HPCs) such as hydroxylated polybrominated diphenyl ethers (OH-PBDEs) have been found in many marine species from the Baltic Sea, e.g. cyanobacteria, red algae, blue mussels and a variety of fish species. Although these substances seem to be primarily natural products they can also be produced by in vivo metabolism of PBDEs. It has been shown that many marines species (e.g. algae, cyanobacteria and marine sponges) are able to produce OH-PBDEs. The amount of product formed depends on environmental factors like temperature, light, wind or nutrient supply. Variations, e.g. due to eutrophication and climate changes might increase the levels of OH-PBDEs produced Recent studies have shown that one of the most ubiquitous OH-PBDE found in marine fish, 6-OH-BDE47, is very toxic to zebrafish Danio rerio embryos. This developmental toxicity is, at least in part, due to potent inhibition of mitochondrial oxidative phosphorylation (OXPHOS), thereby disrupting the main source of cellular energy. In this study, we hypothesize that other HPCs may also modify energy metabolism and that this effect might explain some of the severe health effects observed in Baltic Sea wildlife, such as wasting syndrome, decrease in fat content and reproductive insufficiency (e.g. low hatchability in herring roe). To this end we have developed a novel method for monitoring the disruption of OXPHOS in vivo in a small fish species (Danio rerio). The potential to disrupt OXPHOS of 19 commonly found HPCs was studied in vitro and in vivo. Our results indicate that many HPCs found in marine species have OXPHOS disrupting potency. Mixture experiments indicate strong synergistic effects.

175

Genomic and gene expression responses to genotoxic stress in zebrafish (Danio rerio)

M. Srut, A. Stambuk, University of Zagreb Faculty of Science / Department of Zoology; J. Bourdineaud, Géochimie et Ecotoxicologie des Métaux dans les systèmes Aquatiques (GEMA team), UMR 5805 CNRS - Université Bordeaux 1; A. Karaga, Nature Park Vrana lake; G.I. Klobucar, University of Zagreb Faculty of Science

Sublethal exposure to genotoxicants in the environment may influence genome integrity in affected organisms and potentially cause permanent alterations in the genome, thus posing the need to more adequately estimate not only DNA damage but also its longevity. Therefore, in this study we assessed primary DNA damage and existence of potentially persistent DNA alterations in the zebrafish genome using three different models (PAC2 cell line, embryos, adults) upon exposure to model genotoxic agents and the following recovery period. Genotoxicity assessed using Comet assay served as an initial screening for evaluation of general impact on DNA integrity under genotoxic stress. To test for genomic effects upon genotoxic stress quantitative RAPD and AFLP were applied. Furthermore, expression of a suite of genes involved in DNA repair, oxidative stress response and xenobiotic metabolism was monitored in order to get better overview of zebrafish genome responses to genotoxic stressors. Additionally, AFLP method was applied on adult specimens one year after their exposure to genotoxicants at larval stage in order to further evaluate longevity of observed DNA alterations. Comet assay detected DNA damage in all three zebrafish models, which in some cases persisted upon recovery period as well. DNA alterations assessed using qRAPD and AFLP were observed even in cases when Comet assay indicated lack of significant damage proving their sensitivity for detection of various DNA alterations that remain undisclosed by the Comet assay, such as DNA adducts, mutations, structural DNA changes and changes in DNA methylation pattern. Zebrafish larvae proved to be the most sensitive zebrafish model for revealing genotoxic effects, which was evidenced by the high incidence of DNA alterations and the lack of significant DNA repair at the early stages of larval development. Some of the genomic alterations observed in larvae were still detectable in the adulthood, indicating the formation of persistent genomic modifications. These results thus underline zebrafish larvae as particularly sensitive model in such surveys and encourage the simultaneous use of various models and methods for more accurate evaluation of the consequences of the genotoxic insult.

176

'Mode-of-action' of human pharmaceuticals in fish: The effects of ibuprofen on Fathead minnow (Pimephales promelas)

A. Patel, Brunel University / Biosciences; H. Trollope, Brixham Environmental Laboratory; Y. Glennon, K. Hurd, AstraZeneca / Brixham Environmental Laboratory; G.H. Panter, Brixham Environmental Lab; M. Rand-Weaver, Brunel University / Biosciences; J.P. Sumpter, Brunel University / Institute for the Environment

The widespread detection of human pharmaceuticals in the aquatic environments has raised concerns over the potential eco-toxicological effects in non-target organisms. Ibuprofen is a widely used prescription and over-the-counter medicine with an estimated reported usage of ~260,000 Kg in England. To evaluate whether or not ibuprofen poses a risk to fish (fathead minnow, FHM) we tested the 'read-across hypothesis' that stipulates any potential effects will be related to the MoA of ibuprofen, and that these effects will only be seen when plasma concentrations in fish are similar to human therapeutic plasma concentrations (Cmax). Ibuprofen alleviates pain, fever and inflammation by inhibiting the biosynthesis of prostaglandins (PGs) through inhibition of the enzyme (the target) Cyclo-oxygenase (Cox). There are two mammalian isoforms of Cox (1 and 2). The Cmax of ibuprofen is between 15-25 mg/L following a 400 mg dose. Cox gene fragments were identified and characterised in FHMs and we demonstrated that FHMs possess an additional Cox isoform to mammals (Cox 1, 2a and 2b), similar to the closely related zebrafish (Danio rerio). We established that FHMs exposed, via the water for 72-96 hours, to ibuprofen concentrations of 270 and 370 μg/L resulted in plasma concentrations within the Cmax. Uptake of ibuprofen was rapid, however large individual variation was observed, suggesting that drug metabolism in fish, as in humans, is variable. The effects of ibuprofen exposure on FHM tissues were examined by measuring Cox gene expression using 'quantitative real-time polymerase chain reaction' (qPCR) in control and exposed fish. Since PGs are the products of Cox activity, Prostaglandin E metabolite (PGEM) concentrations were also measured using an ELISA assay (Cayman Chemicals, USA). Contrary to expectation, Cox gene expression was increased in exposed fish compared to the control, which may indicate compensatory up-regulation if the enzymes have been inhibited following ibuprofen exposure. However, PGEM concentrations were significantly decreased in exposed fish, compared to the controls (*Unpaired t test, P< 0.0001*). Our data do not suggest that ibuprofen would present an immediate risk to fish at environmental concentrations, however as PGs have been linked to roles in fish reproduction, more work is required to determine the significance of PG inhibition in wild fish.

177

Physiological effects of exposure to ibuprofen in Menidia beryllina.

R.E. Connon, University of California Davis / School of Veterinary Medicine; K. Jeffries, UC Davis; N.A. Fangue, University of California, Davis / Wildlife, Fish, & Conservation Biology; S.M. Brander, University of North Carolina Wilmington / Department of Biology Marine Biology

Ibuprofen is a nonsteroidal anti-inflammatory drug (NSAID) that is often detected in wastewater effluent and in the receiving waters. Ibuprofen has a relatively short half-life and therefore is not persistent in the environment; however its continual introduction into the aquatic environment via municipal wastewater effluent can lead to some fishes experiencing chronic exposures in areas affected by wastewater. Ibuprofen is a non-selective cyclooxygenase inhibitor, which can result in reduced prostaglandin production. Prostaglandins are involved in regulating reproductive hormone production and complex spawning behaviors, among other physiological processes, therefore exposure to ibuprofen may adversely impact fishes. We used inland silversides (*Menidia beryllina*; 66 days old), an estuarine fish species that is a potentially useful indicator of contaminant exposure in estuaries throughout North America, to determine the physiological effects of acute and chronic exposure to ibuprofen on gene expression and reproductive output. Acute 96-hr exposures were used to identify the effects of ibuprofen on survival, which was 98-100% after 96 hr for concentrations as high as 18.8 mg/L and subsequently decreased at higher concentrations. Juvenile fish were then exposed to one of three ibuprofen exposure treatments (0.025, 0.25 and 2.5 mg/L), along with an experimental control group, for 14 days. We used qPCR analysis to determine the effects of ibuprofen on the expression of genes involved in prostaglandin synthesis, arachidonic acid metabolism, steroid synthesis and hormone receptors. We found that ibuprofen affected the transcript levels of several genes involved in prostaglandin synthesis and arachidonic acid metabolism. Additionally, we found that the expression of hormone receptors was non-monotonic and appeared to be more affected by ibuprofen at the lowest exposure concentration than at the higher concentrations. We will use a species-specific microarray to further examine the transcriptomic responses to ibuprofen exposure. Our results show that at low concentrations, chronic exposure to ibuprofen can induce cellular responses in *M. beryllina*. We detected these cellular responses at concentrations that resulted in reduced reproductive output in adult *M. beryllina*, which suggests a potential link to a whole organism-level impact of exposure to ibuprofen.

Wildlife ecotoxicology: from acute toxicity to low level, chronic exposure related effects (I)

An innovative large scale field study to investigate unintentional effects of plan protection product on the grey partridge Perdix perdix reproduction in cereal ecosystems

e. bro, ONCFS / Wildlife Research; F. Millot, ONCFS; J. Devillers, CTIS

Unintentional effects of current plan protection products (PPPs) use on non target animals have been little documented *in situ* on vertebrates living in cultivated farmlands. In this context, we investigated the effects of exposition to PPPs on the grey partridge *Perdix perdix* reproduction. This declining gamebird, typical of cereal ecosystems, is exposed to PPPs during its whole life-cycle and thus appeared as a relevant indicator. We used an innovative approach to characterize the potential exposition to PPPs, combining daily radiotracking of > 400 females in spring & summer and a survey of farmers to know the farming operations they carried out on each of their field plots (*i.e.* PPP used, date of application, dose used, etc.). Birds were monitored twice a day to record their status (surviving, dead or missing) and their locations in crops. Locations were reported on a map of crop cover using a nomad GIS. Clutches (ca. 280) were located once the incubation had started. The biological material (pipped eggshells of hatched eggs, destroyed and intact eggs) was collected after clutches had hatched or failed. Hence we could record *in situ* several reproductive endpoints: clutch fate, cause of failure, clutch size, egg hatching rate. We determined the status of intact eggs (infertile *vs.* dead embryo) and the development stage of dead embryos as well as any potential body defect. In addition, we measured eggshell thickness. We identified the crop plots frequented by females during the incubation, laying and pre-laying periods using the convex envelop of daily locations on QGIS. Then, thanks to the farmer's questionnaire, we identified the PPPs spread on those crop plots for each period. This procedure is relevant from an ecological point of view since it both tooks the spatio-temporal variability in PPP use and partridge habitat use into account. We replicated this field work over 12 study sites to consider a diversity of situations. They were located in north-central France, a region of intensively cultivated farmlands where the grey partridge is still present as wild populations. After a presentation of the whole methodology used, we will characterize the potential direct/indirect exposition of eggs to the different PPP types and present statistics correlating reproductive endpoints and potential exposition to > 100 chemicals. This research is funded by the *Pesticides-Ecophyto 2018* program of the French Ministry of Environment.

179

Chlorophacinone toxicity and threshold for coagulopathy in American kestrels (Falco sparverius)

B.A. Rattner, USGSPatuxent Wildlife Research Ctr / USGS; K.E. Horak, National Wildlife Research Center; S. Knowles, National Wildlife Health Center USGS; R.S. Lazarus, USGS Patuxent Wildlife Research Center / USGS; S.L. Schultz, Patuxent Wildlife Research Center USGS / USGS; S.F. Volker, National Wildlife Research Center USDA; D.A. Goldade, U.S. Department of Agriculture / Animal and Plant Health Inspection Service, National Wildlife Research Center

Recent studies with captive American kestrels (*Falco sparverius*) and Eastern screech-owls (*Megascops asio*) found these raptorial species to be considerably more sensitive to the first generation anticoagulant rodenticide (FGAR) diphacinone than traditional avian test species (mallard *Anas platyrhynchos*, bobwhite *Colinus virginianus*). Using data from these studies, both deterministic and probabilistic risk assessments indicate that diphacinone is far more hazardous to raptorial birds than previously recognized. Chlorophacinone (CPN) is a FGAR that is widely used for the control of pest species in urban and suburban settings, agriculture and island restoration projects. We examined its toxicity in adult male American kestrels fed diets of rat tissue mechanically-amended with CPN and rat tissue containing biologically-incorporated CPN (derived from lab rats fed CPN bait) for 7 days. Nominal CPN levels in these diets were 0.15, 0.75 and 1.5 μg/g food wet weight, and actual concentrations were analytically verified as being close to these target values. Neither food consumption nor body weight were affected by CPN, and exposure and adverse effects were dose-dependent. There were no dramatic differences in toxicity between the mechanically-amended and biologically-incorporated CPN diets. Overt signs of intoxication and anemia were apparent in kestrels receiving 1.5 μg CPN/g food. Both prothrombin time (PT) and Russell's viper venom time (RVVT) were prolonged at doses of 0.75 and 1.5 µg CPN/g compared to controls and the 0.15 μg CPN/g group. Histological examination of tissues revealed evidence of hemorrhage in many CPN-treated kestrels (but not controls), and CPN residues in liver were dose-dependent, averaging about 0.2 μg/g wet weight at the greatest exposure levels. Using benchmark dose software, dietary thresholds at which PT and RVVT were prolonged in 10% of the kestrels corresponded to exposure rates of approximately 70 and 26 μg CPN/kg body weight per day, respectively. Liver CPN concentrations at which PT and RVVT were prolonged in 10% of exposed kestrels were about 0.12 and 0.07 μg CPN/g wet weight, respectively. These data are being used to more fully assess the hazard of CPN to non-target raptorial birds.

180

Exposure of bearded vultures to external antiparasitics used to treat livestock

R. Mateo, UCLMCSIC / Instituto de Investigacion en Recursos Cinegeticos; I.S. Sanchez-Barbudo, UCLMCSIC

Veterinary drugs that are commonly used in livestock production can remain as residues within the carcasses of animals after death. As a result, various scavengers, including vultures, may be exposed to a range of toxic compounds – the implications of which remain very poorly characterised. Across Asia, exposure to diclofenac through this pathway has caused the near global extinction of at least three species of Old World *Gyps* vultures. This highlights the urgent need for far better pharmacovigilance and the requirement for improved, more comprehensive life-cycle assessments for the myriad of pharmaceutical products currently in use. Here we present data regarding the exposure of bearded vulture (*Gypaetus barbatus*) to external antiparasitics in Spain. We have studied 24 suspected poisonings of bearded vultures and the breeding failure of one pair in Aragon (NE Spain) between 2006 and 2013. As evidences were found that external antiparasitics used on livestock were a probable cause of some of these poisonings, 24 feet of pork and 116 feet of lamb were analysed by GC-MS. Brain acetylcholinesterase (AchE) activity was measured in the brain when this sample was available. One of the bearded vultures showed diazinon (12 ng/g) in the gastric content, another one showed permethrin (56 ng/g), and lamb feet associated with two other poisonings showed diazinon (28-29 ng/g). Brain acetylcholinesterase activity in the bearded vulture with diazinon in the gastric content was 16.8 μmol/min/g, which is lower than the activity found in another bearded vulture dead by traumatism with 28.5 μmol/min/g. Pork feet had no residues of external antiparasitics. On the contrary, lamb feet showed residues of diazinon, pirimiphos-methyl, chlorpyrifos, fenthion, permethrin or cypermethrin, with occurrences varying among slaughterhouses (up to 100%). In some cases, lamb feet contained up to 618 ng/g of diazinon and 1,008 ng/g of cypermethrin. Washing the feet with water significantly reduced the levels of external antiparasitics, so this measure was regularly adopted to reduce the risk of exposure in the managed feeding sites. We can estimate an exposure in bearded vultures of up to 0.05 mg/kg, which is lower that the LD_{50} calculated for wild birds of 2 mg/kg. However, this exposure is almost chronic and some evidences exist that organophosphates at levels of a few μg/g can affect serum AchE, metabolism and the immune function of birds.

181

Does pollution increase pathogen infection in terrestrial wildlife?

R. Scheifler, University of FrancheComte / ChronoEnvironnement; C. Bichet, University of Bourgogne CNRS / Biogeosciences; M. Coeurdassier, University of FrancheComte / ChronoEnvironnement; C.C. Fritsch, CNRS / UMR ChronoEnvironnement; G. Sorci, University of Burgundy / Biogeosciences; N. Tete, University of FrancheComte / ChronoEnvironnement; P. Tournant, University of FrancheComte CNRS / TheMA; E. AFONSO, Laboratoire Chronoenvironnement / University of FrancheComte

Among the stressors organisms are exposed to, pollutants have been recognised as having deleterious effects on the immune system. Subsequent variations of immunocompetence may facilitate the infection of organisms by pathogens. We studied the relationships between trace metals (TMs) and various pathogens in the house sparrow *Passer domesticus*, the wood mouse *Apodemus sylvaticus* and the lesser horseshoe bat *Rhinolophus hipposideros*. The composition of the landscape was quantified because it may have a great importance on both pathogen transmission and pollutant transfer in the environment. Pathogens in house sparrows were studied in 5 populations along an urbanization gradient in France. Small mammals were sampled from 7 variously polluted sites around a former smelter in northern France. Droppings of bats were collected in 25 maternity roosts in Franche-Comté region (northeastern France). Pb concentrations in sparrow feathers were positively associated with urbanization while Cd and Zn concentrations were positively associated with forest cover. In mice, prevalence of the bacteria *Anaplasma phagocytophilum* and of the coccidia *Giardia spp*. was related to landscape composition. Richness of coccidia increased with natural forest and decreased with urban areas. The global pathogen richness increased with increased presence of hedgerows and copses and also with landscape diversity. In bats, Cd, Cu, and Zn concentrations and individual pathogen richness were positively related to the percentage of forest cover. *P. relictum* prevalence in sparrows was negatively associated with Cd concentrations but positively associated to Pb. In mice, the prevalence of *Giardia spp*. and *Eimeria spp*. significantly increased with Pb concentrations in kidneys. *Giardia spp*. prevalence and the pathogen richness were positively associated with Cd and Pb concentrations in soils. In bats, prevalence per roost for *E. hessei* was positively related to Cd concentrations. Individual pathogen richness was related to both essential and non-essential TMs. For 3 different animal models and several pathogens having different transmission modes, relationships were found between one and/or several pathogens and one and/or several TM concentrations in tissues. Relationships between pathogens and TMs are complex and modulated by landscape features. Underlying mechanisms and impacts on wildlife are still to be elucidated and constitute promising perspectives within the field of stress ecology.

182

Levels and Risk assessment of DDTs in biota samples from the Ethiopian Rift Valley Region

Y.B. Beyene, Hokkaido Univesity / Laboratory of Toxicology; Y. Ikenaka, Hokkaido University; S.M. Nakayama, Hokkaido University / PhD. Student; M. Ishizuka, Hokkaido University / Graduate School of Veterinary Medicine

Despite restrictions and bans on the use of organochlorine pesticides, developing countries are still using them for agricultural and public health purposes. In African countries suffering from malaria epidemic, an exemption was made possible as DDT is relatively cost effective, easy to produce and highly effective for control of malaria through indoor residual spraying (IRS). Among those countries, Ethiopia is one of the major importer and consumer for the past four decades with a problem of obsolete pesticides. Approximately, 400 metric tons of DDT is used for IRS per year to control malaria throughout the country. Therefore, this study is designed to investigate the levels and risk assessment of DDTs in biota samples from the Ethiopian Rift Valley Lakes - Lake Awassa and Lake Ziway. Surface sediment samples (n=25), and 49 fish samples of Tilapia (n= 20), Catfish (n= 18) and Barbus (n= 11) from Lake Awassa; 105 fish specimens of Tilapia (n = 27), Zillii (n = 19), Carp (n = 27), Catfish (n = 27) and Barbus (n = 5), from Lake Ziway and 23 bird individuals belonging to Hamerkop (n = 5), Sacred ibis (n = 7), Marabou (n = 6), and Pelican (n = 5) resides around lake Ziway were collected. Muscle tissues were taken for analysis. ΣDDTs in surface sediments from Lake Awassa were found in the range of 3.64 to 40.2 ng/g dry weight and high levels of DDTs were observed in the vicinity of the inflow side and from samples next to a village close to agriculture areas. Reidue levels of DDTs in fish samples from Lake Awassa were ranged from 0.63–73.2 ng/g ww in the order of: Barbus > Catfish > Tilapia. The levels of ∑DDTs from Lake Ziway ranged from 0.77–61.9 ng/g ww and 114 to 1600 ng/g ww in fish and bird species, respectively. Generally, *p,p'*-DDE was the predominant congener. Evaluation of risk assessment showed a concern of toxicity for human health and bird population. Assessment based on the cancer risk estimates set at a carcinogenic risk level of 10^{-6} were in the area of concern span and the calculated hazard ratio of DDTs exceeded the threshold value of one, indicating daily exposure to DDTs is a potential concern. The main DDT metabolite, *p,p'*-DDE had significantly high burden in bird species, which may be sufficient to cause adverse effects on eggshell thinning and survival of young birds.

Increased temperatures and pesticide exposure: a double threat to population of amphibians? A microcosms experiment on embryos development

V. Silva, Universidade de Aveiro; S.M. Marques; R. Pereira, University of Aveiro / CESAM, Center of Environmental and Marine Studies, University of Aveiro; F. Goncalves, University of Aveiro CESAM / Department of Biology; J. Keizer, Department of Environment Centre for Environmental and Marine Studies CESAM University of Aveiro Aveiro Portugal; N. Abrantes, University of Aveiro / CESAMDAO

Amphibian populations are declining worldwide, and the increase application of pesticides in agricultural activities may be one factor contributing for the decreasing abundance of this group. Climate changes are expected to constitute an additional threat to amphibian populations being also able of enhancing the toxicity of some chemicals. Thereby, the present work aims to use microcosm experiments to study the combined effects of temperature and pesticide exposure on the normal embryo development of amphibians. To assess the developmental effects of these factors, embryos of *Pelophylax perezi* (Iberian green frog) were submitted simultaneously to three temperature regimes (18, 23 and 25 ºC) and three concentrations of the pesticide FORUM C - active ingredients: dimethomorph and copper oxychloride - (0.5, 0.75 and 1.125 mg L^{-1}). Embryos in midblastula (stage 8) were used to start the test and throughout the assay growth, survival and malformations of the tadpoles were evaluated. Basic water quality parameters (D.O., pH and temperature) were measured in the beginning, before renewing the test solution and at the end of the test. Each temperature test finished once every tadpole in the control reached the 25th stage of development. Besides mortality, growth and teratogenesis parameters, a battery of antioxidant biomarkers including Glutathione peroxidase (GPx), Glutathione-s-transferases (GSTs) and Glutathione reductase (GRed) were assessed. In addition lipid peroxidation (LPO) was also determined at the end of the assay in order to assess oxidative damage. These biochemical parameters provide further comprehension of the subcellular effects resulting of the tested combined exposure, allowing to understand some toxicity pathways. The results of these experiments using the combination of two stressors will provide a more realistic overview of the threats faced by amphibian populations in the wild. This information is of crucial importance to anticipate the effects of chemical pollution in the rapidly changing environment.

A novel approach to study human habits through mass spectrometric analysis of urban wastewater

S. Castiglioni, Mario Negri Inst / Environmental Health Sciences; A. Borsotti, E. Gracia Lor, N. Rousis, Mario Negri Institute; C.P. Martins, Thermo Fisher Scientific; E. Zuccato, Istituto Mario Negri

The chemical analysis of urban wastewater for the excreted biomarkers of endogenous human metabolism is a potent approach for monitoring habits and lifestyle of an entire community. Mass spectrometry is the strong base of this novel approach since this technique is sensitive and specific enough to detect analytes at trace levels even in a complex matrix such as raw urban wastewater. This study presents several applications of this approach performed in Italy both at local and national scale. The aim was to estimate temporal and spatial trend of illicit drug use, monitoring drinking and smoking habits and identify the presence of new psychoactive sustances by using high resolution mass spectrometry (HRMS). Raw wastewater samples were solid phase extracted using mixed-mode polymeric phases and analysed by high performance liquid chromatography tandem mass spectrometry (HPLC-MS/MS) and HRMS. The daily mass loads of each biomarker were used to back-calculate the use of the selected substances in a population. The profile of cocaine use obtained during a seven-years long monitoring campaign in Milan, showed a marked decrease between 2008 and 2009 (1100-600 g/day of cocaine daily use). On the other hand, a progressive increase of methamphetamine use was observed from 2008 to 2011 (from 10 to 150 g/day). Different patterns of cocaine use were observed according to geographical location and population size in 17 Italian cities. Cocaine use resulted higher in Central Italy and in large cities. On the other side, cannabis use was equally distributed in all the cities investigated. The same approach has been applyed to monitor alchool and smoking habits obtaining specific daily profiles of alcohol and nicotine use in different cities. The smoking habits estimated by wastewater analysis were in line with the Italian prevalence data from epidemiological surveys. The presence of new psycoactive substances in urban wastewater has been screened by HRMS for new drugs such as phenetylamines and cathinones. This study presents a novel and very promising approach, based on mass spectrometry analysis, to provide objective and updated information on human habits in a defined population. It can be considered a complementary tool for epidemiological studies, due to its ability to monitor changing trends in populations, to identify the use of new substances, and to assess

the efficacy of dissuasive campaigns.

Occurrence of 940 organic micro-pollutants in environment waters in Hanoi, Vietnam

T.T. Duong, The University of Kitakyushu / Environmental Systems; K. Kadokami, The University of Kitakyushu

This study provides the first widespread information on 940 organic micro-pollutants in environment waters in Hanoi, Vietnam. Surface water (15) and groundwater (18) were collected from 5 rivers/canals and 18 wells, respectively in Hanoi areas from 2011 to 2013. Nine hundred and forty semi-volatile organic compounds (SVOCs) were analyzed by a newly developed comprehensive analytical method using GC-MS, GC-MS-MS and an automated identification and quantification database. The number of detected chemicals in river water ranged from 51-103 (median 82) and 8-30 (median 20) in groundwater. Substances detected in surface water at the highest concentrations were sterols, pharmaceuticals and personal care products (PPCPs) and pesticides, indicating that rivers were heavily polluted with untreated wastewater discharged from domestic sources. Sterols (coprostanol, cholesterol, beta-sitosterol) and fenobucarb were found in 100% samples, followed by PPCPs (caffeine, L-menthol) (90%), whereas permethrin-1 and -2 were only found in urban canals. Concentrations in groundwater were low levels, ranging from 0.67 µg/L to 33 µg/L. However, L-menthol, squalane, diethyltoluamide and caffeine, which were the most frequently detected in the surface water, were also observed in well water, and reaching the maximum values of 0.11 µg/L, 0.21 µg/L, 0.08 µg/L and 5.4 µg/L, respectively. Cholesterol residues (0.05 - 1.3 µg/L) were present in 10 wells and stigmasterol residues (0.05 - 12 µg/L) as well as beta-sitosterol (0.03 - 1.2 µg/L) contaminated 7 wells. Benzyl alcohol was detected in 15 wells with concentration ranged from 0.03 µg/L to 7.1µg/L, which was similar to those observed in surface waters (0.09 - 4.0 µg/L). These results imply that the groundwater is contaminated with wastewater leakage from sewage canals. In addition, calculation concentration ratios of contaminants between the surface water and groundwater using the geometric mean values revealed that contaminants having lower octanol–water partition coefficient values showed higher contribution to the groundwater contamination. Furthermore, since a large number of chemicals detected in surface waters, it is suspected that ground water is contaminated with many chemicals, especially hydrophilic compounds. Consequently, in order to elucidate pollution status of groundwater by organic micro-pollutants, a more detailed survey on hydrophilic chemicals in groundwater is needed.

186

Chiral pharmaceuticals and illicit drugs stereoselective degradation in activated sludge: methodology and results of quantification in microcosm study

S. Evans, University of Bath; B. Kasprzyk-Hordern, University of Bath / Chemistry

Pharmaceuticals are routinely found within aquatic ecosystems, entering, usually, via wastewater treatment plant (WWTP) effluent, however chirality is rarely considered. Many drugs, including pharmaceuticals and illicits, are chiral i.e. the structures can be present in two or more non-superimposable mirror images, each of which is known as an enantiomer. Each enantiomer, due to its configuration, interacts with biological systems in a unique way. This often results in different adsorption, distribution, metabolic pathways and excretion rates (ADME). Consequently potencies, toxicities and even modes of action may differ between enantiomers. The ADME may also alter when the enantiomers are used in combination due to potential synergistic and/or competitive relationships between the two enantiomers. Post administration, in vivo chiral switching and preferential metabolism often results in an altered enantiomeric fraction being excreted. This new mix of enantiomers is then exposed to biological treatment at WWTPs and ad hoc degradation within aquatic ecosystems, which may continually change the enantiomeric fraction. Chirality, and its implications, are well recognised in drug development with each enantiomer and the mixture being assessed separately. However this phenomenon is not taken into consideration within the European Medicines Agency Guideline on the Environmental Risk Assessment of Medicinal Products for Human Use[1]. This presentation introduces the detection of chiral drugs within the environment and details the analytical technique, chiral LC-MS/MS, used to quantify a range of drugs, including anti-depressants, beta-blockers and illicits, at the enantiomeric level. In addition it will detail the sample preparation techniques used prior to analysis for liquid and solid matrices, e.g. microwave assisted extraction and SPE; illustrating the challenges associated with this, particularly combining the requirements of SPE with chiral-LC. The presented results indicate changes in the enantiomeric fraction during activated sludge treatment. 1. European Medicines Agency, *Guideline on the Environmental Risk Assessment of Medicinal Products for Human Use*, 2006: London, available at: http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2009/10/WC500003978.pdf.

LC-MS/MS Screening for Antibiotics in U.S. Seafood for Consumption

H.Y. Done, Center for Environmental Security; R.U. Halden, Arizona State University / Center for Environmental Security

Aquaculture, the farming of seafood for human consumption, is the fastest growing agricultural sector, providing over 40 percent of edible fish worldwide. This expansion is due to many improvements in the field, such as feed nutrition enhancement and facility conditions, but also due to better control of disease with antibiotics. However, the expanded use of antibiotics in aquaculture also poses significant health risks, one of which is lingering drug residue in the seafood meant for human consumption. We screened for 47 antibiotics in 27 samples of shrimp, salmon, catfish, trout, tilapia, and swai obtained from common grocery stores in SW U.S. Using liquid chromatography/tandem mass spectrometry (LC-MS/MS) in 2 analytical methods, 4 antibiotics were detected above the limits of detection: sulfadimethoxine, ormetoprim, oxytetracycline, and 4-epioxytetracycline. All found concentrations (0.34-8.6 ng/g fresh weight) complied with U.S. regulations. This study provided data on previously unmonitored antibiotics and is the largest screening of antibiotics in U.S. seafood to date. Although results indicate a low risk of drug exposure from seafood consumption, monitoring studies such as the present work are still required to understand and manage potential risks posed by use of antibiotics in aquaculture and in society at large.

Investigation of the in vivo uranium-binding protein targets in hepatopancreas and gills of crayfish (Procambarus clarkii) under various aquatic uranium exposure levels

M. Xu, LCABIE UMR; S. Mounicou, LCABIE; O. Simon, IRSN; R. Lobinski, LCABIE; S. FRELON, IRSN

Uranium (U) is a naturally occurring and/or anthropically (nuclear and military applications) released element in the environment, and its chemical/radiological toxicity is an emerging threat to human beings. As the most stable U species, uranyl ion (UO_2^{2+}) in aerobic media, is able to link oxygen and nitrogen atoms of biomolecules to form non-covalent complexes. However, due to the limited knowledge about *in vivo* U-biomolecules (e.g. protein), it is urgently needed to gain more information for understanding and explaining the toxicity and metabolism of U in organisms under various exposure levels. In our previous works, crayfish (*Procambarus clarkii*) has been used as a biological model to study the U accumulation and identify the potential *in vivo* U-binding proteins after 0, 30, 600 and 4000 µg/L U exposure concentrations [1, 2] representing low-, intermediate- and high-level waterborne exposure. In this study, to have a deeper view of molecular level changes, the cytosolic U-protein complexes were extracted from the gills (organ of entry) and hepatopancreas (organ of storage and detoxication) of crayfish *P. clarkii* and analyzed by non-denaturing one- and two-dimension gel electrophoresis (ND-PAGE and ND-2-DE) coupled to LA-ICP MS and μRPC-ESI MS/MS. The potential U-binding protein targets were identified and compared for the different U-exposure groups. 20 and 6 target proteins likely to bind U were identified in gills and hepatopancreas, respectively. Among those U-haemocyanin and U-ferritin complex were analyzed under all conditions. Furthermore, the U-coeluted haemocyanin and ferritin was quantitatively analyzed and the results showed it had a positive correlation with the aquatic U-exposure concentration.

Pesticides in bees, beebread and beeswax: levels and distribution

C. JABOT; A. Bulete, Institut des Sciences Analytiques UMR TRACES Team / Service Central dAnalyse; B. Giroud, A. Vauchez, M. Fieu, L. Wiest, H. Casabianca, E. Vulliet, Institut des Sciences Analytiques UMR TRACES Team

Pesticides used in agriculture are nowadays more and more toxic, such as neonicotinoids, pyrethrinoids and carboxamids three pesticides families which are studied here. These pesticides are in particular highly suspected to be involved in bee's abnormally high death rate. When this phenomenon occurs, bees' dead bodies are most often lost and do not allowed a direct analysis on dead bees. The only matrix available to conduct investigations to better understand effects of pesticides on bee health is the beehive and its products. At present, very few data of occurrence and levels of these three molecule families are available in beebread and beeswax, mainly due to lack of analytical methods. Indeed, these matrices represent a real analytical challenge due to their complexity (presence of interfering substances) and the presence of pesticides at very low dose. In this context, the aim of this work was to set up an innovative analytical procedure able to quantify traces of 13 neonicotinoids, pyrethrinoids and carboxamids in bees, beebread and beeswax at low levels (ng/g) in order to evaluate the global view of hive pollution and identify the source of bees' contamination. For this, efficient sample

preparation procedures were developed, based on Quick, Easy, Cheap, Efficient, Rugged and Safe (QuEChERS) extraction for bees and beebread and on solid-liquid extraction using diatomaceous earth as solid support for beeswax. They were followed by a selective and sensitive analysis based on Ultra Performance Liquid Chromatography (UPLC) separation and electrospray tandem mass spectrometry detection (ESI-MSMS). These analytical procedures were validated based on the Guideline validation of analytical procedure 2005 (ICH Norm). For example concerning beebread, extraction recoveries range from 70% to 120%, and limits of Detection (LOD) and Quantification (LOQ) range from 0.014 ng/g to 12 ng/g and from 0.58 ng/g to 40 ng/g respectively. This method was successfully applied to 60 real samples of beebread and beeswax of several areas of France. The final results are presented and discussed. Keywords: pesticides, trace levels, apiarian product contamination, sample preparation

Ecological Consequences of Exposure to Pharmaceuticals: From the Laboratory to the Field (I)

190

Pharmaceuticals in the Environment – the global perspective

S. Hickmann; T. aus der Beek, IWW Water Centre; A. Bergmann, IWW Water Centre / Department of Water Ressources Management; G. Gruettner, adelphi consult GmbH; I. Ebert, Umweltbundesamt / Pharmaceuticals Department; F. Weber, IWW Rheinisch-Westfaelisches Institut fuer Wasser / Bereich Wasserressourcen-Management; A. Hein, Federal Environment Agency UBA / Section IV Pharmaceuticals; J. Koch-Jugl, Federal Environment Agency / International Chemical Management; A. Kuester, Federal Environment Agency Umweltbundesamt / Environmental Risk Assessment; H. Stolzenberg, Federal Environment Agency Umweltbundesamt / Chemicals Unit IV

In the past two decades a large number of studies has shown that pharmaceuticals are ubiquitary in the environment in industrialised countries. A concise picture on the prevailing concentrations and potential effects on human and ecosystem health in these countries is still elusive. Therefore, we have started a research project to investigate the state of knowledge on the global relevance of pharmaceuticals in the environment. The project also aims at collecting regional consumption data and trends. We assess the relevance of different emissions pathways and local conditions such as infrastructure, agricultural practice, etc. on the occurence of pharmaceuticals in the environment. The extensive literature review has shown that in 71 countries at least one active ingredient is detected. Globally, 631 active ingredients or transformation products have been detected. Pharmaceuticals in the environment are thus not only an issue of industrialised countries, but a global issue.

191

Risk Based Prioritisation of Pharmaceuticals in the UK

J. Guo, The University of York; A. Boxall, University of York / Environment Department; C. Sinclair, Food Environment Research Agency / EcoChemistry; K. Selby, The University of York

A range of pharmaceuticals has been detected in the natural environment across the world. While a large amount of data has been published in the past decade on the occurrence, fate and effects of pharmaceuticals, information is still only available for a small proportion of the 4000 pharmaceuticals that are currently in use. Prioritisation approaches are a potentially useful tool to focus monitoring, testing and research resources and to identity those compounds that are likely to pose the greatest risk in a particular situation. In this project, we developed and applied a risk-based prioritization system for pharmaceuticals in use in the UK. The prioritization approach incorporated on usage, metabolism, environmental fate, standard acute and chronic ecotoxicity endpoints and endpoints related to therapeutic models of action. Unlike previous prioritisation exercises, the approach took a holistic view to try to identify pharmaceuticals posing the greatest risk to aquatic and terrestrial species, including wild birds and mammals and humans. The risk posed by the 143 candidate pharmaceuticals (and/or metabolites) were characterised by calculating risk characterisation ratio's (RCRs). Substances were then ranked based on their RCRs. Total of 57 compounds were identified in the top 20 of each of the 9 ranking lists. For many of these substances, no information is available on either the ecotoxicity or occurrence of these substances in the environment. We would advocate that consideration should be given to adding compounds in the top priority list with no or minimal data to future monitoring campaigns and ecotoxicological investigations.

192

Human pharmaceuticals and the Read-Across hypothesis: mammals and fish together at last?

L. Margiotta-Casaluci, Brunel University / Institute for the Environment; S. Owen, AstraZeneca / Safety Health Environment; G.H. Panter, Brixham Environmental Lab; A. Patel, Brunel University / Biosciences; J.P. Sumpter, Brunel University / Institute for the Environment; M. Rand-Weaver, Brunel University / Biosciences

Pharmaceuticals interact with high affinity to specific molecular targets in the organism, and the drug-target interaction is the key event leading toward the desired therapeutic effect. The evolutionary conservaton of human drug targets in wildlife species suggests that human pharmaceuticals present in the environment may cause pharmacological effects by acting *via* the same targets. The so-called "Read-Across Hypothesis" states that a drug will have an effect in non-target organisms provided that its molecular target is conserved, resulting in a specific pharmacological effect only if blood concentrations are similar to the human therapeutic concentrations. If this hypothesis is correct, it should be possible to predict the likelihood of an effect occurring in fish by using the mammalian data derived from the drug development process, such as pharmacodynamic and pharmacokinetic data, together with genomic and physiological knowledge of the non-target organism. The validation of this hypothesis would represent an important step forward in the large-scale application of predictive approaches based on the maximisation of mammalian data to assess the risk posed to wildlife by pharmaceuticals in the environment. Similar approaches could also be used to prioritise and rank the risk of the 3000 pharmaceuticals on the market, and guide the design of tailored eco-toxicity tests that can efficiently inform the ERA process, avoiding un-necessary tests with low informative power. In this context, we discuss to what extent the Read-Across hypothesis has been validated so far, providing examples of studies performed both at Brunel University and in other laboratories. The applicability of the Read-Across approach, as well as its strengths and limitations are also discussed. Finally, we evaluate the impact that this approach may have on the ERA of pharmaceuticals, since a mere qualitative description of the biological events triggered by chemical exposure would fail to adequately inform regulators and therefore prevent a reliable ERA. The Read-Across approach aims at addressing this issue by answering a fundamental biology question: does the same blood concentration of a given pharmaceutical produce the same pharmacological effect in humans and fish? \n

193

Prioritisation of Pharmaceutical Substances for Monitoring Purposes

A. Hein, Federal Environment Agency UBA / Section IV Pharmaceuticals; S. Berkner, Federal Environment Agency / Pharmaceuticals Washing Agents and Nanomaterials; I. Ebert, Umweltbundesamt / Pharmaceuticals Department

In 2012 UBA introduced a prioritisation list of pharmaceuticals for monitoring purposes in surface water. The list was presented as proposal for institutions being interested or involved in the monitoring process. The list was especially offered to the federal agencies because until now pharmaceuticals are not part of legally regulated monitoring programmes in Germany and Europe. With this prioritisation work the co-operation between federal and state authorities regarding monitoring programmes will be enhanced because federal states asked for support about data on effects, environmental behaviour and consumption of pharmaceuticals to update their own monitoring programmes. Since then the supporting data base for the prioritisation list was updated annually and also used to prioritise pharmaceuticals for groundwater monitoring programmes. From about 2300 active pharmaceutical ingredients marketed in Germay in 2012 approx. 1200 substances were identified as environmentally relevant as starting point for the way of prioritisation. The prioritisation was based on the following parameter: consumption data and their tendency during the last ten years, pharmaceuticals with RQ>1, monitoring data, data about ecotoxicity and behaviour in the environment besides transformation in the body and the environment, expert judgment. Based on the first very positive feedback UBA decided to update and expand this list regularly with pharmaceuticals which arise in regulation with an identified risk to the environment or with increased consumption tendency. Unfortunately, there is a lack of data for high consumption APIs because there are marketed since decades and are thus not covered by the environmental assessment procedure. Especially data about ecotoxicity and environmental behavoiur are missing. This holds true also for most veterinary pharmaceuticals. Consumption data of veterinary substances are not available. Only usage data of antibiotica groups are published recently by the EMA and since 2011 Germany.

194

Defining safe discharge ranges of pharmaceutical compounds in receiving water bodies

R. Tarpani, The University of Manchester / School of Chemical Engineering and Analytical Science; A. Azapagic, The University of Manchester

Despite the increasing number of studies concerning the presence of pharmaceutical compounds in the environment, data and knowledge gaps are still numerous. The peculiar physical-chemical properties of these substances contribute to a more complex behaviour in aquatic environments. The main paths for the discharge of these compounds in the environment are wastewater treatment plants (WWTPs), which are inefficient in removing these contaminants by conventional treatments. Most approaches to evaluate the concentration of these substances in WWTPs are based in nationals consumption estimates, which predict overall discharges reasonably well; however, this approach is not suitable when applied to specific locations without knowledge of their characteristics. Furthermore, the removal capacity of conventional wastewater treatments can vary greatly. Thus, aiming to contribute to a better understanding of the presence of pharmaceutical compounds in the environment, a graphical approach to define safe ranges for

discharge of these substances in water bodies has been developed and is discussed in this paper. This work considers the inflows and discharges from WWTPs of five different pharmaceutical compounds: acetaminophen, ibuprofen, carbamazepine, erythromycin and metoprolol. Metabolites, degradation and previous contamination of the water body were not considered, but will be included in future work. The first step was defining ranges in which the target compounds are likely to be discharged from treatment plants in developed countries. For these purposes, measurement data from 31 WWTPs were compiled from literature. Using statistical analysis, minimum, mean and maximum concentration values for the considered compounds were then defined. Afterwards, the removal capacities of three different conventional municipal wastewater treatments were considered to evaluate their removal potentials for these contaminants. Following this, different flows for the receiving water body were analysed to evaluate the dilution factor for different amounts of wastewater released from WWTPs. Lastly, values from chronic ecotoxicity tests were considered to define ranges in which a specific plant could release its effluents without posing any apparent environmental risk. The graphical approach can aid assessing the extent of the environmental exposure to some compounds, strategically defining WWTPs that should be monitored or when attention should be paid to a discharge.

195

How Feasible is Greener Drug Design?

J.R. Snape, Astrazeneca UK Ltd / AstraZeneca Global Environment; G. Le Page, AstraZeneca Brixham Environmental Laboratory; L. Rice, Astrazeneca UK Ltd; R. Brown, AstraZenenca; R. Maunder, AstraZeneca Brixham Environmental Laboratory

The issue of pharmaceuticals in the environment (PIE) has received significant coverage in the last decade, both in the academic literature and the wider media. The issue, however, is not a purely recent one. Reviews on PIE have appeared for at least 3 decades, and some have included remarkably prescient content. As early as 1981, a number of pharmaceutical-derived compounds were detected in the River Lee in the United Kingdom. More recent reviews of the literature shows that a wealth of data now exists on PIE and that residues of active pharmaceutical ingredients (API) are widespread, albeit mostly at very low levels, in the aquatic environment. Recent discussions within Europe have resulted in two pharmaceuticals (diclofenac and 17 alpha-ethinylestradiol) and a natural estrogen (17 beta-estradiol) being included within a Watch List so that Europe-wide monitoring data can be obtained about the wider presence of these chemicals in the environment. Consequently, most risk management options are aiming to reduce the environmental burden of PIE by exploring the efficacy of end of pipe tertiary treatment technologies to remove pharmaceuticals and other chemicals from sewage effluent. Parallel to these end of pipe technological solutions, some stakeholders are exploring the feasibility of greener drug design i.e. designing APIs that are biodegradable, non-bioaccumulative and less toxic. This presentation will discuss the challenges faced with designing greener drugs, together with some experimental work validating medium- to high- throughput ecotoxicology assays that will enable the environmental properties of drugs to be studied earlier in drug discovery and development. Results to date, have validated microplate assays with green algae and rotifers against eight human pharmaceuticals for which full OECD test data exist according the 2006 EMA guidance. A microplate assay for anti-infective compounds was also validated with three species of cyanobacteria. These microplate assays predicted the final EC50 and NOEC values for each of the pharmaceuticals obtained in the standard OECD 201 and 211 test guidelines with a high degree of accuracy. They also resolved the relative toxicity of each API. The availability of these validated assays may also assist with the screening and prioritisation of the large number of legacy drug products for which little or no data exist.

Fate and effects of nanomaterials in soil

196

Uptake and elimination kinetics of Ag NPs and ionic Ag in the isopod Porcellionides pruinosus exposed to contaminated soil and food

P.d. Tourinho, University of Aveiro / Department of Biology CESAM; C. Calhoa, CESAM Centro de Estudos do Ambiente e do Mar / Biology; C.A. van Gestel, Vrije Universiteit Amsterdam / Ecological Science; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; S. Loureiro, Universidade de Aveiro / Biology

Silver nanoparticles (Ag NPs) are widely used, especially due to their bactericidal properties. They may enter the soil through the land application of sewage sludge. However, little is known about their possible risk to soil invertebrates. This study aims at determining the uptake and elimination kinetics of Ag NPs and ionic Ag in the isopod *Porcellionides pruinosus* exposed to contaminated soil and food. Lufa 2.2 soil was spiked at nominal concentrations of 30 and 60 mg Ag/kg, while alder leaves were soaked into Ag NPs or $AgNO_3$ solutions (10 and 20 mg Ag/L). Isopods were exposed individually to contaminated soil or food. Exposure to Ag contaminated soil or food lasted 21 days (uptake phase), and then the isopods were transferred to clean soil or food for another 21 days (elimination phase). Isopods were sacrificed at different time points to determine Ag body burdens. Uptake (K1) and elimination (K2) rate constants were estimated using a one-compartment model, fitted simultaneously to uptake and elimination data. After 21 days exposure, mean Ag body burdens ranged from 90 to 136 µg Ag/g for Ag NPs and from 84 to 164 µg Ag/g for ionic Ag at 30 and 60 mg Ag/kg soil, respectively. K1 did not differ significantly between low and high concentrations of Ag NPs and ionic Ag nor between Ag forms ($X^2_{(1)}$< 3.84). K2 was similar between Ag forms. Bioaccumulation factors (BAF) were 3.0 and 3.6 for Ag NPs and 3.0 and 2.2 for ionic Ag at 30 and 60 mg Ag/kg, respectively. Ag concentration in food was up to 9 times higher for ionic Ag than for Ag NPs (500-800 and 4500-4700 mg/kg for Ag NPs and ionic Ag, respectively). After 21 days exposure, Ag body burdens ranged from 370 to 414 and from 435 to 658 µg Ag/g for Ag NPs and ionic Ag, respectively. K1 differed significantly between low and high concentrations of Ag NPs and ionic Ag, and also between Ag forms ($X^2_{(1)}$> 3.84). Elimination was slower in Ag NPs exposures than for ionic Ag. Bioaccumulation factors were higher for Ag NPs (5.6 and 2.8 for low and high concentrations, respectively) than for ionic Ag (0.4 and 0.3, respectively). Steady state in Ag body burden was not reached in isopods exposed via soil and food after 21 days exposure. When comparing both routes of exposure, dietary exposure resulted in higher body burdens. Moreover, the bioavailability of Ag in soil and food may differ as both mediums present different characteristics.

197

The influence of soil properties on the bioavailability and toxicity of Ag nanoparticles to the earthworm Eisenia fetida

E. Lahive, Centre for Ecology Hydrology NERC; M. Matzke, Centre for Ecology Hydrology NERC / Molecular Ecotoxicology; M. Diez-Ortiz; A. Romero, UGR / edafologia y quimica agricola; A. Lawlor, Centre for Ecology and Hydrology; D. Spurgeon, Centre for Ecology Hydrology; C. Svendsen, CEH Wallingford / Pollution and Ecotoxicology; S. Lofts, Centre for Ecology Hydrology / Shore Section

Metal and metal oxide nanoparticles (NPs) present a series of challenges for terrestrial ecotoxicology. Both chemical transformations of the NPs (e.g. dissolution) and the chemistry of the soil may modify the organism exposure and response in NP–dosed soils. Previous work has shown that soil type influences toxicity of ZnO NPs to earthworms, with soil pH playing a major role. In this study we investigated how soil properties influence the bioavailability and toxicity of silver (Ag) NPs and ionic silver to the earthworm *Eisenia fetida*. Worms were exposed to both a 50nm diameter PVP-coated Ag NP and to an ionic silver reference, silver nitrate (AgNO3). Four soils were used for this study. Soil organic matter (SOM) content ranged from 1.8–16.7% and soil pore water pH from 4.5–8.3. Earthworms were exposed to the nominal concentration range 9 – 5500 mg Ag/kg, with survival and reproduction assessed after 28 and 56 days, respectively. Soil pore waters were extracted from all soils at the beginning (t=0days) and end (t=56days) of the experiment, ultra-filtered (10kDa) and analysed for silver, pH and dissolved organic carbon. Tissue silver concentrations were measured in depurated worms after 28 days of exposure. Based on nominal soil concentrations of silver, the reproduction EC50s in the various soils ranged from 33 - 209 mg Ag/kg for AgNO3 and from 4 - 358 mg Ag/kg for Ag NPs. In the soil with the highest pH and high SOM the EC50 calculated for Ag NPs was lower than that for AgNO3. Furthermore, in two other soils the EC50s calculated for Ag NP and AgNO3 overlapped. This study has shown evidence for NP-specific effects in earthworms exposed in a range of soils. Furthermore, we have seen that soil properties influence the bioavailability and toxicity of silver, whether dosed as a NP or in an ionic form. The results suggest that modelling toxicity in Ag NP-dosed soils needs to consider the dissolution of the NPs to form ionic Ag and the influence of the soil chemistry on the bioavailability and toxicity of both.

198

Preparing soils amended with nano-sized copper oxide, micron-sized copper oxide, and with a copper salt for a nanotoxicity test and results of a 14-day barley growth test

H. McShane, McGill University / Dept of Natural Resource Sciences; J.K. Whalen, McGill University / Natural Resource Sciences; G.I. Sunahara, National Research CouncilCanada / NRCBiotechnology Research Institute; W.H. Hendershot, McGill University / Dept of Natural Resource Sciences

Toxicity tests determine whether terrestrial organisms such as plants exhibit nanoparticle-specific toxicity when exposed to soluble nanometer-sized metal oxide particles. In these tests, treatments with micrometer-sized particles differentiate effects caused by the material in its non-nanosized form, and metal salt treatments quantify the effects of the metal ions released during particle dissolution. However, differences between, and temporal changes in, soil solution chemistry in the different treatments during tests may obscure nanoparticle-specific effects. In this study on the toxicity of nanosized CuO to plants, we first evaluated temporal changes in Cu^{2+} activity, pH, and dissolved Ca and Mg concentrations in two soils amended with 500 mg/kg Cu as nanometer-sized CuO (nano), micrometer-sized CuO (micron) or $Cu(NO_3)_2$ (salt) over 56 d. The Cu^{2+} activity in the nano-amended

soil was higher than in the micron amended soil and lower than in the salt amended soil for at least the first 14 d. The pH in the nano-amended soil was significantly higher for at least the first 14 d, and dissolved Ca and Mg concentrations significantly lower than in the salt-amended soils for the duration of the test. To minimise differences in soil solution chemistry between the different treatments, salt-amended soils were leached and limed, and all soils were aged for 28 d, prior to the toxicity test. A standard 14 d seedling growth test was then conducted to determine the relationship between Cu^{2+} activity and barley (*Hordeum vulgare* L.) growth. Shoot and root length, and root biomass, in the nano-amended soils were similarly correlated with Cu^{2+} activity as growth in soils amended with non-nanosized Cu sources. Shoot Cu concentrations were similar in all treatments. Barley toxicity in the nano-amended soils was equal to or less than that in soils amended with a similar concentration of the Cu salts. These results contrast with those from some studies conducted in hydroponic systems, and emphasize the importance of conducting nanotoxicity tests in environmentally relevant media.

199

Influence of physico-chemical soil properties on the effect of silver nanoparticles in soils

K. Schlich, Fraunhofer IME Institute for Molecular Biology and Applied Ecology; K. Hund-Rinke, Fraunhofer IME / Ecotoxicology

The rising use of silver nanoparticles (AgNP) increases the potential for environmental contamination. AgNP will inevitably reach the environment, especially the terrestrial environment. There is a need to gather detailed information about their fate and behaviour within soils. The main goal of this study was to investigate the effects of NM-300K from the OECD Sponsorship Programme on soil microorganisms in five well charaterised soils (RefeSol 01A, 02A, 04A, 03G and 05G) differing in their physico-chemical soil properties. Concentrations of 0.56, 1.67 and 5.0 mg/per kg dry matter soil (dms) for tests with 01A, 02A and 04A and 1.67, 5.0 and 15.0 mg/kg dms for 03G and 05G were observed. Each test was conducted at least twice with 4 replicates per treatment. Standardised test systems were used: C-Transformation (OECD 217) and Ammonium Oxidation (ISO 15685). All experiments met the validity criteria. The C-transformation test was less sensitive. Only in one test (01A) an EC_{50} of 5.6 mg/kg dms was calculated. In contrast nitrifying bacteria (ISO 15685), were extremely sensitive to 28 days exposure to AgNP. In each test a dose-response relationship was found. Considering the EC_{50} values the highest toxicity occurred in the tests with 04A (1.2 mg/kg dm soil), whereas the lowest toxicity was observed for 03G (28.4 mg/kg dm). A comparison of the toxicity of AgNP with the physico-chemical soil properties showed a decreasing toxicity with increasing clay content (04A: 4%; 03G: 27%). The pH value also appears to play an important role in soils in relation to the toxicity of AgNP. The strongest toxicity was found at pH values of 5.03 (04A), 5.30 (01A) and 4.59 (05G). Here is evident that the toxicity at a pH of 4.59 (05G) was lower than at a pH of 5.30 or 5.03, while the clay content and C_{org} of the 05G were significantly higher than in the soils with a higher pH value (04A, 01A), which may reduce the influence of the low pH. Based on the present results a dependence of the toxicity of AgNP on the C_{org} content could not be shown. The study shows that toxicity of AgNP cannot be attributed to only one soil parameter. The same soil parameters as for conventional chemicals influence toxicity, e.g. for metals, soil pH and parameter affecting sorption behavior are also important. Therefore, concerning ecotoxicity studies the recommendations in the test guidelines on soils are considered to be applicable to achieve maximum effect and to simulate worst case scenarios.

Combining physico- chemistry and microbial ecotoxicology to assess the impact of TiO2 nanoparticles in 6 agricultural soils

M. Simonin, Laboratoire dEcologie microbienne; J.M. Martins, LTHE University of Grenoble; J.P. Guyonnet, Ecologie Microbienne University of Lyon; A. Richaume-Jolion,

Titanium dioxide nanoparticles (TiO_2-NP) are one of the most widely used nanomaterials to date. TiO_2-NP are chronically released into the environment, especially in agricultural soil through sewage-sludge application as fertilizers. Information regarding the impact of a realistic concentration of NP on soil organisms is currently limited and the importance of soil characteristics is often neglected in ecological risk assessment. As yet, there are few data on transport of NP through soils, and hence characterization of NP behavior and associated potential bioavailability remains to be elucidated. Extrapolation of results from one contaminated soil to another is difficult because of the great variability in soil composition and structure. Thus establishing the relationships between soil properties and (i) NP behavior and (ii) ecotoxicity is urgently needed in order to evaluate the vulnerability of soils, and especially of microorganisms to NP. In this study using 6 contrasted soils, we characterized the size and surface charge of TiO_2-NP in soil solutions and we studied their transport in a soil column experiment. In addition, we assessed the response of soil microorganisms in a microcosm experiment, where the 6 soils were exposed for 90 days to a realistic concentration or an accidental spiking of TiO_2-NP (1 and 500 $mg.kg^{-1}$ dry soil). Soil respiration and microbial activities of the nitrogen cycle (nitrification and denitrification) were measured, in order to assess the effect of TiO_2-NP on soil functioning. Microbial abundance of bacteria, nitrifying and denitrifying microbial communities were also determined by quantitative PCR targeting *16S rRNA* and functional genes (*amoA*, *nirK*, *nirS*). We found that soil properties, especially pH and ionic strength, can influence the aggregated size and surface charge of TiO_2-NP. In the column experiment, we observed that TiO_2-NP exhibited very different transport capacities depending on the clay content of the soil. In most soils, TiO_2-NP had no impact on microbial communities, except in a silty-clay soil where microbial activities and abundances were significantly lowered, even with the realistic NP concentration. Altogether, our results demonstrate the importance of assessing the impact of a realistic concentration of NP in different soils and the relevance of NP characterization in realistic conditions such as soil solutions, in order to get a better assessment of the impact of NP on soil functioning.

201

Diversity, activity and abundance of microbial functional groups as descriptors of soil disturbance: Example of contamination with TiO2 nanoparticles

A. Richaume-Jolion; M. Simonin, Laboratoire dEcologie microbienne; J.P. Guyonnet, Ecologie Microbienne University of Lyon; J.M. Martins, LTHE University of Grenoble; T. Pommier, Ecologie Microbienne INRA University of Lyon

According to the conceptual model of Zak et al. (1994), total biodiversity relates to genetic, taxonomic and functional diversity. However, in most studies dealing with soil microbial biodiversity, functional diversity is often neglected, despite the crucial information that can be given about the response of soil to environmental stressors. In soil, key functions related to fertility are carried out by different microbial functional groups that may respond differently to pollutants due to the diverse levels of functional redundancy among these groups. Here, we assessed the impact of an emergent pollutant, titanium dioxide nanoparticles (TiO_2-NP), on soil functioning using the diversity, the abundances and the activities of different microbial groups as descriptors of the response to such disturbance. To evaluate the impact of TiO_2-NP, a silty-clay soil was exposed for 90 days to an environmentally relevant concentration or to an accidental spiking of TiO_2-NP (1 and 500 $mg.kg^{-1}$ dry soil, respectively) in microcosms. The effects on microbial activity (Carbon and Nitrogen cycle) were assessed by substrate-induced respiration (SIR), potential nitrification and denitrification rates. Modifications in bacterial abundance were evaluated by quantitative PCR targeting *16S* rRNA bacterial gene and functional gene of nitrification (*amoA*) and denitrification (*nirK* and *nirS*). We used the Illumina sequencing platform (MiSeq) to explore the effects of TiO_2-NP on the diversity of bacterial and archaeal communities and of two functional groups: the nitrifiers, ammonia-oxidizing bacteria and archaea. We will present the results showing that TiO_2-NP can alter 3 crucial microbial functions in soil, even after a contamination with a realistic concentration (1 $mg.kg^{-1}$). The nitrification which is performed by the AOA and AOB groups exhibiting a low functional redundancy compared to the denitrifiers, appeared to be more affected by TiO_2-NP than the latters. Using path analysis, we will show that the mortality among ammonia-oxidizing archaea group had cascading effects on nitrification and denitrification activities. We will discuss the unexplained variance in this model in the light of the diversity results on functional genes. In conclusion the importance of studying functional diversity in ecotoxicological studies, to have a better assessment of the impact of a pollutant on soil functioning will be highlighted.

Bioavailablity and effects of metals and metal mixtures (I)

Interactions between copper and salinity in the teleost fish sheepshead minnow: a multi-stressor approach

A. De Polo, Brunel University / Institute for the Environment; M.D. Scrimshaw, S. Jobling, Brunel University

Despite having been extensively studied for many decades, metal contamination remains an unresolved environmental problem, as metals display toxic effects on the aquatic biota at environmentally realistic concentrations. It has been long accepted that their bioavailability is strongly affected by chemical factors, such as water hardness and organic matter content, and this knowledge has led to the development of Biotic Ligand Models (BLMs) aiming at predicting metal toxicity on the basis of their speciation and interaction with abiotic factors. However, one side effect of this research pathway has been a general tendency to address metal toxicity mainly from a chemical perspective, partly overlooking the physiological mechanisms underlying their toxicity. Considering copper as a case study, BLMs account for the effects of water chemistry on copper speciation, but do not consider its influence on fish physiology, whereas we argue that chemistry affects copper toxicity by affecting both its speciation and fish osmoregulatory physiology. Applying this perspective, we investigated the interaction between copper and salinity by mimicking the salinity changes taking place in estuaries, which are environments where the combination of anthropogenic impacts and fluctuating

abiotic factors represents the ultimate challenge for toxicity modelling. Since copper toxicity is mainly a consequence of osmotic disruption, we hypothesize that copper exposed fish are more sensitive to osmotic stresses, as copper affects their osmoregulatory system by interacting with some osmotic effector proteins. Among these effectors, we suggest that a common factor linking the physiological responses to both copper exposure and salinity changes is the enzyme carbonic anhydrase (CA), a copper target with salinity-dependant activity. Two *in vivo* studies were performed on the euryhaline fish sheepshead minnow, which was exposed to 10 and 100 μg/L in the first study and 32, 100 and 320 μg/L copper in the second study for, respectively 9 and 21 days. After copper exposure in either freshwater or artificially prepared saltwater (20ppt), a salinity transition was performed. Measurements of gene expression levels of CA in samples of gills and intestine showed that this enzyme significantly responded to copper, making of it a candidate probe to explore the complex response patterns to environmental as well as chemical stressors, such as osmotic stress and metal pollution.

203

Copper toxicity in mussels: do salinity, organic matter and population history matter?

D. Deruytter, University Ghent / Laboratory of Environmental Toxicicology and Aquatic Ecology; M.B. Vandegehuchte, Ghent University / Applied Ecology Environment Bio; K.A. De Schamphelaere, Ghent University UGent / Environmental Toxicology and Aquatic Ecology; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology

Salinity and dissolved organic carbon (DOC) are two abiotic variables that can alter Cu toxicity to marine organisms due to complexation and speciation. In this study the sublethal effects of prolonged Cu exposure on juvenile transformed *Mytilus edulis* were assessed under different conditions of salinity and DOC in 2 populations (North Sea (NS) and Bothnian Sea (BS)). First, separate experiments were set up for each population. Mussels acclimated to 5 salinities were exposed for 2 weeks to 18 different salinity/DOC/Cu combinations, according to a central composite design. At the end of the exposure the clearance rate (CR), oxygen consumption (VO_2) and condition index (CI) were measured. Next, both populations were simultaneously assessed. Now DOC was not varied and salinity was identical for the two populations. For the NS population, no effect of salinity on the CR was observed. An increase in DOC slightly increased the control CR, but the interaction with Cu was marginal. No DOC effect on CR was observed in the BS population. However, salinity had a strong positive effect, increasing control CR without altering Cu toxicity. In the NS population, VO_2 slightly increased with increasing DOC without interaction with Cu. An increase in salinity increased control VO_2 in NS mussels, but in combination with Cu this resulted in a faster VO_2 decline. The effect of salinity was more pronounced in the BS population: an increase in salinity increased the control VO_2 without interaction with Cu. An increase in DOC decreased the control VO_2 with little influence on Cu toxicity in the BS mussels. Salinity and DOC did not affect the CI in either population. The simultaneous experiment yielded similar results. *M. edulis* from the BS population live near the edge of the salinity tolerance range. Increasing metabolic activity with increasing salinity demonstrates that under natural conditions this population experiences salinity stress. Nevertheless, when corrected for this change in baseline metabolism, BS mussels are as (or less) sensitive than NS mussels. Contrary to what was expected based on speciation and complexation chemistry, an increase in DOC or salinity did not, or only slightly, decrease the sensitivity to dissolved Cu. Therefore it seems that free Cu ions are not the only toxic Cu species and Cu-DOC complexes might be available for uptake by the mussel. This indicates that the current BLM concept is not applicable to *M. edulis* for the measured endpoints.

Protectiveness of copper aquatic life criteria/guidelines against olfactory impairment in fish: An international comparison

J.S. Meyer, ARCADIS; D.K. DeForest, Windward Environmental LLC; R.W. Gensemer, GEI Consultants / Ecological Division; J.W. Gorsuch, Copper Development Association Inc; W. Adams, Rio Tinto

Several laboratory studies have demonstrated that short-term exposures to low Cu concentrations can cause olfactory and behavioral effects in Pacific salmon and trout, which may be indicative of adverse effects on olfactory-mediated behaviors in the field (e.g., ability to avoid predators). Concerns have been expressed in North America and Europe that current water quality criteria/guidelines for Cu are not protective against olfactory impairment. Importantly, such concerns are founded on simple comparisons that do not properly account for how water chemistry influences the bioavailability of Cu. We have previously demonstrated that the USEPA's biotic ligand model (BLM)-based aquatic life criteria for Cu are protective against olfactory impairment over a wide range of fresh waters. We further evaluated the influence of Cu on olfactory impairment in additional fish species by critically reviewing recently published studies and evaluated whether Cu criteria/guidelines from states and other countries/jurisdictions (e.g., Canada and its provinces, European Union) are protective against olfactory impairment. Most countries and jurisdictions still apply hardness-based Cu criteria. Overall, 223 different olfactory threshold-to-hardness-based-guideline ratios were derived from the compiled data. The ratio was

Deriving waterborne safe tresholds for Pb in European freshwaters

P. Van Sprang, ARCHE; C. Nys, University of Ghent / Environmental Toxicology and Aquatic Ecology; M.J. Chowdhury, International Lead Zinc Research Organization / Assistant Manager Environment; K.A. De Schamphelaere, Ghent University UGent / Environmental Toxicology and Aquatic Ecology

In the REACH framework, Pb specific information on environmental toxicity and on environmental exposure/fate for key environmental compartments (water, sediment, soil) was compiled in order to assess the potential environmental risks related to the production and use of Pb in the European Union. The methodologies and concepts used in the present study represent the state-of-the-art about the Pb specific aspects related to incorporation of bioavailability and large dataset handling. The proposed methodology encompasses the development of an extensive quality screened database containing 173 individual chronic toxicity data for 25 different freshwater species and takes the effect of 1) Pb precipitation and 2) Pb speciation/competition on Pb toxicity fully into account by the use of newly developed Pb-translator and chronic Biotic Ligand Models (BLM) for 3 different trophic levels (algae, invertebrates and fish). As such the freshwater Pb effects database can be easily normalised towards the geochemical conditions prevailing in the EU surface water under scrutiny, and revealed that the safe toxic threshold for the freshwater environment (HC5-50) is expected to vary between 8.8 and 29.6 µg dissolved Pb/L. The statistical best fitting approaches that were used for the derivation of the freshwater HC5-50 from the species sensitivity distributions will be further discussed. Finally, the conservatism and remaining uncertainty considered for the final HC5-50 setting derivation will be highlighted and a way forward in order to reduce the uncertainties associated with metal risk assessments in general will be proposed.

Trivalent chromium chemistry: when considered, makes it more toxic than the hexavalent chromium in algal toxicity test

i. aharchaou, LIEC; D.A. Vignati, CNRS / LIEC UMR; E. Battaglia, University of Lorraine LIEC CNRS UMR

In surface waters, chromium occurs mainly in two oxidation states, namely Cr(III) and Cr(VI), and there is a general agreement that Cr(III) is less toxic than Cr(VI) for aquatic organisms. However, an increasing number of studies provides evidence that Cr(III) may also be of concern and that, in some cases, its toxicity may have been underestimated. In this study, the temporal variability of filterable (0.22 μm) Cr concentrations in a standard algal culture medium (ISO 8692) was followed over 72h (the typical duration of the corresponding toxicity test). In parallel, the toxicity of three trivalent Cr salts (sulphate, chloride and nitrate forms) and one hexavalent Cr salt (potassium dichromate) to the alga *Pseudokirchneriella subcapitata* was also studied. Over 72 hours, chromium concentration was stable in solutions amended with Cr(VI), but decreased markedly (with losses up to 90% of the initial Cr levels) in solutions containing Cr(III). The nominal EC50 values were similar for both Cr redox forms. However, when the decrease of concentration was considered by calculating the time weighted mean, the Cr(III) EC50 became lower than those for Cr(VI). These results suggest that, provided Cr(III) behavior is properly considered, trivalent Cr may actually be more toxic than Cr(VI); at least in standard laboratory media.

A dynamic Biotic Ligand Model predicting Ni toxicity to Enchytraeus crypticus

E. He, VU University Amsterdam / Department of Ecological Science; K. Dimitrova, VU University Amsterdam; M.M. Ardestani, Ecological Science; C.A. van Gestel, Vrije Universiteit Amsterdam / Ecological Science

Biotic ligand models (BLMs) have been shown to effectively predict metal toxicity to organisms exposed to (soil) solutions of varying composition. Until now only BLMs developed at a fixed time point are available, triggering the question of how to extrapolate such predictions to a dynamic environment with time-variable exposure. In this study Ni-BLMs were therefore developed for *Enchytraeus crypticus* at different exposure times (7, 10, and 14 day) to examine the applicability of the BLM approach for predicting Ni toxicity over time. Results showed that the same cations (Ca^{2+}, Mg^{2+} and Na^{+}) significantly alleviated Ni toxicity at different time points but to different degrees. The stability binding constants of Ni and the competitive cations decreased with increasing exposure time, but the fraction of biotic ligands occupied by Ni causing 50% mortality remained constant in the time course. A novel dynamic BLM model for predicting time-variable toxicity of Ni was developed, which accurately predicted Ni toxicity at different water chemistries and exposure times. Our findings indicate that time needs to be considered as a factor in modelling metal toxicity and that the existing acute BLM may not be applicable for predicting metal toxicity under chronic exposure. More research is needed to investigate the exact mechanisms behind the

time-related changes of BLM binding constants.

Modelling of chemical fate and exposure in a regulatory context (I)

208

Simulation of pharmaceuticals in the environment

S. Trapp, Danmark Tekniske Universitet / DTU Environment

Indirect human exposure to high-volume drugs via wastewater to rivers and via sewage sludge to agricultural soils and bioaccumulation in fish and crops was simulated with coupled mathematical models. Most drugs are ionizable, often zwitterionic, and the models were modified to be valid for such compounds [1,2]. Use data in Denmark from medstat.dk corrected for metabolism in human body were selected as input data. Concentrations in rivers were calculated with the common dilution factor 10. The bioconcentration factor fish was estimated with a dynamic cell model based on the Fick-Nernst-Planck equation, including adsorption to proteins. A validated simulation model [3] considering transfer of water and solutes from soil to plant and leaching to groundwater was adopted and reprogrammed for ionic compounds. Highest human usage of antibiotics in Demark is for erythromycin, tetracycline, ciprofloxacin, doxycycline and trimethoprim. Most antibiotics adsorb strongly to sewage sludge, with resulting concentrations > 1 mg/kg. Sewage sludge application as soil amendment leads to calculated concentrations of some antibiotics in top soil > 10 microg per kg. The results confirm that some antibiotics show good plant uptake. The comparison of measured data to simulation results at all stages (effluent water, sewage sludge, soil, plants) was satisfying. Summarized, the major conclusions are that this simulation system, adopted to ionizable compounds, can be used to predict emissions from wastewater, residues in soil and plant uptake of pharmaceuticals (and pesticides); that dietary exposure to human antibiotics is higher with field crops than with (river) fish; that uncertainties and variations (also of experimental data) are high. Persistent organic pollutants – Analysis of sources, spatial distribution, and reservoirs in Switzerland

J. Glüge, ETH Zurich / Institute for Chemical and Bioengineering; C. Bogdal, ETH Zurich; M. Scheringer, ETH Zuerich / Institute for Chemical and Bioengineering; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

Persistent organic pollutants (POPs) are ubiquitous environmental contaminants because of their appreciable mobility and resistance to degradation by environmental transformation processes. To understand the distribution and transport of POPs in the environment, multimedia fate models are useful. Within the project SwissPOP we developed two models to study sources, reservoirs and sinks of POPs in Switzerland. Main questions in this context are e.g. which environmental compartments represent currently the main reservoirs of POPs in Switzerland and how do these reservoirs behave in the future, how and when are concentrations of POPs in the environment affected by regulatory measures, how relevant are secondary sources compared to primary sources now and in the future, which effect have altitude and distance to the sources on the environmental levels of the chemicals, and are the high Alps relevant in the environmental cycling of POPs. First we developed a one-region multimedia fate model that consists of four well-mixed compartments (air, soil, freshwater and sediment) and describes the distribution of the chemicals between these compartments. Since most measurement data of POPs in Switzerland are available for polychlorinated biphenyls (PCBs), we used the model runs for PCBs to validate our model. The modelled results for PCBs show very good agreement with the absolute concentrations of measurements in soil, air, and water. Also the pattern of individual PCB congeners calculated with our model is consistent with field data, indicating that the model covers all important exchange processes between the compartments. In a second stage, we develop an extended ten-region multimedia fate model that tracks the mass balance of POPs in Switzerland, subdivided in ten regions, where each region is composed of six well-mixed compartments (troposphere, convective boundary layer, nocturnal boundary layer, freshwater, sediment, and soil). Chemicals are emitted to air, and can be distributed within the region or transported to other regions by wind and water. The parameterization of the atmospheric circulation in the model was done with weather forcast data for Switzerland. The model results can be used to confirm measured concentrations, but also to predict concentrations under different regulations scenarios in the future. It will therefore become a very useful tool for science and regulatory authorities.

210

Unravelling the relationship between body mass index and persistent organic pollutant concentrations in humans

F. Xu, J. Armitage, University of Toronto Scarborough / Department of Physical and Environmental Sciences; F. Wania, University of Toronto at Scarborough / Department of Physical Environmental Sciences

Because of their hydrophobicity, persistent organic pollutants (POPs) associate with the lipid compartments in the human body. Individuals vary widely in terms of their lipid content. Human biomonitoring studies often observe that the measured concentrations of POPs are statistically associated with the body mass index (BMI). However, the results are inconsistent, showing negative, positive or no associations. These divergent relationships have been hypothesised to be the result of variable pharmacokinetics of POPs in lean and obese individuals during times of increasing and decreasing exposure. To test the plausibility of that hypothesis, we used the CoZMoMan model to calculate time-variant concentrations of PCB-153 for different human birth cohorts born throughout the 20th century based on time-variant historical dietary contamination. For each cohort, multiple calculations representing five different BMI classes were performed, using generic, but realistic assumptions about weight and lipid gain during the adult life span. The results of cross-sectional human biomonitoring studies were then simulated by “sampling” a cross-section of the simulated cohorts in different years. Using historical data on the BMI distribution in the US, concentrations calculated for different cohorts and BMI classes were averaged to predict population level relationships between POP concentrations and BMI and age that can be expected to be observed in biomonitoring studies conducted during different sampling years. The simulated relationships showed a dependence on both age and sampling year. Whereas the model predicts clearly negative associations between PCP-153 concentrations and BMI for all birth cohorts in monitoring studies conducted in the 20th century, future biomonitoring studies are predicted to reveal more complex relationships. The model results suggest that different age cohorts can display different concentration - BMI relationships. As a result, the PCB-153 concentration - BMI relationship expected in human biomonitoring studies will depend on the sampling year, and on the ranges of age and BMI classes that are represented in the sampled population. Mechanistic models of human bioaccumulation can aid in unravelling the complex relationship between age, BMI and POP concentrations. Doing so is imperative in any effort to understand the potential obesogenic effect of POPs.

211

Influence of climate change on the Arctic Contamination Potential

K.M. Hansen, National Environmental Research Institute / Envrionmental Science; J.H. Christensen, C. Geels, J. Brandt, Aarhus University

Using the Danish Eulerian Hemispheric Model (DEHM) we have calculated the Arctic Contamination Potential (ACP). ACP is defined as the sum of masses in the arctic surface compartments (soil, vegetation, snow and water) at the end of a ten year simulated period normalised either with the total mass within the model domain of with the total amount emitted into the atmosphere during the ten year simulation. In this study we use the emission normalized ACP termed eACP. We have calculated the eACP for the physical-chemical phase space spanned by compounds with log K_{oa} between 3 and 12 and log K_{aw} between -4 and 3 and for each point in this phase space grid we have included a perfectly persistent compound in the model. DEHM is a 3-D atmospheric chemistry-transport model modelling the atmospheric transport of four chemical groups: a group with SOx-NOx-VOC-ozone chemistry, a group with primary particulates, a mercury chemistry group, and finally a group with Persistent Organic Pollutants with 2-d surface compartments (soil, vegetation, ocean water and a dynamic temporal snow cover) with inter-compartmental mass exchange process parameterizations. The model domain covers the Northern Hemisphere and thus includes all important source areas for the Arctic. The spatial horizontal resolution of the model system in this work is 150km x 150km and the model includes 20 vertical levels up to approximately 15km above the surface. The model system was run with meteorology obtain from ECHAM5/MPI-OM (SRES A1B scenario) for two decades: 1990-1999 and 2090-2099. Highest potential (12%) for reaching the Arctic surface compartments for the 1990s is seen for compounds with low log Koa and low log Kaw values. These are relative water soluble compounds referred to as “swimmers”. For the 2090s, the overall pattern of the ACP phase space is similar to the pattern for the 1990s. ACP is generally larger for the 2090s than for the 1990s, with a maximum of 15%.

212

The Dirt on Predicting Veterinary Drug Concentrations in a Canadian Context From A Regulatory Prespective

S. Kullik, Health Canada; G. Rattray, Health Canada / Environmental Impact Initiative Division; G. Stringer, A.M. Belknap, Health Canada

A Canadian regulatory framework has been developed specifically for active pharmaceutical ingredients (APIs) regulated by the *Food and Drugs Act* (F&DA) to assess their potential environmental effects in soils, sediments and surface waters. This regulatory framework was designed to harmonize with the drug development process as well as approaches to environmental assessment in other jurisdictions. APIs in veterinary drugs administered to food animals primarily enter ecosystems

through the application of livestock waste to agricultural land and a means to predict environmental concentrations (PECs) of APIs under various scenarios and in different compartments is required as part of a directed testing approach. The complexity of reducing the uncertainty in the calculation of a predicted environmental concentration of veterinary APIs in soil (PECsoil) and variability in agricultural practices can be a challenge for regulatory authorities. A science-based and transparent methodology to calculate PECsoils, based on an approach used in Europe under VICH, has been established for Canadian scenarios. Default values and livestock categories have been developed which are representative of typical confined animal husbandry and agricultural practices in in Canada and will be used to identify new veterinary APIs that require terrestrial ecotoxicity and fate testing. Adaptation of the European PECsoil calculation to Canadian agricultural practices required the addition and/or adaptation of livestock categories based on an analysis of Canadian production practices and labels for currently registered veterinary drugs. Default intake rates to estimate doses of APIs administered in feed and water were also established. To validate the conceptual basis of this approach PECsoil values for a subset of currently used APIs are compared to data from field experiments and monitoring studies. Measured environmental concentrations of APIs, including those commonly used as feed additives, in agricultural fields and pastures that have received applications of manure from pig, poultry or cattle agricultural facilities will be discussed. A comparison to PECsoil values for APIs generated with approaches used in the United States and the European Union will also be presented. Finally this talk will explore how this model might be utilized to better direct the testing requirements for new veterinary APIs within the proposed regulatory framework.

Multi-dimensional modelling of leaching for ridge-furrow systems

K. Hammel, Bayer CropScience AG / Environmental Safety; T. Schröder, BASF SE / APDEF

The assessment of exposure and leaching of pesticides in soil is most often done with one-dimensional (1-D) models. However, for inhomogeneous soil surface applications (e.g. ridged cultivation systems) these 1-D models are inappropiate, as the geometry plays a significant role in the system characterization, and thus also in the resulting leaching assessment. In this study, two scenarios using ridged systems are investigated and analysed. The first considers a standard spray application to a surface consisting of a furrow and ridge. The second considers the same geometry but with an in-row applied pesticide which is placed at a certain depth below the peak of the ridge. Simulations were carried out using the multidimensional flow and transport model HYDRUS 2D/3D and a 2-D simulation domain. In all calculations, inhomogeneous infiltration was implemented. Moreover, inhomogeneous chemical loading was considered via i) variable pesticide loading at the surface, and ii) in-row application where the applied pesticide is located in a band (10 by 10 cm) which is centered 10 cm below the ridge peak. The soil parameters and the climate data were taken from the FOCUS Hamburg groundwater scenario. For the sake of simplicity an uncropped situation was considered. The pesticide used was carbofuran. The simulation period was set to allow for practically complete breakthrough of leached solutes at the evaluation depth (1 m). The concentration distributions for inhomogeneous spray surface application and in-row application differ strongly. This is on the one hand the result of the inhomogeneous boundary conditions applied to each scenario. On the other hand the difference in leaching is caused by the difference in travelling distance between ridge and furrow towards the target depth of 1 m. This results in largely different ratios of mass leached/applied for spray surface and for in-row application. Spatially inhomogeneous water flow and pesticide application requires a multi-dimensional representation to obtain realistic leaching results. By definition 1-D representations cannot reproduce such transitional behaviour. They cannot consider the spatial variability in leaching caused by the surface geometry, rather they can only assume either complete or no mixing, which will result in either under- or overestimation of the true leaching.

Advancements in life cycle impact assessment and footprint method development (I)

Impact Pathway Characterisation to evaluate sustainability performance of products by addressing six Safeguard Subjects

R. Scheumann, TU Berlin / Chair of Sustainable Engineering; J. Martínez Blanco, S. Neugebauer, K. Wolf, Y. Chang, Technische Universität Berlin; M. Finkbeiner, DaimlerChrysler AG / Chair of Sustainable Engineering

To assess products and services with regard to their potential impacts on sustainability are “of high priority for international, national and local administration and enterprises” (Traverso et al. 2012, p.680). To evaluate the sustainability performance of a product can be done by life cycle based assessment, integrating environmental, social and economic aspects. The integrated assessment method addresses six safeguard subjects: the three (1) human health, (2) ecosystem quality and (3) resource availability commonly used and broadly accepted in LCA as well as the other three (4) social justice, (5) financial stability and (6) man-made environment (Scheumann et al. 2013). Each safeguard subject has one or more endpoint category indicators. A possible solution for addressing the defined endpoints is the development of possible impact pathways emanating from the final endpoint category indicator over midpoint impact indicators down to the inventory data. Data on the inventory level are then assigned to an endpoint category representing sustainability aspects of concern on environmental, social or economic mechanism. Several impact pathways are derived to show exemplarily applicability for the case of fertilizers. The safeguard subject *social justice* is connected to the endpoint category indicator status of working environment, among others. Related midpoint indicators are e.g. income inequality, observing labour rights, occupational status and economic prosperity. On the inventory level time based contracts, typical for seasonal workers, show to have an impact on the employees, which are quantified at the midpoint impact category occupational status as well as at the endpoint category status of working environment. In addition, the short time contracts may cause stress at the level of the employees which leads to an effect on occupational status at the midpoint and damage to human health at the endpoint level. However, time contracts might be a way to regulate the company’s day-to-day routine and may support future development of the enterprise. In that case, the impact indicator economic prosperity has a linkage to the safeguard subject financial stability via the endpoint microeconomic performance. This integrated proposal offers a different approach to evaluate possible impacts of products via LCSA. Still, the environmental impacts related to emissions from e.g. production of fertilizer are better accounted in comparison to the relative reference points of the cause-effect modelling e.g. to address social justice. Scheumann, R. et al., 2013. A new indicator framework for LCSA considering safeguard subjects. In *Proceedings of the SETAC Europe 23rd Annual Meeting*. Glasgow: SETAC Europe. Traverso, M. et al., 2012. Life Cycle Sustainability Dashboard. *Journal of Industrial Ecology*, 16(5), pp.680–688. Available at: http://dx.doi.org/10.1111/j.1530-9290.2012.00497.x.

Proposal for a new normalization reference in LCA based on “safe operating space”: presentation of framework and global factors at midpoint level

A. Bjorn, M.Z. Hauschild, Technical University of Denmark / Department of Management Engineering

Planetary boundaries have been suggested for a range of environmental impacts, such as climate change, eutrophying nutrients and land use. The boundaries demarcate the safe operating space of humanity: Staying within the space ensures environmental sustainability, while exceeding it risks pushing ecosystems into alternative regimes, leading to adverse effects for humanity. Planetary boundaries can be applied as policy targets. To promote a societal development in the direction of these targets, an indicator system is needed that measures the fraction of the safe operating space that a given activity occupies. We propose that such an indicator system can be applied in life cycle assessment (LCA) by integrating planetary boundaries via the normalization step. We present the framework of integration, a literature review of quantified boundaries and resulting normatively consistent global average normalization factors in units compatible with characterized results at midpoint level in LCA. Our suggested framework allows expressing normalized results in units of “sustainable person years”. Normalization factors are derived by dividing the safe operating space by the global population. The proposed normalization factors were compared with existing normalization factors that are based on global impacts currently taking place. The impact categories climate change, land use and terrestrial acidification were found to have their safe operating space exceeded on average globally, while the opposite was true for the remaining six categories assessed. Additional research is needed with respect to spatial differentiation since the derived global normalization factors have reduced environmental relevance for impact categories operating at the regional or local scale. Nevertheless the developed normalization factors represent an important first step in enabling LCA to help guiding society in the direction of staying within the safe operating space.

216

Spatial differentiation of LCI datasets: implication of new characterisation methods and necessity of a finer data collection to reduce LCIA results uncertainties - The example of EEE products

E. Lees-perasso, CODDE; J. Orgelet, Bureau Veritas CODDE / EcoDesign

The electric and electronic (EEE) sector is a globalized market. Industries are spread worldwide, same products can be manufactured in various countries leading to different environmental impacts. Moreover, some newly developed characterisation methods include spatial differentiation of their characterisation factors. Therefore, it is important to keep environmental data concerning EEE products up to date in order to provide to life cycle assessment users the most reliable data and reduce the LCIA results uncertainties. Besides, that strong need of updating LCI datasets is facing the difficulty to access to data on new technologies. Indeed, the manufacturing processes are often trade secrets: industrials are not willing to reveal them because of the highly-competitive market and the risks associated. The EEE sector also has a very complex supply chain, involving many

factories from various countries making an overall vision difficult. Because of that some data have to be extrapolated considering available scientific and industrial data sources, and some hypotheses have to be made. These hypotheses induce uncertainties that must be qualified and/or quantified. This presentation aims at qualifying and quantifying the uncertainties on LCIA results led by both the spatial differentiation of LCI datasets and of the characterisation methods, then determining what the improvement of LCI dataset and LCA data collection must be to achieve coherent LCA results and interpretations. A generic silicon semiconductor component will be used as an example through the presentation.

Connecting damage-oriented and resource-oriented environmental footprints

Z. Steinmann, Radboud University Nijmegen / Departmenf of Environmental Science; A.M. Schipper; M. Hauck, Radboud University Nijmegen; M.A. Huijbregts, Department of Environmental Science

Two main schools of thought can be distinguished in the field of life cycle impact assessment. One school uses very simple resource-oriented methods as approximations of environmental impact while the other school uses sophisticated models to determine the impact of as many environmental interventions as possible. An advantage of the resource-based indicators is that they are relatively easy to calculate and communicate. It is unclear however whether these simple indicators are truly representative of the total environmental burden. In this study we determine whether the simple resource based footprints are good approximations of the environmental damage. Therefore we have used a multiple linear regression model in which the environmental damage (to humans, ecosystems and resource availability) was predicted based on four resource use indicators (land, non-renewable energy, water and material). The environmental damage for 959 commodities was determined by using an updated version of the ReCiPe methodology. Data on the environmental interventions of these commodities was taken from the ecoinvent database (version 3.0). Our results showed strong correlations between the two approaches (R^2 values were between 0.79 and 0.94). The most important predictors of environmental damage varied per area of protection and (to a lesser extent) per cultural perspective. However, non-renewable energy demand was found to be a good predictor for all three areas of protection. For human health, material use was found to be important as well, while for ecosystems taking into account land use was of added value. Our results indicate that policies that are aimed towards reducing one resource footprint (for example, energy use) are *ceteris paribus* likely to also reduce the overall environmental damage substantially.

218

The EU Organisation Environmental Footprint Sector Rules (OEFSR) Retailers pilot testing

S. Pedrazzini, S. Humbert, C. Dubois, A. Adams, Quantis; A. Grossmith, Carrefour; F. Vermeiren, Colruyt; P. Leglise, Carrefour; S. Van Hemelryck, Colruyt; H. Schreiber, Umweltbundesamt GmbH EAA; R. Poivet, ADEME; M. Wildenberg, K. Comploi, Global; A. Zamagni, P. Masoni, ENEA / LCA and Ecodesign Laboratory; E. Aubry, Oxylane

On April 9th 2013, the European Commission published: "Communication from the Commission to the European Parliament and the Council: Building the Single Market for Green Products, facilitating better information on the environmental performance of products and organisations". An open call for volunteers was announced by the European Commission for the Product Environmental Footprint (PEF) and the Organisation Environmental Footprint (OEF), inviting companies, industrial and stakeholder organisations in the EU to participate in the development of product-group specific and sector-specific rules. A group of public and private organisations has been selected by the European Commission to develop the guidance for surveying and reporting environmental impacts in the European retail sector. The Technical Secretariat which is responsible for developing the OEF sector rules in two years (official launch in November 2013), is composed by three retailers: Carrefour SA, Colruyt Group and Oxylane Group (Decathlon); three public agencies: Environment Agency Austria (EAA), French Environment and Energy Management Agency (ADEME) and Italian National agency for New Technologies, Energy and Sustainable Economic Development (ENEA); one non-governmental organization: Global 2000; and one Life Cycle Assessment (LCA) consultant: Quantis. This pilot will test how approaches such as Product Environmental Footprint Category Rules (PEFCRs) and the "Chain OEF" (approach covering the indirect/upstream part of the value chain) will interact with or benefit the proposed OEFSR. The project, challenges and expected results and benefits of this pilot test will be presented highlighting feedback in reference to specific modelling issues related to the application of LCA to a sector as vast as the retail sector such as defining system boundaries (e.g., direct, as well as upstream and downstream indirect contributions) and choosing life cycle impact assessment methods (e.g. which indicators are relevant, which weighting scheme to use). These points also include the issue pertaining to consistency with the product approach for a sector as interdisciplinary as the retail sector.

Risk assessment of chemical mixtures: strategies, bottlenecks, and the steps ahead (I)

219

Towards a common conceptual framework for chemical footprint bridging Risk Assessment and Life Cycle Assessment: Short review and way forward

T.V. Rydberg, IVL Swedish Environmental Research Institute; S. Sala, Joint Research Centre European Commission / Sustainability Assessment Unit Institute of Environment and Sustainability; A. Bjorn, Technical University of Denmark / Department of Management Engineering; S. Molander, Environmental Systems Analysis Chalmers University of Technology / Energy Environment; J. Payet, Cycleco; L. Posthuma, RIVM / Centre for Sustainability Environment and Health; L. Sorme, Statistics Sweden; M. Vighi, University of Milano / Earth and Environmental Sciences; M. Zijp, RIVM / DMG

Several studies have been presented recently, applying the chemical footprint (ChF) concept trying to address a variety of questions, often, but not always, to aggregate pollution of many chemicals to one or a few indicators. Furthermore, the possiblity to link chemical pollution to the concept of planetary boundaries, e.g. through the ChF concept, has also been discussed in recent publications. While the planetary boundary concept is pointed out as very difficult for chemical pollution, because of its local or regional nature, there is a need for an integrated chemical assessment and management approach on the regional and global level. This paper provides a short review and conceptual analysis regarding ChF, and suggests a way forward towards a common science based Conceptual Framework for Chemical Footprinting methods, bridging Risk Assessment (RA) and Life Cycle Assessment (LCA) science and methods. Although varying, the approaches reviewed typically are rooted in the knowledge basis of both RA and LCA. Questions for further elaboration are, e.g.: (a) Is a ChF assigned to an object in the technosphere: point source, value chain, sector, or the whole economy, and if so, on what scale (Sub-national to Global), (b) Is a ChF assigned to an object in the biosphere: specific location, or a specific organism (man?), (c) Is the number of chemicals involved one, several, all?, (e) Are chemicals treated as individuals, or grouped, or aggregated by means of toxicity related summation (TCDD-TEQ, UseTox, else). (f) What position to indicate in the cause-effect chain: from occurrence in the technosphere, to the "n-th" order effect in the environment? (f) Are also metabolites included?, and (g) What are relevant impacts, i.e. human health, or ecosystem integrity (only), or also e.g. photo chemical oxidant formation, among others? Given the apparent versatility of the concept and its potential use in chemicals management, a substantial motive to collate the initiatives exists. A SETAC-Working group would be a functional way forward with the goal to e.g.: 1) frame the existing methodologies according to applications and 2) evaluate and fill gaps and weaknesses of proposed methodologies. Input from both the RA and LCA communities are necessary to reach sound and versatile methods which are useful for chemical risk reduction and management, and to underpin development towards the definition of a planetary boundary, or boundaries, for chemical pollution.

220

Initial risk assessment of mixtures of plant protection products

K. Petersen, Norwegian Institute for Water Research; M. Stenroed, Bioforsk; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment

In 2013, more than 100 active compounds of plant protection products (PPPs) are approved for use in Norway. Even though PPPs are risk assessed individually, effects on organisms in the aquatic environment might occur through combined toxicity as co-occurrence of PPPs in agricultural streams are more the rule than the exception. In this study a cumulative risk assessment based on available effect and exposure data was performed to assess the environmental risk of mixtures of PPPs to non-target organisms. Effect data for algae, crustaceans, fish and aquatic plants were collected from various databases and used for calculating predicted no effect concentrations (PNEC). Measured environmental concentrations (MEC) of PPPs at six different sampling sites in Norway were obtained through the Norwegian Agricultural Environmental Monitoring Program, JOVA. The composition and concentrations of PPPs varied between the different sampling sites and different sampling time-points. A risk quotient based on the sum of MEC/PNEC ratios of the detected PPPs in each sample ($RQ_{MEC/PNEC}$) was calculated. In addition, a taxa-specific risk was calculated by summing the toxic units (TU) to obtain the risk quotient RQ_{STU} after application of an assessment factor of 100. Risk was identified when RQ > 1. Of the total 56 samples, eight had a calculated $RQ_{MEC/PNEC}$>1; two samples from Hotranelva, four samples from Mørdrebekken, one sample from Skuterudbekken and one sample from Vasshaglona. The cumulative risk was lowest at Timebekken ($RQ_{MEC/PNEC}$ of 0.121) and highest at Skuterudbekken ($RQ_{MEC/PNEC}$ of 32.5). The identified risk scenarios based on $RQ_{MEC/PNEC}$ were confirmed by RQ_{STU} values above 1 for aquatic plants based on the samples from Hotranelva, Mørdre and Vasshaglona, and for algae in samples from Vasshaglona and Skuterudbekken. The risk at each site appeared to be driven by only a few of the detected compounds. As risk assessment of combined toxicity of complex mixtures is still in early phases of development, a need for in-depth experimental and theoretical effort to improve both the data support and verify the predictive

modeling approaches were identified. However, the results obtained in this study and previous studies utilizing similar approaches suggest that summation of MEC(PEC)/PNEC ratios appear to be an acceptable approach for initial risk assessment of mixtures of PPPs.

221

Mixtures in the environment – development of assessment strategies for the regulation of chemicals under REACH

D. Bunke, ÖkoInstitut eV / Sustainable Products Material Flows Division; N. Aust, Federal Environment Agency / Biocides; E. Hassold, Federal Environment Agency UBA; R. Gross, ÖkoInstitut eV; T. Juffernholz, German Federal Environment Agency UBA / Section IV Chemicals; J. Oltmanns, F. Kalberlah, FoBiG GmbH; A. Reihlen, Ökopol; N. Reineke, Environment and Health Consulting; M.A. Schwarz, FoBiG GmbH

This poster / presentation describes and discusses approaches for the environmental risk assessment (aquatic compartment) of mixtures under REACH. Different types of mixtures are defined. The focus lies on technical mixtures and discharge mixtures. Cumulative and aggregated exposures are considered. A tiered component based approach for the risk assessment of technical mixtures is proposed. It links the state of the art in mixture risk assessment methodology with data requirements and the assessment philosophy according to REACH. Therefore the use of REACH generated data, necessary amendments, and feasibility constraints under REACH in order to perform such a mixture risk assessment are analysed. As possible supplemental elements, mixture assessment factors and whole mixture testing are considered. Current limitations for risk assessment of technical mixtures under REACH are identified and acknowledged. Those are, inter alia, the generic and very crude substance exposure levels (PECs) generated by REACH risk assessment tools, the disparity in the availability of suitable data across the supply chain limiting the possibilities of different actors to assess mixture risks and the missing link between the responsibilities of the single REACH actor (producing or using technical and discharge mixtures and the components (quantitatively and qualitatively) of the actual local coincidental mixture in the receiving water volume which, however, determine the real environmental risk. Priority setting is essential for the risk assessment of mixtures. For this purpose, "Mixture Assessment Triggering Substances (MATS)" are proposed. MATS are selected based on single substances' risk related data indicating a relevant contribution to mixture effects according to concentration additivity assumptions, if they are present in a specific technical mixture. Further approaches for the identification of priority mixtures refer to critical components in mixtures, critical composition and critical uses of mixtures. End-users of technical mixtures can focus on aggregated exposures due to the parallel use of the same substance in more than one technical mixture. Options to assess technical mixtures under REACH have been developed for industry and for authorities. The feasibility of these options is analysed. Possible next steps for validating and refining the proposed mixture risk assessment strategy and for implementation are described.

SINGLE AND MIXTURE TOXICITY OF PHARMACEUTICALS ON ATYAEPHYRA DESMARESTII IN GLOBAL CHANGE SCENARIOS

E. NIETO, INSTITUTE FOR MARINE SCIENCE OF ANDALUSIA ICMANCSIC / ECOLOGY AND COASTAL MANAGEMENT; M. Hampel, Instituto de Ciencias Marinas de Andalucía CSIC / Consejo Superior de Investigaciones Cientificas; P. DRAKE, INSTITUTE OF MARINE SCIENCE OF ANDALUSIA ICMANCSIC; E. GONZALEZ-ORTEGON, INSTITUTE OF MARINE SCIENCE OF ANDALUSIA / ECOLOGY AND COASTAL MANAGEMENT; J. Blasco, Inst Ciencias Marinas de Andalucia / ECOLOGY AND COASTAL MANAGEMENT

Lethal, sublethal and mixture toxicity tests of three pharmaceutical compounds Diclofenac (DF), Ibuprofen (IB) and Carbamazepine (CBZ) were carried out with the freshwater shrimp *Atyaephyra desmarestii* at two different temperatures (20º and 25ºC). Obtained lethal concentrations (LC_{50}) for each individual compound after 96 hours of exposure were 6.3 $mg{\cdot}L^{-1}$, 13.3 $mg{\cdot}L^{-1}$ and 94.3 $mg{\cdot}L^{-1}$ in organisms exposed at 20ºC and 6.4 $mg{\cdot}L^{-1}$, 10.1 $mg{\cdot}L^{-1}$ and 66.4 $mg{\cdot}L^{-1}$ at 25ºC for DF, IB and CBZ respectively. Based on obtained mortality data, Predictive No Effect Concentration (PNEC) was calculated for each of the compounds and compared with Predicted Environmental Concentrations (PEC) reported in surface waters. Environmental risk of each compound was estimated as the ratio between PEC/PNEC and revealed that IB could represent a medium risk in freshwater environments. Additionally, binary and ternary mixture toxicity assays of the selected compounds were carried out. The obtained data was applied to two predictive toxicity models: Concentration Addition (CA) and Independent Action (IA). Finally, risk assessment was carried by estimating risk quotients (RQ). In this study, the mortality produced by binary mixtures at 20°C is lower than that produced at 25°C and the predictive model that fits best is CA presumably because two of the compounds (DF and IB) present a similar mode of action. The selected sublethal endpoints: food ingestion, osmoregulatory capacity and respiration rates were monitored at environmental relevant concentrations, ranging between 10-70$\mu g{\cdot}L^{-1}$ for the three selected compounds. No significant differences in both ingestion rate and haemolymph osmolality were found between controls and treatment (Dunnett´s test p>0.05) neither at 20º nor 25ºC. A decrease in the degree of oxygen independence was observed in shrimps exposed to DF at 20ºC under anoxia conditions (1 mg $O_2{\cdot}L^{-1}$). For respiration rates there was a decrease in the oxygen consumption in organisms exposed to CBZ at 25ºC even in well oxygenated water (5 mg $O_2{\cdot}L^{-1}$). Ecotoxicological action models can be considered useful tools to assess the expected effects of complex mixtures of pollutants in the environment. The results obtained provide relevant information on the combined effect of contamination and temperature variation in aquatic organisms in scenarios subject to global warming.

223

Influence of environmental factors on the joint toxicity of chlorpyrifos and mancozeb to the terrestrial isopod Porcellionides pruinosus

R. Morgado, University of Aveiro / Department of Biology and CESAM; N.G. Ferreira, CESAM Universidade de Aveiro / Departamento de Biologia and CESAM; M. Santos, CESAM DeptBiology / Department of Biology and CESAM; D.N. Nunes Cardoso, CESAM University of Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; P. Gomes, University of Aveiro / Department of Biology and CESAM; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; S. Loureiro, Universidade de Aveiro / Biology

The increasing evidences that environmental factors can act along with pesticides, influencing their individual effects, have been attracting a growing attention between ecotoxicologists. Albeit the considerable amount of work published on this area in the last few years, the influence of environmental conditions on the behaviour and toxicity of pesticide mixtures remains still poorly understood. Aiming to contribute for this discussion, in this work, we evaluated the joint effects of the insecticide chlorpyrifos and the fungicide mancozeb to the terrestrial isopod *Porcellionides pruinosus*, under several temperature and soil moisture conditions. Both these pesticides are extensively used in several crops and their application is frequently simultaneous. A full factorial design, with three treatments of each pesticide, was repeated for each abiotic condition. The experiments lasted for 14 days, and the endpoints assessed included survival, consumption ratio and biomass gain/loss. The reference model of independent action was used in order to evaluate if there were any deviations to the additivity pattern, that could possibly be related to the different environmental conditions assessed. Despite the absence of interactions registered between these pesticides on survival, in some situations, this parameter did, however, differed with the environmental conditions. For instance, different survivals were found when exposing isopods to mixtures containing the same pesticide concentrations at different temperatures. Moreover, the significant effects registered for the feeding parameters, suggest that long-term consequences on the populations dynamics can occur. Since this species' ecological role is mostly related with its feeding activity, this can also entail deleterious effects on the edaphic ecosystems they are in.

Integrated chemical and biological assessment of sub-lethal toxicity of binary mixtures of Zn, HTO and DOC to Mytilus galoprovincialis

H.B. Pearson, Plymouth University / geography earth and environmental sciences; L. Dallas, University of Plymouth; S. Comber, Plymouth University / Environmental Science; C.B. Braungardt, Plymouth University / School of Geography, Earth and Environmental Sciences; A.N. Jha, Plymouth University / Biological Sciences

Concerns over the presence of radioactive contaminants in the marine environment are growing in the light of recent nuclear accidents and the effects rising sea levels may have on the mobilisation of radionuclides from contaminated soils in coastal locations. Therefore, it is a high priority for scientific and regulatory bodies to gain a deeper understanding of the potential impacts of ionising radiation on aquatic biota and to derive appropriate standards to protect the environment from radionuclides, which are often co-disposed with (more abundant) stable metals. This is particularly the case for chronic exposure of marine invertebrates to low levels of metals or radionuclides. This study contributes data to hazard and risk assessment by elucidating the mechanistic processes and quenching effects that arise when marine species are subjected to binary combinations of metals or dissolved organic carbon (DOC) with radio-isotopes. The response of a model species (*Mytilus galoprovincialis*) exposed to a fixed concentration of a radionuclide (5 MBq L^{-1} tritium, HTO), with varying concentrations of a trace metal (25, 125, and 250 $\mu g\ L^{-1}$ Zn) or a source of DOC (0.1, 1, and 10 mg L^{-1} humic acid), was investigated. The study reports the biological effects at gene and DNA level and their potential link to physiological effects (e.g. feeding rate/ clearance rate). The speciation of zinc, a ubiquitous trace element with numerous estuarine sources and a UK Specific Pollutant under the EU Water Framework Directive, and its influence on the biological response of the test species will be discussed. \n

Chemical pollution in sustainable management of aquatic ecosystems – challenges and approaches from a

Swiss perspective (I)

225

Future challenges for the Swiss water sector: outlook based on the National Research Program Sustainable Water Management

C. Stamm, Eawag / Uchem; E. Rahn, R. Siber, K. Lanz, Eawag

Water is a vital resource for a large variety of sectors. Different societal needs and demands such as drinking water production, flood control, energy production and a good ecological status of water bodies may be in conflict with each other, but may also profit from potential synergies. Future oriented water management needs to be based on a comprehensive understanding of the societal sectors affecting water resources and how they interact under present and future conditions. As a contribution to the Swiss National Research Programme 61 on Sustainable Water Management, we investigated trade-offs and synergies among the various water-related societal objectives. The analysis used the present situation as a starting point and expanded to projected future changes due to climate and societal changes. The analysis focused on four dimensions: water quantity, water quality, hydromorphology and finally water conflicts as a consequence of land-use. This presentation summarizes the main findings and aims to put the issue of water quality into a broader context. On the one hand, existing conflicts such as the demand for increased hydropower generation and its impact on stream ecology will continue to be relevant topics in the future. In addition, new issues are developing, for instance the steady increase of heating and cooling uses of surface and groundwater, or conflicts over land-use between urban development and drinking water protection areas. Regarding water quality, Swiss politics have recently decided to invest substantially in the removal of micropollutants from wastewater, intending to markedly reduce their input into the aquatic environment over the coming years. However, this measure will only affect about 10% of the stream network. Hence, to further improve aquatic ecology, diffuse pollution with pesticides and heavy metals will have to be tackled more stringently in the future. Industry is another as yet insufficiently understood source of potential pollution in Switzerland. These qualitative aspects of Swiss water bodies require inspection from a broader perspective. This also applies to on-going river restoration programmes (4.000 km over the next 80 years) which may yield unsatisfactory outcomes as they consider only part of the ecological stressors. Quantitative aspects which long seemed secondary due to the abundance of Swiss water resources were identified to pose an additional challenge, mainly for agricultural development under warmer and potentially drier summer conditions.

226

The chemical status of Swiss surface waters and the role of diffuse pollution with focus on pesticides

N. Munz , I. Wittmer, I. Strahm, Eawag; C. Leu , Federal Office for the Environment FOEN; C. Stamm, Eawag / Uchem

Diffuse pollution in surface waters includes inputs from many various sources and substances, like i.e. plant protection products (PPP) or animal drugs from crop land, biocides from facades in housing areas or heavy metals in road runoff. One of the main challenges to monitor inputs of micropollutants from diffuse sources is the mostly rain-driven dynamic release to surface waters (i.e. runoff). Pesticides are clearly one of the most important substance groups regarding diffuse pollution and one of the most intensively monitored substances in Switzerland. In Switzerland, surface water monitoring, including the assessment of pesticide exposure, is mainly the task of the 26 cantonal authorities. Between 2005 and 2012 more than 345’000 concentration data of 203 pesticides, either registered only as PPP (n= 149) or biocides (n=18) or for both uses (n= 36), were measured at 565 sampling sites in Swiss streams. This study presents the main results of the first nation-wide compilation of pesticide data from cantonal and federal monitoring data. 98 of the 162 detected pesticides were measured above the numerical requirement of the Swiss law of 0.1 µg/l. These exceedances were observed at over 70% of all sites. 18 pesticides (only 1 biocide) were even measured at concentrations above 10 µg/l. Of the pesticides with the highest maximum concentrations, only one is registered as biocide, the rest are PPP or registered for both uses. The highest concentrations were found in small streams (Strahler order 1 and 2). Although the stream network in Switzerland consists of 75% of small streams most of the sampling sites are located at medium-sized or large streams (Strahler order 3 to 9), thus small streams being clearly underrepresented in the data set. Most samples were taken as monthly grab samples or composite samples; high resolution monitoring data were scarce and thus peak concentrations most probably rarely captured. When comparing highly resolved monitoring data of small catchments with the whole data set, maximum concentrations can be up to one order of magnitude higher. Further, the combination with land use data indicates that this elevated pesticide exposure can be widely expected in the small streams of the Swiss Plateau. It can be concluded that due to the site selection and the applied sampling strategies data collected in standard monitoring programs represent only the lower limit of the real pesticide exposure in small streams.

Effects of micropollutants on fishes and macroinvertebrates

R. Triebskorn, University of Tuebingen / Animal Physiological Ecology

228

EcoImpact – assessing the ecological impact of micropollutants in Swiss streams

F. Burdon, Eawag; M. Reyes; K. Räsänen; C. Ort, Eawag Aquatic Research / Urban Water Management; A.C. Alder, Eawag Aquatic Research / Environmental Chemistry; A. Joss, Process Engineering Swiss Federal Institute of Aquatic Science and Technology EAWAG; J. Jokela, Eawag Swiss federal Institute of Aquatic Science and Technology; M. Ackermann; R.I. Eggen, Eawag; C. Stamm, Eawag / Uchem

There is mounting concern about the impacts of human populations on biodiversity and ecosystem services at a global scale, although many of the effects contributing to these changes are exerted at spatially discrete, local scales[1,2]. These concerns, in part, have generated questions of scaling impacts across differing levels of biological organisation (e.g., genes to ecosystems) and their inherent spatio-temporal arrangement, leading to the development of macroecology and ‘macrosystems’ ecology as emerging sub-disciplines within the biological sciences[3,4]. Stream ecosystems are model examples of spatially discrete habitats with hierarchical linkages to larger receiving environments, and where adverse changes are often manifested through increased environmental degradation[2,5] with complex outcomes mediated through interactions of multiple stressors[6,7]. In particular, micropollutants (e.g., low concentrations of pharmaceuticals and pesticides) from municipal wastewater and intensive agriculture may be a serious threat to the biodiversity and ecology of streams and their receiving environments[8]. Efforts to improve point-source pollution through advances in water-treatment technologies have led to the beneficial upgrading of municipal wastewater treatment plants (WWTPs) in developed countries including Switzerland. However, although nutrient loads have been greatly reduced, the biological consequences that wastewater discharges and associated micropollutants, which can bypass conventional treatment methods, have in real ecosystems remains poorly understood. In particular, there is a deficit of knowledge in understanding the impacts that mixtures of low-concentration toxic compounds have on receiving environments, and if changes are mediated through indirect effects (e.g., species interactions), in addition to the direct effects of acute and chronic toxicity. To address these knowledge gaps, we are assessing changes to stream ecosystems through observational and experimental approaches using a range of structural and functional indicators. EcoImpact is an ambitious Eawag project testing the effects of micropollutants entering stream ecosystems via wastewater treatment plant (WWTP) discharges in Switzerland. There are two main components to the study; an observational approach involving field surveys and the other using flow-through stream flumes for an experimental approach. For the observational component of the study, 24 sites across the Swiss Plateau are to be surveyed over two years. Currently, data from 12 streams has been collected above and below WWTP discharges, with basic water chemistry, macroinvertebrate communities, and ecosystem functions, including decomposition and stream metabolism recorded. Almost 400 micropollutants are currently being screened from water samples collected at study sites. This approach is useful for assessing existing influences of WWTP discharges on stream ecosystems, but also provides baseline data to help evaluate the effectiveness of system upgrades in the future. However, basic water chemistry data collected monthly provides confirmation of the altered stream environment below wastewater (WW) discharges, and the majority of variables measured, including nutrients, show elevated concentrations downstream. Analysis of stream invertebrate data using permutational multivariate analysis of variance (PERMANOVA) shows that community composition changes below WW discharges. This change reflects in part increased numbers of oligochaete worms and decreased abundances of baetid mayflies, leading to a large decrease in community evenness. Using the BETADISPER command in R demonstrates that this reduction in beta-diversity potentially also leads to more nested community structure exposed to WW, as evidenced by the lower dispersion of downstream sites in community similarity plots. Similarly, SPEAR (Species at Risk) indices and reduced EPT species diversity confirm these patterns by showing that abundances of pollution-sensitive taxa decrease below the WW discharge. Partial redundancy analysis (*p*RDA) of relative abundance data indicates that water chemistry variables appear to explain the most variation in community abundances after partitioning out the influences of habitat and spatial location. Interestingly, these structural changes to stream invertebrate communities may be associated with impaired and/or altered ecosystem functioning. Preliminary analysis of litter breakdown assay data shows that breakdown rates of leaves were lower in coarse-mesh bags below the WW discharge, thus indicating decreased function by ‘shredding’ invertebrates. In contrast, fine-mesh litter bags (excluding invertebrates) showed a small positive increase in litter decomposition, suggesting a positive influence of WW on microbial processes. Using the cotton-strip assay, another functional indicator of decomposition, confirmed this pattern by showing increased microbial activity and cellulose fibre degradation below the WW discharge. These changes were apparent in measures of ecosystem metabolism using single-station diurnal oxygen logging,

which showed increased community respiration and a shift to a more heterotrophic state. In summary, our findings show that discharges from WWTPs significantly alter stream-water chemistry and influence invertebrate community composition and ecosystem functioning. Less clear, however, are the links between structural and functional changes, and the underlying processes driving apparent effects (e.g., the contribution of micropollutants remains unresolved). However, the observational data we have collected from the field survey helps to better formulate hypotheses that will be tested using the flow-through stream flumes. Thus, in the future, the functional consequences of structural changes and underlying mechanisms will be investigated more rigorously through experimentation.

Benefits and limitations of using fish embryos in applied ecotoxicology

M. Fenske, Fraunhofer Gesellschaft IME / Ecotoxicology; E. Muth-Koehne, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Department of Ecotoxicology; V. Schiller, Fraunhofer IME / Institute for Molecular Biotechnology Biology VII; V. Delov, Fraunhofer IME / Ecotoxicology; M. Macherey; S. Kampe; L. Bodewein, IME Fraunhofer / UNIFISH; A. Wichmann, Fraunhofer Institute for Molecular Biology and App / Institute for Environmental Research (BioV); H. Hollert, RWTH Aachen University / Institute for Environmental Research; R. Kriehuber, Forschungszentrum Jülich GmbH / Department of Safety and Radiation Protection; C. Schaefers, FraunhoferInstitut / Ecotoxicology

Over the last six years, we have been exploring the scope of the fish embryo toxicity assay (FET) for testing different chemicals of a wide mode of action range in terms of sensitivity, meaningfulness and practicality. Many lessons have been learnt from this endeavour, but the overall résumé shows that this test is a resource- and powerful tool to study toxicity at different biological levels. The aim of this presentation is to summarise some interesting results and key outcomes from our investigations into the practical application of the FET. Examples of studies of different exposure scenarios and with different compound groups will be shown to demonstrate how the conventional FET can be enhanced and refined by combination with additional cellular and molecular methods. Correspondingly, the test has certainly some limitations, which have to be considered and recognised, but these are by far outweighed by the benefits. Fish embryo toxicity tests were conducted, using different exposure times from 48 to 120 hours post fertilisation. Most FETs were performed using wild-type zebrafish; however for investigations on mode of action specific effects, like vasotoxic or neurotoxic effects, embryos of transgenic zebrafish lines were used. Post exposure analysis methods ranged from fluorescent immunohistochemistry to acridine orange vital staining for apoptosis detection to RNA extraction with subsequent gene expression analysis using real-time PCR or microarrays. Exemplary results of studies investigating endocrine disrupters, nanoparticles and other specific MOA chemicals demonstrated that the FET is more than just an alternative for the acute fish toxicity test. Transcriptome data of 48h embryos e.g., showed that estrogenic chemicals can be discerned from anti.androgenics based on the expression profile and the regulation of specific signalling pathways. Also,chemicals affecting the vascular or the neuronal development of the embryos could be identified more sensitively with transgenic zebrafish than using the conventional FET with wild-type embryos. Overall, the FET offers huge potential as an animal alternative toxicity test when its limitations are taken into consideration.

Impact of an agricultural contaminant on reproductive behaviour and morphology in a freshwater fish

M.G. Bertram, Monash University / Biological Sciences; M. Saaristo, Monash University / School of Biological Sciences; J.B. Baumgartner, University of Melbourne / School of Botany; C.P. Johnstone, Monash University / School of Biological Sciences; M. Allinson, The University of Melbourne / School of Chemistry; G. Allinson, University of Melbourne / Future Farming Systems Research Division; B.B. Wong, Monash University / School of Biological Sciences

One class of chemical pollutants, known as endocrine disrupting chemicals (EDCs), have the capacity to disrupt the natural endocrinology of organisms. While the morphological and physiological consequences of exposure to EDCs are well known, their effects on behaviour have received less attention. Further, of the behavioural studies to date, the vast majority have focussed on estrogenic endocrine disruptors, while the behavioural impacts of androgenic EDCs are less well understood. One androgenic EDC of particular concern is 17β-trenbolone. This chemical is a metabolite of the hormonal growth promotant trenbolone acetate, which is used globally in beef cattle production. Prior research has repeatedly identified 17β-trenbolone in the environment, and has established its ability to disrupt development and reproduction. The behavioural consequences of exposure to 17β-trenbolone are, however, poorly understood. The aim of this study was to investigate the impacts of short-term (21-day) exposure to an environmentally relevant concentration of 17β-trenbolone (22 ng/L) on male and female reproductive behaviour and morphology in the guppy, *Poecilia reticulata*. Male guppies use two alternate mating strategies, either courting females to solicit copulations or achieving forced copulations via sneaking behaviour. The relative usage of these tactics varies with environmental conditions, providing a useful framework to analyse the effects of EDCs. To investigate the impact of 17β-trenbolone on guppy reproductive behaviour, four treatments were employed: (1) unexposed male with unexposed female, (2) unexposed male with exposed female, (3) exposed male with unexposed female, and (4) exposed male with exposed female. Our study revealed that exposure to 17β-trenbolone, for males, was associated with changes in the total duration and number of courting events, and the number of sneaking attempts, performed across treatments. However, no effect of 17β-trenbolone was detected in females, indicating sex-specific vulnerability at this dosage. This study is the first to show altered reproductive behaviour in male animals in response to an environmentally relevant exposure to 17β-trenbolone. Given potency and ubiquity of 17β-trenbolone, continued multidisciplinary scrutiny of this EDC is necessary to reveal the consequences of its presence in the environment. Keywords: endocrine disrupting chemicals, sexual selection, behaviour, fish

Use of an estuarine model teleost to evaluate pollutant impacts at multiple biological scales

S.M. Brander, University of North Carolina Wilmington / Department of Biology Marine Biology; K. Jeffries, UC Davis; B. Cole; B. DeCourten, University of North Carolina Wilmington; B. DeGroot, University of North Carolina, Wilmington / Dept. of Biology and Marine Biology; J. White, University of North Carolina Wilmington; N.A. Fangue, University of California, Davis / Wildlife, Fish, & Conservation Biology; R.E. Connon, University of California Davis / School of Veterinary Medicine

Estuarine teleosts are rarely used in the study of fish ecotoxicology, and hence knowledge is sparse for many important species. As such, we have developed the euryhaline species *Menidia beryllina* as an model for the study of endocrine disruption at the gene, protein, reproductive, and population levels. We chose to evaluate bifenthrin, a pyrethroid frequently utilized for urban and agricultural applications. Bifenthrin acts as both an estrogen receptor agonist and antagonist at the pptr concentrations commonly present in aquatic ecosystems. Recently, additional concerns have arisen regarding the endocrine activity of bifenthrin metabolites. As such, our experiments seek to expand upon what is already known regarding the mechanisms by which bifenthrin interferes with endocrine signaling in fish and to link changes in gene and protein expression with higher biological scales. We conducted exposures to three pptr concentrations of bifenthrin and evaluated the expression of a suite of endocrine genes. We found that these genes were down-regulated in response to bifenthrin exposure, indicating either antagonism or negative feedback mechanisms. We also conducted 7d exposures to pptr concentrations of a bifenthrin metabolite and to a mixture of bifenthrin and piperonyl butoxide, which inhibits P450 enzyme activity, to determine the role of metabolism. Results of these experiments indicate that bifenthrin increases the expression of the estrogen-dependent protein choriogenin, and that bifenthrin metabolite(s) appear to have greater estrogen agonist activity than the parent compound. Results from a newly-developed *Menidia beryllina* microarray and RNA seq further clarify the mechanisms underlying bifenthrin’s modulation of the endocrine system. These results, along with a current evaluation of reproductive behavior, will be considered in the context of reproductive output via data collected from spawning trials, which found reduced egg output after 7d exposure to 0.5 ng/L bifenthrin. Furthermore, a population model parameterized with these results indicates the potential for population decline at these exposure levels. This model can be used both in the lab and in the field to examine the effects of emerging contaminants and could be used as a surrogate for other estuarine fishes. \n

Sentinel medaka detect multiple mechanisms of steroid signalling disruption

M. Leleu, A. Sebillot, G.F. Lemkine, Watchfrog SA; B. Demeneix, MNHN/CNRS; A.J. Tindall, Watchfrog SA

Aromatase is the key enzyme in regulating the balance between androgen and

oestrogen signalling. Development of *in vitro* tests to identify chemicals altering the expression or activity of aromatase has shed light on their widespread use, particularly in agriculture. Another key enzyme involved in steroid signalling is 5α-reductase which is responsible for the conversion of testosterone into the more powerful androgen dihydrotestosterone (DHT). To carry out large scale screening programs to identify endocrine disrupting chemicals (EDCs) altering oestrogen signalling, rapid and robust screening tools are required capable of identifying EDCs not only acting at the receptor level but also interfering with steroid metabolism. The use of pre-feeding aquatic larvae presents the advantage of being able to perform experiments in multi-well plates. We present a novel and robust exposure protocol for use with medaka fry harbouring the ChoriogeninH-GFP (ChgH-GFP) transgene. Exposure studies were carried out on 20 ChgH-GFP medaka fry per group exposed in 7ml of medaka medium. Exposures began at day post hatch zero for a duration of 48 h. Solutions were renewed every 24 h and fluorescence was quantified every 24 h. All test substances were tested in the presence and absence of testosterone. Colour images of the ventral region of the abdomen of each fry were captured at 8x magnification using GFP longpass filter sets. Background fluorescence of the fry resulting from endogenous pigments was removed by subtracting the red layer from the green layer and applying a 10-255 threshold. GFP signal was generated in response to exposure of fry to the aromatisable androgen testosterone. The lack of signal observed when fry were cotreated with testosterone and the pharmacological aromatase inhibitor anastrozole demonstrated that conversion of tesosterone to oestradiol via aromatase is necessary for a fluorescent response. By exposing ChgH-GFP fry to a variety of chemicals, we determined that EDCs acting via at least seven different mechanisms of action can be identified using ChgH-GFP fry exposed in the presence or absence of testosterone. The protocol described here provides a reliable method to screen potential EDCs acting on the oestrogen axis via a variety of mechanisms. In addition this protocol provides information on steroid signalling from an entire intact organism whilst complying with the three R's principle of animal replacement.

Assessment of the estrogenic potency of chemicals, alone or in combination, and complex environmental mixtures using a novel transgenic cy19a1b-GFP in vivo zebrafish assay (EASZY assay)

F. Brion, n. hinfray, INERIS / Ecotoxicology Unit; N. Creusot, INERIS; O. Kah, IRSET; J. Porcher, S. Ait-Aissa, INERIS / Ecotoxicology Unit

One major challenge to ecotoxicology is to develop species-specific biological tools that allow rapid and cost-efficient assessment of Endocrine Disrupting Chemicals (EDCs) for environmental hazard and risk assessment but also for monitoring the contamination of aquatic systems by EDCs. In this context, the use of zebrafish (*Danio rerio*) embryo assay allowing the detection and quantification of EDCs based on their mode of action appear as usefulness and relevant to address these issues. We recently developed a mechanism-based *in vivo* zebrafish assay called EASZY that allows the detection of Endocrine Active Substance, acting through zebrafish estrogen receptors, using transgenic cyp19a1b-GFP Zebrafish embrYos (EASZY). The Cyp19a1b gene is a strictly ER-regulated gene that codes for the brain aromatase which is mainly expressed in radial glial cells of the brain of fish. In the present work, the relevance of EASZY assay for assessing the estrogenic potency of substance was evaluated by testing more than 50 different compounds belonging to various chemical classes. We found that in EASZY, GFP is induced in a ER-specific manner by (i) compounds that bind directly to estrogen receptors as agonists (ii) compounds that require metabolic activation into estrogenic metabolites (iii) aromatizable androgens as well as some non aromatizable androgens. By studying combined effects of estrogenic chemicals, we showed that mixtures of estrogenic compounds generally acted in an additive manner on *th*e expression of GFP, their combined effects being predicted by the CA model although antagonism was observed in a specific case. Finally, Polar Organic Chemical Integrative Sampler (POCIS)-based bio-monitoring using EASZY allowed screening for estrogenic activity of various surface waters from French rivers resulting in the detection of estrogenic activities at some sites. Overall, our studies show that EASZY assay clearly emerges as a simple, fast and reliable *in vivo* assay for screening the capacity of chemical, alone or in combination, as well as complex environmental mixtures. The sensitivity of EASZY assay to activate ER-signalling by chemicals and complex mixtures at very early critical developmental stages makes it an outstanding screening in vivo tool for hazard assessment of chemicals and EDCs detection in aquatic environment.

Application of Molecular Methods for Understanding the Effects of Endocrine Disrupting Chemicals in Fish Models

C.R. Tyler, Biosciences College of Life and Environmental Sciences; T. Kudoh, University of Exeter / Biosciences College of Life and Environmental Sciences; T. Iguchi, National Institute for Basic Biology / Molecular Environmental Endocrinology; A. Lange, Biosciences College of Life and Environmental Sciences; A. Takesono, O. Lee, J. Moreman, University of Exeter / Biosciences College of Life and Environmental Sciences; J. Green, University of Exeter; R. Cooper, University of Exeter / Biosciences College of Life and Environmental Sciences; P.B. Hamilton, University of Exeter / Biosciences; T. Iguchi, Natl Institutes of Natural Science

A wide range of chemicals are now known to mimic hormones structurally or interfere with their biosynthesis and/or degradation. Exposure to these so called endocrine disrupting chemicals (EDCs) can cause disruptions in development, alter sexual differentiation and function, and impact adversely on reproduction. In this presentation, we illustrate the application of a suite of oestrogen receptor (ER) reporter gene assays, transgenic fish and DNA microsatellites to advance understanding on the mechanisms of oestrogen action in fish and the functional consequences for both individuals and populations. Fish ERs in reporter assays showed similar responses to the natural ligand oestradiol-17b (E2, and also for the oestrogen receptor subtypes) but very different responses to oestrogen mimics, with implications for risk assessment. We show that the ligand binding domain of the ER confers differences in responsiveness to oestrogen mimics between different fish species. Applying an oestrogen responsive element transgenic (ERE-TG) biosensor zebrafish (ERE-TG fish) we show that a variety of tissues respond to oestrogens, including the liver, heart, muscle and forebrain illustrating the wide potential health effects associated with oestrogen exposure. Exposure studies with BPA reveals valves in the heart as a target site and the breakdown product of BPA, MBP,is around 1000X more potent that the parent compound. Male roach (*Rutilus rutilus* L) feminised by exposure to oestrogenic effluents can be compromised in their reproductive fitness however using DNA microsatellites, we did not find that this impacted on the effective population sizes (N_e) of wild roach (*Rutilus rutilus* L) living in UK rivers, and it appears that populations in oestrogen contaminated environments were self sustaining.

Wildlife ecotoxicology: from acute toxicity to low level, chronic exposure related effects (II)

Energy normalized diet concentrations as measure for secondary poisoning of birds and mammals

E. Verbruggen, RIVM Expertise Centre for Substance / Centre for Safety of Substances and Products

The risk assessment of secondary poisoning of birds and mammals is usually performed by either the dietary approach or the dose based approach. Both methods however, have their disadvantages. The dietary approach does not take into account the differences in energy content between food items, leading to sometimes substantial differences in food intake. This concerns both the food provided in the laboratory toxicity studies and the food items from the field (e.g. fish, bivalves or earthworms). The dose based approach actually only considers the intake rate of the chemical. Because the dose is the highest for small mammalian and avian species, these species are selected as indicator species for this approach. The species with the highest intake rate will have the fastest buildup of the chemical concentration in the organism. This is relevant for acute poisoning, as often addressed in risk assessment of pesticides. However, also the clearance rate is equally dependent on the body weight, and therefore, upon long-term exposure these effects will cancel each other. The dose might therefore be a less suitable metric for long-term exposure. A method is presented here, which uses dietary concentrations normalized to the energy content of the diet. Diet concentration can be directly normalized to the energy content, or the normalized concentration can be calculated from the dose and the ratio of daily energy expenditure and body weight. Daily energy expenditure can be accurately estimated from body weight. Chronic toxicity of hexachlorobenzene for mink was taken as an example. Both methods to calculate the diet concentration normalized to energy content gave very similar results. This value can then be recalculated to different food items relevant for the food chain considered (freshwater, marine, terrestrial) by means of the energy content of these food items. Together with the bioaccumulation parameters it can be decided which food item is critical for the food web. The method differentiates better between different food items. Further, it is flexible, because it can be applied to less common food items as well.

Can stable isotopes explain contaminant load in birds of prey?

M.G. Pereira, Centre for Ecology Hydrology / Lancaster; R.F. Shore, CEH Lancaster; L. Walker, Centre for Ecology Hydrology; E. Potter, Centre for Ecology and Hydrology; H.K. Grant, Centre for Ecology Hydrology

Measurement of polychlorinated biphenyls (PCBs) and mercury (Hg) in the eggs of predatory birds has been undertaken as part of the long-term monitoring work of the UK Predatory Bird Monitoring Scheme (PBMS—http://pbms.ceh.ac.uk). We have measured PCB and Hg concentrations in the eggs of a marine sentinel species, the Northern gannet (*Morus bassanus*) from two Scottish colonies (Ailsa Craig in the Eastern Atlantic and Bass Rock in the North Sea). We have also monitored these contaminants in the eggs of golden eagles (*Haliaeetus albicilla*), a species of high conservation concern in Britain. Our analyses revealed higher levels of

contaminants in the eggs of Ailsa Craig than Bass Rock gannets and in the eggs of coastal nesting compared with inland nesting golden eagles. The intra-specific differences in gannet eggs have been assumed to reflect colony-differences in diet and/or trophic level position, although alternatively there could be differences in contaminant loadings between eastern Atlantic and North Sea fish. The higher contaminant loadings in coastal-nesting than inland nesting golden eagles have been attributed to coastal nesting birds preying, at least partly, on seabirds and being exposed to marine contaminant pathways. However, there is no real information to support the assumptions about the role of diet influencing egg contaminant loads for either species. We measured stable isotopes (^{15}N, ^{13}C and ^{34}S) in eggs as proxy indicators for diet to test if intra-specific differences in contaminants could be explained by differences in diet. We used $\delta^{15}N$ as a marker of trophic position, $\delta^{13}C$ as a marker of the carbon source in the diet and $\delta^{34}S$ a marine marker. The gannet eggs from Ailsa Craig were significantly more enriched in δC^{13} and δN^{15} than those from Bass Rock, suggesting increased consumption by Ailsa Craig gannets of higher trophic level prey and/or an increased proportion of demersal fish discards in the diet. This may account to some extent for the higher levels of ΣPCB concentrations and Hg concentrations in eggs from Ailsa Craig.

Effects of As, Cd and Pb on blackbirds: a multi-marker study

C.C. Fritsch, CNRS / UMR ChronoEnvironnement; L. Bervoets, University of Antwerp / Biology; R. Pinxten, University of Antwerp / Dept of Biology Ethology research group; R. Mateo, UCLMCSIC / Instituto de Investigacion en Recursos Cinegeticos; M.E. Ortiz Santaliestra, Institute for Environmental Sciences University of KoblenzLandau / Institute for Environmental Sciences; N. Vallverdu Coll, IREC; M. Poisbleau, University of Antwerp / Dept of Biology Ethology research group; R. Scheifler, University of FrancheComte / ChronoEnvironnement; M. Eens, University of Antwerp / Dept of Biology Ethology research group

The present study aimed to get insights into the pathways linking effects at individual and population level and how gender-specific responses may affect such links. We used a multi-marker approach on the European blackbird *Turdus merula* in order to investigate population structure parameters, potential metal toxicity with health biomarkers (haematology, blood biochemistry/enzymatic activities, oxidative stress), potential depletion of quantity/quality of food with nutritional status biomarkers (body condition index, blood biochemistry), and relate these different parameters with exposure to As, Cd and Pb (blood and feather concentrations). Eighty-three blackbirds (55 males, 28 females) were captured during the breeding season in five sites along a pollution gradient in Antwerp (Belgium). The levels of As, Cd and Pb in tissues increased along the pollution gradient and did not vary with gender. Levels in blood and feathers were highly correlated, strongly suggesting that birds were chronically exposed. The sex-ratio did not vary with pollution. The age structure, for males only, differed between sites with an increase of yearling proportion in the most polluted sites, which may be interpreted as a result of higher mortality or emigration in these polluted sites. The proportion of female carrying a visible egg decreased with pollution level although not significantly. No relationships were observed between exposure and markers related to nutritional status. In males, the results suggested some health disorders (anemia, myopathy, kidney dysfunctioning and metabolic homeostasis disorders). No oxidative stress was detected but a modification of oxidative status, with an increase of some circulating antioxidants (lutein, tocopherol) with metals. In females, only few correlations were found, most of them being significant only for females carrying an egg. Like in males, no oxidative damages were detected but an increase of lutein with metal levels. A decrease of GSH with metals, not observed for males, was also found. Altogether, the results suggested a higher sensitivity of males to toxic effects, but may also mirror trade-offs between reproduction and individual survival in the most polluted sites for females. The modification of circulating lutein and tocopherol may be related to the effects of metal(loid)s on oxidative status, but may also be linked to changes in hormone levels, notably stress hormones.

238

Are immunotoxic effects of lead shot ingestion linked to oxidative stress?

N. Vallverdu-Coll, Instituto de Investigacion en Recursos Cinegeticos; M.E. Ortiz-Santaliestra, University of WI-Madison / Forest and Wildlife Ecology; F. Mougeot, EEZA; R. Mateo, UCLMCSIC / Instituto de Investigacion en Recursos Cinegeticos

The ingestion of lead (Pb) shot used for hunting constitutes the main cause of Pb poisoning in avifauna, but very little is known about the sublethal effects on birds and their consequences at a population level. We studied the relationship between Pb shot ingestion, oxidative stress biomarkers and the immune function in red-legged partridge (*Alectoris rufa*). Partridges (n=60) were housed in pairs and assigned to three experimental groups: Control (no shot), low dose and high dose. Pb concentration and δ-aminolevulinic acid dehydratase (δ-ALAD) activity, were determined in blood. Malondialdehyde concentration (MDA), total glutathion levels (GSH) and superoxide dismutase activity (SOD) were quantified in red blood cells homogenates. Vitamins (retinol, α-tocopherol) and carotenoid (lutein) levels were analyzed in plasma. Carotenoid-based coloration was studied by digital photographs and beak and eye ring spectrophotometry. Cell-mediated immune and humoral responses were studied using the phytohemagglutinin (PHA)-skin test and the haemagglutination test after antigen injection, respectively. Acute-phase and antibacterial proteins were measured in plasma. Constitutive immune response was tested determining bactericide activity of fresh whole blood. A negative relationship between Pb concentration and δ-ALAD was found. Pb exposure increased levels of GSH and the primary inflammatory response to PHA. In females, δ-ALAD activity was positively correlated with intensitiy of carotenoid-based red coloration and with relative amount of the eye ring area pigmented by carotenoids. GSH concentration was positively associated with blood Pb concentration. Cellular immune response increased with Pb exposure, while humoral immune response decreased. Exposure to Pb in males decreased retinol and lutein levels in plasma. Antioxidant mechanisms appear to be affected by Pb exposure in a different way in females and males. Females may show a hormetic response with the increase of GSH and enhanced cellular immune respose, but at the cost of a loss on carotenoid ornamentation and a reduced humoral immune response. Males exposed to Pb maintained the pigmentation of ornaments and the competence of both immune functions, but showed a more marked decrease of plasma antioxidants. This may reflect a handicap of the carotenoid-antioxidant allocation trade-off in males between the expression of sexual signals and the immunitary response or other oxidative stress-sensitive functions.

In ovo exposure to BDE-99 affects the song control system of a model songbird species, the zebra finch

M.L. Eng, V. Khamzina, Simon Fraser University; S.A. MacDougall-Shackleton, University of Western Ontario; T.D. Williams, Simon Fraser University / Department of Biological Sciences; J.E. Elliott, Environment Canada / Science Technology Branch

2,2',4,4',5-Pentabromodiphenyl ether (BDE-99) is a brominated flame retardant congener that has pervaded global food chains, being reported in avian egg and tissue samples throughout the world. There is evidence that BDE-99 has endocrine disrupting effects, and exposure to BDE-99 in the early life stages could have significant impacts on development. One component of the nervous that develops during the embryonic and early post-hatch period is the song-control system, which is involved in song learning and production. There are concentrations of androgen and thyroid hormone receptors in the song-control nuclei, and there is the potential that the development of the song control system could be affected by exposure to xenobiotics such as PBDEs. Singing is an important aspect of reproduction in birds, serving to define territories and attract females. Developmental conditions that result in smaller song-control nuclei and reduced song quality in males could ultimately disrupt pair formation and lower reproductive success. In the present study, the effects of *in ovo* exposure to environmentally relevant levels of BDE-99 were assessed in a model songbird species, the zebra finch (*Taeniopygia guttata*). Embryos were exposed via egg injection to a vehicle control (DMSO), 10, 100 or 1000 ng BDE-99/g egg on the day the egg was laid. Chicks were raised to sexual maturity to investigate long-term effects of BDE-99 on the adult male brain. Three key song control nuclei (AreaX, HVC, RA) all showed non-significant decreases in volume as BDE-99 concentration increased. As these three nuclei all correlated with each other, we used a principle components analysis of these three varaibles to get a single measure of the song control system. The first principle component (PC1) explained 60% of the variation in nuclei volumes. We compared PC1 scores across doses and found a significant effect on the song control system, with BDE-99 exposed birds having significantly smaller PC1 scores compared to control birds. This study has shown that current environmental levels of BDE-99 are high enough to have significant effects on the song control system in birds, and may therefore be impacting the reproductive rates of free-living birds. We have previously shown that there is no effect of BDE-99 exposure during the nestling period on the song control system. Taken together, these results demonstrate that the timing of exposure can significantly alter the effects of contaminant exposure.

240

The effects on steroidogenesis and cellular structures of adult male Japanese quails (Coturnix coturnix japonica) testis following pre-pubertal exposure to di (n-butyl) phthalate (DBP)

U. Muhammed Bello, M. Madekurozwa, University of Pretoria / Department of Anatomy and Physiology; H. Groenewald, University of Pretoria; T. Aire, St Georges University; A. Arukwe, NTNU / Department of Biology

Phthalates esters (PE) are synthetic chemicals widely used as plasticizers and ubiquitous in the environment. Many laboratory studies have shown generally that phthalates, including the di (n-butyl) phthalate (DBP) are anti-androgenic causing adverse biological effects on male reproduction, growth and development in both human and wildlife. Phthalates are known to interfere with the transcription of several key genes involved in cholesterol transport and testosterone biosynthesis. The down-regulation of several genes involved in steroid biosynthetic pathways is thought to be central to phthalate-esters induced anti-androgenic disruption. In present study, we investigated the effects of 30d dietary (prepubertal) exposure to different doses (0 (control),1,10,50,200and 400 mg/kgbw)of DBP on testis (Leydig

cells) of adult male Japanese quails by quantifying the transcript expression of $P450_{scc}$, $P450c_{17}$, aromatase (cyp_{19}), androgen receptor, 3β-and 17β-HSD using qPCR. In addition, the plasma testosterone levels was analysed using radioimmunoassay; and testis was examined for evidence of gross- and histopathology. Our overall objective was to test the effects of DBP on cellular and molecular processes that underlie testicular steroidogenesis, using the male Japanese quail, as a sentinel avian model. We hypothesized that exposure of male quails to the environmental DBP at pre-pubertal period, will produce differential expression patterns of selected genes involved in testicular steroidogenesis, and may subsequently leads to alterations in testosterone levels and gonadal development. Our data showed that prepubertal exposure to DBP resulted in alterations in testicular architecture as evident by poorly developed or mis-shaped testis, and disturbed spermatogenesis due to degeneration and slight atrophy of seminiferous tubules especially in the DBP treated high dose groups. In addition, DBP disrupts several key enzymes involved in testicular steroidogenesis pathways in a dose-dependent manner. P450scc mRNA expression was up-regulated at low dose 10 mg/kg bw, and thereafter, a dose-dependent decrease (down-regulation) was observed between 50 and 400 mg/ kg bw. In conclusion, the present data is consistent with previous reports showing that DBP modulate Leydig cell steroidogenesis in several species, with a potential negative effect on reproduction in those avian species that are vulnerable to EDCs in the wild populations.

Innovations in environmental analytical chemistry: the quest for pollutants at trace levels (II)

The use of scripting filters for the identification of potential novel persistent organic pollutants following GC×GC-ToF MS analysis

M. Pena, University of Toronto / Laboratory Services Branch; K. Jobst, Ontario Ministry of the Environment; R. Ruffolo, Ontario Ministry of Environment; R. McCrindle, Wellington Laboratories Incorporated; P.A. Helm, Ontario Ministry of the Environment / Environmental Monitoring and Reporting Branch; E.J. Reiner, University of Toronto

Comprehensive two dimensional gas chromatography coupled to mass spectrometry (GC×GC–MS) represents a valuable approach when dealing with the simultanous screening of different families of organic micropollutants in environmental samples. Depending on the complexity of the sample matrix, hundreds to thousands of peaks can be detected in a single analytical run. Interpretation of these large data sets can be a challenging task for the analyst, especially if some analytes are unknown compounds for which no MS data or information is available. The possibility of defining identification criteria could facilitate the interpretation of the data obtained. Recent studies have shown that threshold criteria can be used for the identification of potential bioaccumulative and persistent chemicals based on physicochemical properties. The majority of compounds classified as “potential POPs” are halogenated and therefore, pre-defined MS scripting filters for the determination of halogenated compounds during GC×GC–MS analysis can provide direct information regarding both conventional and unknown potential persistent organic pollutants (POPs) in the sample. With the focus on the goal of early identification of emerging halogenated substances, this study evaluates the use of a single script during GC×GC–MS analysis for the determination of potential novel POPs in sediments collected in Ontario (Canada).The script was designed to classify peaks based on the recognition of a common halogenated isotope pattern present in the mass spectrum of any compound that contains at least one chlorine or bromine. Once validated, the script was applied to sediments analysed by GCxGC–MS in order to detect prevalent halogenated compounds. A compound with a mass spectrum showing sequential loses of chlorines and bromines and with an odd molecular weight was detected in 27 out of 69 sediments. Ultra high resolution MS experiments indicated that the molecular mass of compound was 390.8162 da. The most logical molecular formula obtained from the elemental composition calculator was: $C_{12}H_5NCl_2Br_2$ (error: 0.438 ppm). A halogenated dibenzocarbazole was the most probable structure for the chemical. Extra experiments with different dibenzocarbazole isomer standards showed a good match with the 1,8-dibromo-3,6-dichloro-substituted isomer. This is the first time that a mixed halogenated carbazole has been identified in environmental samples.

Rapid post-screening of a sediment sample with complex matrices by GC × GC-HRTOFMS with R-based peak sentinel tool (T-SEN)

Y. Zushi, Center for Environmental Measurement; S. Hashimoto, A. Fushimi, Y. Takazawa, K. Tanabe, National Institute for Environmental Studies; Y. Shibata, National Institute for Environmental Studies / Director

Recently, comprehensive two-dimensional gas chromatography coupled to mass spectrometry (GC × GC-MS) draw attention as a powerful instrument for comprehensive analysis of organic pollutants. In this study, we developed an analytical method using GC × GC with data processing tool for rapid and accurate identification and quantification of compounds in environmental samples with complex matrices. Specifically, an automatic peak sentinel tool, (T-SEN), was developed with free programming software, R. This tool consists of a simple algorithm for peak finding based on a compound database and peak shape identification. It allows rapid screening of target compounds, even for large data sets from GC × GC coupled to high resolution time of flight mass spectrometry (HRTOFMS), typically up to 2 GB. The tool automatically assigns and integrates peak area of compounds that are listed in user databases. T-SEN for GC × GC-HRTOFMS works on a typical 64 bit workstation, and the reference calculation speed is 10–20 min for approximately 170 compounds for peak finding based on five compound-derived ion and integration from 1–2 GB of sample data. We demonstrated an ability to quantify 17 PCDD/F congeners and 24 PCB congeners in a crude lake sediment extract by both GC × GC coupled to quadrupole mass spectrometry (qMS) and GC × GC-HRTOFMS with T-SEN. Whereas GC × GC-qMS with T-SEN showed false results in the first step of identification, GC × GC-HRTOFMS with T-SEN provided accurate quantification of compounds in addition to correct identification in the crude sediment sample. The differences between the values measured by GC × GC-HRTOFMS with T-SEN and the certified values for the sediment as a certified reference material ranged from 7.3 to 36.9 % for compounds with concentrations above the limit of quantification. Except for the case of co-elution, false positives/negatives were not observed. GC × GC-HRTOFMS in combination with the tool T-SEN provided rapid and accurate screening in this demonstration, and represents a powerful new approach as post-screening in GC × GC-MS which expands the potential for comprehensive analysis.

Diagnostic derivatization: A novel approach to identify (aromatic) amines in environmental matrices

m. muz, UFZ Helmholtz Centre for Environmental Research / Effect Directed Analysis; W. Brack, M. Krauss, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis

The presence of aromatic amines in the environment has been in the focus of research, as many of these compounds are known or suspected mutagens and carcinogens. To facilitate the detection of aromatic amines in complex environmental samples by LC-high resolution mass spectrometry, a diagnostic derivatization method to label (in an ideal case) all aromatic amines in complex environmental matrices was developed and evaluated. About 40 compounds containing one or more aromatic or aliphatic amino groups were analyzed for method development. 4-fluoro-7-nitro-2,1,3-benzoxadiazole (NBD-F) was selected as the labeling reagent due to its high reactivity with both primary and secondary amines and its very low ionization by ESI in positive mode. As a post-column on-line derivatization did not result in sufficient yields of derivatives, our study focused on pre-column derivatization in vials prior to LC-HRMS analysis. Two strategies were tested for the detection of derivatized amines: (i) a search of peaks present in the derivatized, but not the original sample in full scan chromatograms, followed by a search for the amine precursor compound in the original sample; (ii) pseudo-neutral loss scans of the derivatized samples based on in-source fragmentation (LTQ Orbitrap) and all-ion HCD fragmentation (Q-Exactive) and search for diagnostic neutral losses from the derivative. Most of the selected aromatic amines but also the aliphatic ones result a derivative except some sterically hindered compounds and some heterocyclic amines. The reaction yield was always below 90% enabling us to detect both the analyte and the derivative in the derivatized samples for higher peak intensities. A common neutral loss of two –OH groups (m/z 17 and 34) and in some cases a subsequent –NO loss (m/z 64) were observed for most of the compounds. Chromatogram deconvolution was executed by the software MZmine and the peak lists with intensity, retention time and accurate mass were further processed by the R-Nontarget package. The full scan peak lists were used to find matching peaks of analyte and derivative. This approach performed successfully to detect derivatives and corresponding precursor compounds and allowed the detection of aliphatic and aromatic amines in environmental samples. Keywords: Diagnostic derivatization, aromatic amines, high-resolution mass spectrometry

Integrated Accessible Computational Strategies to Identify Emerging Environmental Pollutants using HR-MS/MS

E. Schymanski, Eawag Swiss Federal Institute of Aquatic Science; M. Gerlich, IPB Leibniz Institute of Plant Biochemistry; S. Neumann, Leibnitz Institute of Plant Biochemistry IPB; J. Hollender, Eawag / Environmental Chemistry

The recent developments in liquid chromatographic techniques coupled with high resolution mass spectrometry (LC-HRMS/MS) to capture the more polar range of environmental contaminants has resulted in an explosion in the number of target and non-target compounds for consideration in environmental analysis. Most instruments now provide data acquisition methods that allow the screening of suspect and non-target compounds post acquisition, while many emerging compounds that are of high environmental relevance have structural characteristics (substructures) that can be used to streamline identification efforts. However, no automated strategies exist to streamline the identification efforts in the environmental context. Thus, integrated computational strategies for identifying emerging pollutants on the basis of HR-MS/MS data were developed and tested. R packages were used to extract high resolution isotope, adduct and homologue information (package “non-target”) as well as the MS/MS information (“RMassBank”) from the data. MOLGEN-MS/MS was used to calculate molecular formulas, while MetFusion was used to retrieve candidate structures using ChemSpider and rank them according to *in silico* fragmentation and spectral information from MassBank. MetFusion was extended to additionally restrict the compound database search by substructures. MetFusion was first evaluated on known environmental target compounds, from standard measurements and samples. Then the integrated strategy was successfully applied to the identification of transformation products of benzotriazoles and on non-target compounds detected in wastewater effluents from Switzerland. It is clear that not all identification efforts can end in complete success with confirmation via reference standards. Thus, this work also involved the assessment of the confidence in identification efforts, ranging from a “non-target mass of interest” (Level 6) through to “Confirmed identification” (Level 1). An appropriate communication of the identification confidence is necessary to enhance the exchange of potential emerging compounds between environmental institutes, for example via the upload of MS/MS spectra of tentative and unknown compounds to MassBank.

Carbamazepine and its metabolites in wastewater, surface water and drinking water: Occurrences, potential risks and analytical pitfalls

A. Bahlmann, HelmholtzZentrum fur Umweltforschung UFZ / Effect Directed Analysis; M. Krauss, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis; P.C. Von der Ohe, UFZ Helmholtz Centre for Environmental Research / Department of Ecological Chemistry; R. Schneider, BAM Federal Institute for Materials Research and Testing / Dept. of Analytical Chemistry; Reference Materials; W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis

Carbamazepine (CBZ) is a widely used anticonvulsant pharmaceutical that is known to be very persistent in the aquatic environment. In this work, we comprehensively followed the fate of its main metabolites in wastewater, surface water and drinking water. The occurrence of the parent compound and its metabolites was investigated in a total of 104 water samples from Germany and Portugal by liquid-chromatography tandem mass spectrometry. The five metabolites 10,11-dihydro-10,11-dihydroxy-CBZ (DiOH-CBZ), 10,11-dihydro-10-hydroxy-CBZ (10-OH-CBZ), 10,11-epoxy-CBZ, 2-hydroxy-CBZ and 3-hydroxy-CBZ were very persistent with little to no removal during wastewater treatment. The highest concentrations were found in wastewater, with up to 4.8 and 1.1 μg/L for DiOH-CBZ and 10-OH-CBZ, respectively. In drinking water, CBZ and DiOH-CBZ could be quantified at average concentrations of 0.10 and 0.16 μg/L, respectively. Furthermore, the related pharmaceutical oxcarbazepine and the metabolites 9-hydroxymethyl-10-carbamoylacridan, 1-hydroxy-CBZ (1-OH-CBZ) and 4-hydroxy-CBZ (4-OH-CBZ) were detected in wastewater and surface water. Explicit care was taken to achieve a good chromatographic separation of the numerous isomers that were difficult to distinguish by mass spectrometry alone. Using a phenylether HPLC column combined with high resolution mass spectrometry and hydrogen-deuterium exchange, 1-OH-CBZ and 4-OH-CBZ were identified in the environment for the first time in this work. A preliminary risk assessment for CBZ revealed potential risks for the parent compound, whose measured environmental concentration level exceeded the predicted no-effect concentration of 0.5 μg/L for 37% of the surface water samples. Similar concentration levels of some metabolites suggest that risks for them cannot be excluded.

246

Investigation of micropollutants and transformation products from a waste water treatment plant with full scale ozonation using LC-HRMS

C. Portner, Institute of Energy and Environmental Technology IUTA eV / Enviromental hygiene micropollutants; S. Westrup, Thermo Fisher Scientific; J. Tuerk, Institute of Energy and Envionmental Technology eV IUTA

Due to the extensive use of industrial chemicals, pesticides, personal care products and pharmaceuticals, many anthropogenic organic micropollutants and their biological metabolites have become ubiquitously detectable in the aquatic environment. The emission of these substances into the aquatic environment occurs through both direct and indirect discharge into the sewage in combination with insufficient biological or chemical degradation efficiency of conventional municipal waste water treatment plants (WWTPs). The impact of environmentally relevant micropollutants on human health and aquatic organisms has been studied not comprehensive enough; however, within the implementation of the EU Water Framework Directive it is increasingly important. Actually many research projects are focused to determin micropollutants and evaluate different elimination techniques. Ozonation as an advanced treatment step in WWTP is a relatively new approach to reduce the emission of such substances. However, using economically efficient operation conditions the oxidation generally does not result in a complete mineralization of organic substances but rather leads to partially oxidized transformation products. In North-Rhine-Westphalia the ozonation was implemented on a large scale and tested in practical operation. Against this background, samples from the influent, effluent and after ozonation from the WWTP in Duisburg-Vierlinden were picked up and analyzed using liquid chromatography high-resolution mass spectrometry (LC-HRMS). The data investigation was focused on occurrence of suspected and non-target micropollutants, biological metabolites and transformation resulting from the oxidation. For the suspected substances, a comparison of this data has been conducted with a custom-made database for micropollutants, metabolites and transformation products. The data evaluation for the non-target screening approach followed by a principal component analysis (PCA) and *in silico* methods for metabolism, transformation reactions and fragmentation pattern. The combination of a database screening approach for suspected substances and *in silico* methods to identify substances in the non-target screening analysis offers the opportunity to detected a large scale of micropollutans and their metabolites and transformation products in the waste water treatment process. Detailed results will be presented.

Ecological Consequences of Exposure to Pharmaceuticals: From the Laboratory to the Field (II)

Ecotoxicological assessment of antibiotics: state-of-the-art and needs for improvement

K.K. Brandt, University of Copenhagen / Department of Plant and Environmental Sciences; A. Amezquita, UnileverSafety Environmental Assurance Centre; T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; A. Coors, ECT Oekotoxicologie GmbH; T. Heberer, Federal Office of Consumer Protection and Food Safety / Department Veterinary Drugs; J.R. Lawrence, Environment Canada / Water Science and Technology Directorate; J.M. Lazorchak, US EPA / Office of Research and Development; J. Schonfeld, Umweltbundesamt Federal Environment Agency; J.R. Snape, Astrazeneca UK Ltd / AstraZeneca Global Environment; E. Topp, Agriculture and Agri-Food Canada; Y. Zhu, Key Laboratory of Urban Environment and Health Institute of Urban Environment Chinese Academy of Sciences

Current environmental risk assessment (ERA) of antibiotics seek to protect the biodiversity and ecological functioning of ecosystems. However, ecosystem protection goals are only vaguely described in current guidelines for regulatory risk assessment for human and veterinary pharmaceuticals. Here we critically review the ecotoxicological assessment of antibiotics as related to ERA. Special attention is paid to environments comprising primary recipients of antibiotic residues (e.g. agricultural soils, aquaculture, and waste water impacted environments), and we focus on microbial communities as bacteria comprise the primary targets for antibiotics. We initially discuss the need for more specific protection goals for ERA of antibiotics, and key ecosystem services provided by microbes including their key drivers (i.e. ecosystem service-providing units such as taxa or functional groups) are identified. We propose that ERA should be designed to protect microbial community functions, microbial ‘species’ richness, and antibiotic susceptibility of environmental bacteria. We subsequently review the methods currently in use for ecotoxicological assessment of new human, agricultural and veterinary medicinal products and discuss the need for the development and inclusion of improved microbial test methods that allow for targeted protection of the ecosystem services provided by microbes. Specifically, we discuss the appropriateness of different ecotoxicological endpoints (i.e. community function, structure or tolerance) for ERA. Ecotoxicological endpoints focused on ‘higher’ trophic levels are also emphasized due to their high priority for ERA. Hence, antibiotics may adversely affect non-target organisms such as selectively grazing bacterivores or higher-order consumers indirectly through trophic cascades. We also discuss the accumulative risk of mixtures of antibiotics as there is a need to address the potential for additive or synergistic impacts of mixtures of antibiotics on bacterial communities and higher trophic levels. Finally, we discuss the effects of sub-inhibitory concentrations of antibiotics, which may lead to disruption of microbial signaling thereby potentially affecting some ecosystem services provided by microorganisms. Major knowledge gaps will be highlighted in order to propose promising areas for future research that will enable a more solid foundation for assessing risks associated with antibiotic residues in the environment. The views expressed in this presentation are those of the authors and do not necessarily represent the views or policies of the U.S. Environmental Protection Agency.

A multi-species approach to evaluate the acute and chronic toxicity of carbamazepine, ibuprofen and propranolol spiked in sediment samples.

L.A. Maranho, Universidad de Cadiz / Department of Chemistry and Physics; M. Garrido-Perez, Andalusian Center for Marine Science and Technology (CACYTMAR), University of Cádiz; T. Del Valls Casillas, Physical Chemical Department University of Cádiz Faculty of Marine and Environmental Sciences; M. Martin-Diaz, University of Cádiz Center for Marine Science and Technology CACYTMAR / Chemical Physical

In a way to bring information about suitable tools for ERA of pharmaceutical products, a battery of conventional bioassays was applied using marine organisms exposed to sediment samples spiked with pharmaceutical products: carbamazepine (CBZ), ibuprofen (IBU) and propranolol (PRO): (500$\mu g \cdot L^{-1}$, 50$\mu g \cdot L^{-1}$, 5$\mu g \cdot L^{-1}$, 0.5$\mu g \cdot L^{-1}$, 0.05$\mu g \cdot L^{-1}$), including the environmental concentrations (underlined). Microalgae growth inhibition of *I. galbana* and *T. chuii* was significant different to the control for CBZ (50$\mu g \cdot L^{-1}$, 5$\mu g \cdot L^{-1}$, 0.5$\mu g \cdot L^{-1}$, 0.05$\mu g \cdot L^{-1}$) and PRO (50$\mu g \cdot L^{-1}$ only for *T. chuii*) ($p < 0.05$). Concerning the sperm and embryogenesis assays of sea-urchin *P. lividus*, embryogenesis success showed significant effect after exposure to CBZ (500$\mu g \cdot L^{-1}$, 5$\mu g \cdot L^{-1}$, 0.05$\mu g \cdot L^{-1}$), IBU (500$\mu g \cdot L^{-1}$, 50$\mu g \cdot L^{-1}$, 0.5$\mu g \cdot L^{-1}$) and PRO (all) ($p < 0.05$). Microtox® Basic Test represented hormesis for elutriate samples. The ranking of EC_{50} for the acute toxicity observed was: CBZ>IBU>PROP for Microtox® BSPT. After 15-days of polychaetes exposure, chronic responses were determined through biomarkers of exposure and effect . The activity of the Phase I of the metabolism was activated for PRO (increase EROD and decrease DBF) and IBU (decrease DBF for 500$\mu g \cdot L^{-1}$ and 0.5$\mu g \cdot L^{-1}$) ($p < 0.05$). Phase II (GST) was activated for CBZ (increase for 500$\mu g \cdot L^{-1}$ and 50$\mu g \cdot L^{-1}$, and decrease for 0.05$\mu g \cdot L^{-1}$) and PRO (decrease for 500$\mu g \cdot L^{-1}$, 5$\mu g \cdot$L-1, 0.5$\mu g \cdot L^{-1}$) ($p < 0.05$). Antioxidantenzymes showed significant increase compared to the control for 0.05$\mu g \cdot L^{-1}$CBZ (GPX) ($p < 0.05$). Lipid peroxidation significantly increased compared to the control for CBZ (500$\mu g \cdot L^{-1}$), IBU (5$\mu g \cdot L^{-1}$) and PRO (5$\mu g \cdot L^{-1}$, 0.5$\mu g \cdot L^{-1}$, 0.05$\mu g \cdot L^{-1}$) ($p < 0.05$). Genetic damage significantly increased compared to the control for IBU (500$\mu g \cdot L^{-1}$,5$\mu g \cdot L^{-1}$) and significantly decreased for PRO (50$\mu g \cdot L^{-1}$) ($p < 0.05$). Described results showed the bioavailability of these substances in marine sediments and the confirmation of the metabolism of detoxification in benthic invertebrates.

Investigating various modes of action and potential adverse outcomes of pharmaceuticals in marine mussels

E. Fabbri, University of Bologna / Interdepartment Centre for Environmental Science Research CIRSA; P. Valbonesi, University of Bologna; S. Buratti, S. Franzellitti, University of Bologna / Interdepartment Centre for Environmental Science Research CIRSA

Pharmaceutical concentrations in marine coastal waters are in general very low, however dilution cannot be considered a safety factor. Indeed, pharmaceuticals are designed to interact with specific biological targets and produce effects at the lowest possible doses. These effects are not necessarily revealed by acute or chronic toxicity tests on standard organisms, and the need for new approaches is underlined. The application of the Mode of Action (MOA) approach may provide a substantial contribution to the understanding of subtle, specific effects of pharmaceuticals on non-target organisms, since the evolutionary conservation of molecular targets in a given species potentially increases the risk of effects of bioactive compounds. We explored several MOA-relevant endpoints and biomarkers responses to investigate possible adverse outcome pathways of fluoxetine (FX) and propranolol (PROP) on the Mediterranean mussel, *Mytilus galloprovincialis*. Mussels were exposed for 7 days to FX or PROP (0.3 - 300 ng/L range) or to the combination FX+PROP (each at 0.3 ng/L). MOA-relevant endpoints, including cAMP levels and PKA activities, were analysed in digestive gland. Biomarkers of lysosome functionality, and catalase and GST activities were measured in digestive gland, lysosome membrane stability (LMS) in haemocytes. Both FX and PROP decreased cAMP levels and PKA activities, in agreement with the inhibition of the cAMP pathway through 5-HT1 receptors. The presence of 5-HT1 receptors in mussels and modulation of their mRNA levels by 5-HT and FX was confirmed by real time PCR. The main effects of FX+PROP on cAMP levels and PKA activity were ascribed to PROP, supporting a prevalent adrenergic control in digestive gland. Both FX and PROP caused a dose-dependent reduction of LMS in haemocytes, at all concentrations tested. LF, NL, Lys/Cyt ratio and CAT activity were significantly affected, although the effects did not appear dose-dependent. FX+PROP lowered LMS stability, and increased Lys/Cyt ratio, LF and NL accumulation. In conclusion, environmental pharmaceuticals may be highly active on wildlife possessing specific molecular targets, therefore MOAs should be explored to reveal adverse outcome pathways of pharmaceuticals and interactions occurring between them. The use of biomarkers demonstrated drug effects at environmental concentrations. Approaches based on MOAs and biomarkers are suggested as a priority task for pharmaceutical risk assessment.

250

Fate and effects of pharmaceutical antibiotics differ among single substances and mixtures

S. Thiele-Bruhn, University of Trier / Soil Science

It is the rule rather than the exemption that livestock animals are medicated not only with a single pharmaceutical antibiotic but combinations of antibiotics are administered simultaneously or consecutively. As a consequence, excreta stored in tanks or lagoons contain mixtures of several antibiotics that are subsequently spread as fertilizer on agricultural soils. However, knowledge on the fate and effects of such mixtures is scarce. In laboratory experiments, the fate and effects of mixtures of antibiotics was investigated compared to that of single substances. To this end different tetracycline and sulfonamide antibiotics as well as trimethoprim were tested in selected combinations. Sorption and dissipation was determined in batch and microcosm experiments; the iron(III)-reduction test was used to determine dose-response curves. Competitive sorption was found among antibiotics of one structural class and between structural classes, resulting in significantly higher mobility of the antibiotics. Also, the dissipation rate in microbially active as well as in sterile soil was retarded in the presence of antibiotic mixtures. While concentration additivity (CA) was found for tetracyclines, mixtures of two sulfonamides and of a sulfonamide with trimethoprim and tetracyclines, respectively, showed increased adverse effects on soil microorganisms. These were best described by the model of independent action (IA). The isobologram of the combined action of chlortetracycline and sulfadiazine showed clear superadditivity of effects (Loewe synergism). It is concluded that the existing knowledge on ecotoxicity of antibiotics is insufficient to assess the existing contaminations with mixtures of antibiotics.

251

Dilute concentrations of an anxiolytic drug alters behaviour and species interactions of wild fish

T. Brodin, Umea University / Department of Ecology and Environmental Science

Environmental pollution by pharmaceuticals is increasingly recognized as a major global threat to aquatic ecosystems[1]. Many pharmaceuticals enter waterways via treated wastewater effluents [2-6] and remains biochemically active in aquatic systems [4,7]. Several ecotoxicological studies have been made but generally, little is known of the ecological effects of pharmaceuticals [4,8]. Here I present data from a laboratory exposure-study of wild caught fish showing that a benzodiazepine anxiolytic drug (*Oxazepam*) alters ecologically important behaviours (e.g. activity and sociality), feeding rate and predation risk of wild European perch *(Perca fluviatilis)*at concentrations close to those encountered in effluent influenced surface waters. Individuals exposed to water with dilute drug concentrations (1.2 $\mu g\ l^{-1}$) exhibited increased activity, reduced sociality, higher feeding rate and increased predation risk. In aquatic environments, predation is an important driver of species numbers, community composition, and productivity [9,10]. As such, the results show that anxiolytic drugs in surface waters can profoundly alter both species interactions and animal behaviors that are known to have ecological and evolutionary consequences.

252

The striking sensitivity of invertebrates to antidepressants

A.T. Ford, University of Portsmouth / Biological Sciences; P.P. Fong, Gettysburg College

Antidepressants are among the most commonly detected human pharmaceuticals in the aquatic environment. Since their mode of action is to modulate the neurotransmitters serotonin, dopamine, and norepinephrine, aquatic invertebrates that possess transporters and receptors sensitive to activation by these pharmaceuticals are potentially affected by them. We review the various types of antidepressants, their occurrence and concentrations in aquatic environments, and the actions of neurohormones modulated by antidepressants in invertebrate models. Recent studies on the effects of antidepressants, on particularly crustacean and molluscan groups show they are susceptible to a wide variety of neuroendocrine disruption at environmentally relevant concentrations (pg-ng/L). For example molluscs show that antidepressants affect spawning and larval release in bivalves, disrupt locomotion/reduce fecundity in snails and camouflage/memory function in cephalopods. In crustaceans, antidepressants affect activity patterns, photo- and geotactic behaviour, gene expression, reproduction and development. In contrast, studies to date have primarily been finding effects in fish at considerably higher concentrations (μg/l-mg/l). We discuss possible reasons for the discrepancy in these results in relation to the "read-across" hypothesis, variation in biomarkers used, phylogenetic distance, and the affinity to different targets and differential sensitivity to receptors. We also highlight the increasing reported occurrence of non-monotonic dose responses curves, often with effects at low concentrations, but not at higher concentrations, and we suggest future experiments consider testing a broader range of concentrations. There is growing evidence to suggest antidepressants do affect aquatic invertebrates at concentrations currently found in the environment. However, providing strong evidence for effects in the field will be a tough new challenge for ecotoxicologists.

Detection and characterisation of nanomaterials in complex aqueous matrices

253

Behaviour and fate of silver and manufactured silver nanoparticles along the wastewater-biosolid exposure pathway

E. Donner, University of South Australia / Centre for Environmental Risk Assessment and Remediation; G. Brunetti, University of South Australia; R. Sekine, University of South Australia / Centre for Environmental Risk Assessment and Remediation; G. Laera, Water Research Institute National Research Council

Italy; M. Khaksar, University of South Australia; K. Vasilev, University of South Australia / Mawson Institute; K. Scheckel, US EPA; E. Lombi, University of South Australia / Centre for Environmental Risk Assessment and Remediation

Silver nanoparticles (Ag-NPs) are present in more products that any other nanoparticles, and studies using probabilistic material flow analysis have consistently shown that the major environmental release pathway for Ag-NPs is the wastwater-biosolids pathway. It is important to understand how the characteristics of Ag-NPs, in terms of core structure and surface functionality, affect their behaviour and fate along this pathway. Here, we report a comprehensive set of studies which investigated the following aspects of this release pathway: a) Stability of Ag-NPs in a simulated sewer network, including pumping stations (sewer retention time 16 hours; total experiment duration 14 days).; b) Transformations of various Ag-NPs (with different surface functionality and core composition) in municipal wastewater sludge and during anaerobic sludge digestion; c) Speciation and lability of Ag in a collection of experimentally derived, contemporary (fresh and aged) and historical biosolids (some of which had been aged in open-air stockpiles for up to 50 years) from Australia, the USA and UK. Silver speciation was measured using X-ray absorption near edge spectroscopy (XANES) and silver lability was assessed via an isotopic dilution technique using ^{110m}Ag (E values). Various supporting parameters were measured (e.g. pH, Eh, sulfides), and we also investigated the use of a novel device incorporating immobilised Ag-NP on plasma polymerised surfaces for assessing their transformation in situ. The results reported here clearly demonstrate that: (a) the speciation of Ag in the wastewater-biosolid exposure pathway is largely independent of the form released from urban sources in wastewater (e.g. ionic, Ag/AgCl-NPs); (b) Ag bound to reduced S is the dominant form of Ag along this exposure pathway; and (c) Ag sulfides persist as the dominant species in biosolids even after prolonged stockpiling, and Ag lability is accordingly very low.

254

Fate dynamics of silver nanoparticles in sewage treatment studied with FAST single-particle ICP-MS

G. Cornelis, University of Gothenburg / Department of Chemistry and Molecular Biology; M. Hassellov, University of Gothenburg / Department of chemistry and Molecualr Biology; M.D. Juergens, Centre for Ecology and Hydrology

FAST spICP-MS is a new development of conventional single particle ICP-MS (spICP-MS) where ion clouds originating from nanoparticles (NP) in suspension are measured using very short subsequent acquisition times, so that multiple datapoints per particle event are obtained. The benefits for conventional spICP-MS have been shown for acquiring number-based particle size distributions (PSD) of NP in complex aqueous samples. The current work progresses further by presenting an application of the FAST spICP-MS methodology to particularly challenging samples of Ag NP spiked into a wastewater treatment plant (WWTP) microcosm. A mixture of samples taken freshly from a real WWTP in the Gothenburg area was used for the sake of realism. Three stages (anaerobic, aerobic and settling) of a WWTP were thus simulated and the PSD of spiked AgNP was measured using FAST spICP-MS as a function of time, allowing to monitor the dynamics of AgNP fate in WWTP such as aggregation, dissolution and sedimentation. Benefits of FAST spICP-MS such as fewer multiple and incomplete particle events and the size and particle number concentration detection limit are discussed. The results also demonstrate the fast dissolution and sedimentation AgNP undergo in a WWTP, explaining the high partitioning of AgNP to biosolids.

Microsecond spICP-MS and its application to environmental samples

M.D. Montano, Colorado School of Mines / Chemistry; H. Badiei, S. Bazargan, Perkin Elmer Inc; R. Reed, Colorado School of Mines / Department of Chemistry and Geochemistry; J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry

The potential release of engineered nanomaterials into the environment has required the development of more sophisticated, selective, and sensitive analytical techniques to detect and characterize these materials in complex environmental matrices. In recent years, single particle ICP-MS (spICP-MS) has been used as a sensitive, high throughput technique for the detection and sizing of nanomaterials at environmentally relevant concentrations (ng/L). This is accomplished by using short dwell times (milliseconds) to record a discrete pulse of intensity resulting from a nanoparticle event that is consequently much larger than the background. However, this technique has been hampered in cases of high particle number concentration and elevated dissolved backgrounds. The work presented here shows that these obstacles are overcome by reducing the dwell time to microseconds. In this range, the particle is presented as a distribution of pulse intensity relating to temporal detection of the particle ion cloud as it reaches the detector. This allows for great improvements in particle resolution to be made, allowing for analysis of samples with higher dissolved backgrounds and high particle number concentrations. In addition, as a nanoparticle detection event occurs over the span of a couple hundred microseconds, it is now possible to detect two elements within a single nanoparticle. By switching between two monitored isotopes, elemental and isotopic ratios can be determined on a particle-by-particle basis. This enables for the possibility of an analytical method to differentiate between naturally occurring nanoparticles, which may have a natural abundance of two elements, and their elementally/isotopically enriched engineered analogues. In addition, more complex nanomaterials with a core-shell structure can be characterized with these improvements. The addition of microsecond spICP-MS to the growing number of nano-analytical techniques should provide a new approach to overcoming some of the challenges in the detection of ENPs in complex matrices.

Evaluating Bioaccumulation of Silver and Gold Nanoparticles Using spICPMS-Enabled Tissue Extraction and Analysis

E.P. Gray, Colorado School of Mines / Civil and Environmental Engineering; J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry; J.G. Coleman, US Research and Development Center / Environmental Laboratory; A.J. Bednar, US Army Engineer Research and Development Center / Environmental Laboratory; A.J. Kennedy, CEERDEPR; C.P. Higgins, Colorado School of Mines / Civil Environmental Engineering

Expanded use of engineered nanoparticles (ENPs) in consumer products increases potential for environmental release and unintended biological exposures. As a result, measurement techniques are needed to accurately quantify ENP size, mass, and particle number distributions in biological matrices. This work combines single particle inductively-coupled plasma mass spectrometry (spICPMS) with tissue extraction to quantify and characterize metallic ENPs in environmentally relevant biological tissues for the first time. ENPs were extracted from tissues via alkaline digestion using tetramethylammonium hydroxide (TMAH). Method development was performed using ground beef and was verified in *Daphnia magna* and *Lumbriculus variegatus*. ENPs investigated include 100 and 60 nm Au and Ag stabilized by polyvynylpyrrolidone (PVP). Mass- and number-based recovery of spiked Au and Ag ENPs was high (83-121%) from all tissues tested. Additional experiments suggested ENP mixtures (60 and 100 nm Ag ENPs) could be extracted and quantitatively analyzed. Biological exposures were also conducted to verify the applicability of the method for aquatic organisms. Size distributions and particle number concentrations were determined for ENPs extracted from *D. magna* exposed to 98 μg/L 100 nm Au and 4.8 μg/L 100 nm Ag ENPs The *D. magna* nanoparticulate body burden for Au uptake was 613 ± 230 $\mu g/kg_{ww}$, while the measured nanoparticulate body burden for *D. magna* exposed to Ag ENPs was 59 ± 52 $\mu g/kg_{ww}$. Notably, the particle size distributions determined from *D. magna* tissues suggested minimal shifts in the size distributions of ENPs accumulated, as compared to the exposure media.

Visualisation of silver nanoparticle uptake by Laser Ablation - Inductively Coupled Plasma Mass Spectrometry

S. Böhme, Bioanalytical Ecotoxicology; H. Staerk, Helmholtz Centre for Environmental Research UFZ / Department of Analytical Chemistry; T. Reemtsma, D. Kühnel, HelmholtzCentre for Environmental Research

According to the unique size, surface area, and reactivity of nanoparticles (NP) an improvement in the toxicological testing, the uptake quantification and risk assessment is required. As a consequence, the testing and exposure strategies for nanoparticles have to be adjusted. Beside the observation of biological effects of nanoparticles *in vivo* and *in vitro*, there is a need of adequate analytical detection and quantification methods. The quantification of uptake of metal containing nanoparticles by environmental organisms or cells can be performed by digestion of the organic material to dissolve the particles, followed by Inductively Coupled Plasma Mass Spectrometry (ICP MS) as a robust element detection method. However, this approach only provides information on the total amount of NP taken up, it is not possible to distinguish between particles or a dissolved porportion. Additionally, the connection to the localisation of particles inside the biological tissues and the correlation with mechanisms leading to the occurrence of toxic effects is still missing. Such information can be obtained by imaging techniques. Up to now, most imaging methods utilize the modification of physical and chemical particle properties, e.g. by fluorescence labelling, to make particles visible. In this study, a reliable and quantitative imaging method was developed by coupling a Laser Ablation system with an ICP MS (LA-ICP MS) to enhance the knowledge of how nanoparticles are taken up and how they are distributed in environmental organisms (e.g. *Danio rerio*, *Daphnia magna*). With this method quantitative data on NP uptake can be gathered and particles were detected without the need for (fluorescence) labelling. By using this imaging method the interaction between the processes of particle uptake, the bioaccumulation, and the occurrence of toxic effects can be understood in a more detailed manner. The benefits of this approach will be shown with respect to silver nanoparticle (AgNP) uptake.

Detection and quantification of nanoparticles in aqueous matrices by means of field flow fractionation and mass spectrometry

P.S. Bauerlein, KWR / Analytical and Environmental Chemistry; P. de Voogt, University of Amsterdam / IBED; A. Kolkman, KWR Watercycle Research Institute; A. van Wezel, KIWA Water Research; E. Emke, KWR Watercycle

Research Institute; P. Herrero, E. Pocurull, Universitat Rovira i Virgili
Because of their chemical and electrical properties, nanoparticles such as fullerenes or Ag have been widely applied in personal care products, drug delivery systems and solar cells. The fate of manufactured nanoparticles have been increasingly studied because of their potential risks to the environment and human health. In commercial applications such as organic photovoltaic cells, derivatised fullerenes are used to modify their solubility and electronic properties. Silver nanoparticles are being employed in health care and consumer products. Aim of the present work is to develop and optimise a method that allows the detection, size determination and quantification of fullerenes (and their clusters) in aqueous matrices by means of Orbitrap MS and FFF, both stand-alone and combined. For the size determination a MALS detector is used. For the extraction of fullerenes from different aqueous matrices SPE was applied. Various materials were tested and recoveries determined. Additionally, the influence of other parameters (ionic strength, humic acid) was assessed/evaluated.The size distribution of fullerenes in water was determined with FFF coupled to a MALS detector. After optimization of the separation method, the FFF was linked to the Orbitrap to allow quantification of the different size fractions. Different SPE column materials (C18, C18e, C8, CN) were tested, and recoveries appeared to be the highest for the C18-material. Recoveries were improved by adding NaCl to the water during extraction and higher concentrations of humic acid had an negative effect on the recovery. Very low limits of detection (LOD) values were obtained for all compounds with this method, ranging from 0.17 ng/L for [70]PCBM to 0.28 ng/L for C60, and subsequent limit of quantitation (LOQ) values of 0.57−0.91 ng/L. Recoveries for the fullerenes were on average 120% in ultrapure and drinking water. Recoveries appeared to be lower, but still acceptable (e.g., >78%), in surface water. The FFF/MALS-analysis of aqueous samples of fullerenes showed that the sizes of the aggregates range between 4 nm to 200 nm. Fractograms show that the void peak and the first fullerene clusters are clearly separated. Analysis by FFF coupled to the Orbitrap confirmed that the particles observed are fullerene (clusters).

Bioavailablity and effects of metals and metal mixtures (II)

Mixed stress? Growth and bioaccumulation of freshwater algae Pseudokirchneriella subcapitata under combined zinc and phosphate supply

C. Gao, Department of Earth and Environmental Sciences; K.A. De Schamphelaere, Ghent University UGent / Environmental Toxicology and Aquatic Ecology; E.E. Smolders, Katholieke Universiteit Leuven
In the past, researches have observed P-metal interactions on the growth of algae while inconsistent results were found across those studies. We propose that probably due to methodologies adopted in different experiments. The objectives of this work are to investigate Zn×P interactions (growth and Zn-P uptake) under steady state supplies of P. A constant P supply in exponentially growing algal cultures was obtained by exponential dosing of P at various exponents. The algae were grown at semi-steady state under 3 different constant growth rates (0.8 day^{-1},1.15 day^{-1} and 1.45 day^{-1}). Toxicity test with 7 factorial Zn concentrations from 13 μg/L to 256 μg/L was afterwards performed. Cell P as well Zn concentration was measured by acid dissolution followed by the analysis of the ICP-MS. It was observed that the cell P concentration increases with Zn supply. At the same time, the cell Zn exhibited an increasing trend with P supply. P-Zn precipitation was suspected to occur inside the cell. Furthermore a 3-D kinetic model was fitted for the intrinsic interactions between P and Zn toxicity. The growth rate μ was depicted as a function of cell P concentration and external Zn concentration and the entire process of the toxicity experiments were stimulated. The model was optimized by non-linear regression.

260

Development of a chronic metal mixture bioavailability model for Ni-Zn toxicity to Daphnia magna based on the independent action model

C. Nys, University of Ghent / Environmental Toxicology and Aquatic Ecology; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; E.E. Smolders, Katholieke Universiteit Leuven; K.A. De Schamphelaere, Ghent University UGent / Environmental Toxicology and Aquatic Ecology
Risk assessment of metals is generally based on ecotoxicity test results conducted with individual metals. However, organisms in the environment are mostly exposed to mixtures of metals. Both non-interaction, synergism and antagonism have been observed in metal mixture assays. This uncertainty about metal mixture interactions hinders the development of a metal mixture toxicity model to predict the toxicity of metal mixtures in the environment and therefore also the incorporation of metal mixture toxicity in risk assessment. Furthermore, most metal mixture studies consider acute toxicity, while chronic effects of metal mixtures are rarely considered. Moreover, although metals have often a dissimilar mode of action, the Concentration Addition (CA) model is commonly used to describe metal mixtures. In this study, we studied binary metal mixture interactions in a Ni-Zn mixture in two independent chronic reproduction tests with *Daphnia magna*. As these metals have (at least partly) dissimilar known modes of action, we used the Independent Action (IA) model to analyze metal mixture interactions. Possible metal interactions were assessed with the IA model by evaluating if the concentration response curve on the basis of Me^{2+} activity of one metal changes in the presence of the other metal. If the EC50, expressed as Me^{2+} activity; of the first metal is significantly higher (lower) in the presence of the second metal, the metals are interacting antagonistic (synergistic). Both Ni and Zn were shown to interact synergistically at high concentrations (based on Me^{2+} in the solution) for *D. magna*. A Metal Mixture bioavailability model was developed by combining the existing bioavailability models for individual Ni and Zn toxicity with the IA model, and by integrating a model term expressing the synergistic interaction. This model showed reasonable predictive capacity. These models can be valuable in future risk assessment processes for metals.

261

Toxicity of binary mixtures of nickel, copper, cadmium and zinc to Daphnia magna

E. Traudt, J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry; J. Williamson; S. Smith, Colorado School of Mines; R. Pastorinho, CESAM & Department of Biology, Aveiro University / Biology; J.S. Meyer, ARCADIS
Although metals are regulated on a metal-by-metal basis in most jurisdictions, metals usually occur in mixtures instead of alone in water. However, the toxicity of metal mixtures is difficult to predict accurately. As part of a project to provide mixture-toxicity data for development of multi-metal toxicity models, we tested the toxicity of binary Cd-Ni, Ni-Cu, and Ni-Zn mixtures. To analyze the interactions of these metals, *Daphnia magna* neonates were exposed to the metals alone and in binary combinations in standard 48-h lethality tests. For each combination of metals in the binary mixtures, one metal was held constant at a specified concentration while the second metal was varied through a series that ranged from nonlethal to lethal concentrations; then the roles of the two metals were reversed in a separate series of tests. Based on dissolved-metal concentrations, the toxicity of Ni-Cd mixtures was less-than-additive (i.e., less toxicity than predicted from single-metal tests); the toxicity of Ni-Cu mixtures was more-than-additive (i.e., greater toxicity than predicted from single-metal tests); and in preliminary results, the toxicity of Ni-Zn mixtures was additive or slightly less-than-additive. These results provide evidence for the dominance of competition of metals for complexation to biological ligands or to dissolved organic matter, depending on the metal combination in question.

262

Mixture toxicity and interactions of copper and zinc to barley in three different soils

L. Versieren, EES; N. Herregods, KULeuven; K.A. De Schamphelaere, Ghent University UGent / Environmental Toxicology and Aquatic Ecology; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; E.E. Smolders, Katholieke Universiteit Leuven
Soil metal contamination mostly occurs as a mixture of different metals, rather than as a single metal. Risk-evaluation of metal contamination in soil, however, is almost always based on the effects of single metals. This is only justified if the exposure to mixtures does not bear the risk of an increased toxicity relative to the toxicity at single exposure. Therefore, there is a need to understand how metals act together in producing combination effects. Metals may interact in mixtures and these interactions in soil may partly be related to interactions on their bioavailability. It is postulated that metals may act synergistically because of the limited specific sorption sites that can reduce the metal bioavailability. Hence, mixture toxicity and interactions of copper (Cu) and zinc (Zn) to barley are assessed in three soils, differing in cation exchange capacity (2, 7 and 85 $cmol_c$/kg). The interactions will be assessed based on both total metal concentrations and free metal ion concentrations. To model mixture toxicity, two basic models: the concentration-addition (CA) model and independent action (IA) model will be used and compared. The hypothesis is that synergistic interactions will be observed based on total concentrations with the IA model as reference model and that perfect addition will be observed with the CA model as reference model. In addition, we postulate that the interactions are most pronounced in the soil with the highest CEC. These synergistic interactions with the IA model as reference model can be explained by competition effects between the metals for binding to soil binding sites. Metal toxicity depends on the free metal ion activity. When a second metal is added to a soil, it will (partly) bind to the binding sites, thereby releasing the previously bound first metal, increasing its free ion activity and toxicity. It is expected that when mixture toxicity is modeled based on free metal ion concentrations, perfect IA will be observed. Preliminary results for two soils (CEC 7 and 85 $cmol_c$/kg) confirm perfect CA based on total metal concentrations. Significant synergistic interactions between Cu and Zn, with the IA model as reference model, however, are only observed in the potting soil (highest CEC). The EC50 of Cu decreases ($p< 0.05$) from 474 to 296 mg Cu/kg soil, when 1100 mg/kg Zn is added to the soil compared to the no Zn amended soil. The combination

toxicity data will be presented at the meeting.

263

Metal accumulations in diffusive gradients in thin films (DGT). Mixture and low ionic strength effects.

S. Cruz-Gonzalez, Universitat de Lleida; C. David, Universitat de Lleida / Department of Chemistry; J. Puy, Universitat de Lleida / Dep Chemistry; C. Rey-Castro, J. Galceran, Universitat de Lleida / Department of Chemistry
DGT [1] is a powerful technique for in situ measurement of metal fluxes. It consists of a resin immobilised and embedded in a gel (the resin disc) that strongly binds the metal ions that arrive to it after crossing a diffusive gel disc. The metal complexes able to diffuse through the diffusive gel also penetrate into the resin layer [2,3]. This penetration of complexes leads to an important contribution to the total metal accumulation. Additionally, the influence of the composition of the mixture of ligands is reduced to the effects acting in the gel domain [4]. In the presentation, results showing the influence of the mixture composition on the metal accumulation will be presented together with the impact of low ionic strength. The penetration of complexes into the resin disc can be strongly influenced by an electrostatic effect derived from the electrical charges of the resin beads. For decreasing ionic strengths, negatively charged complexes will experience stronger electrostatic exclusion leading to a reduction of the accumulated mass, while positively charged complexes will contribute to enhanced metal accumulations. Experimental evidences for this behaviour will be provided as Ni, Cd and Co accumulations in presence of nitrilotriacetic acid (NTA) or ethylenediamine (Etdiam) which form negatively and positively charged complexes, respectively. A simple electrostatic model can quantitatively explain the results. Simple expressions for the metal accumulation can be obtained and fitted to the experimental accumulations leading to values of the Boltzmann factors which can be used in other systems. All these effects were not previously described and are extremely important for a correct interpretation of DGT measurements in pristine waters [5]. Likewise, the increased kinetic dissociation constant in the resin domain (in comparison to the Eigen value in the gel domain) is an important phenomenon that lends support to the interpretation (in a large number of applications reported in the literature) of DGT probing mostly the labile concentrations. A toxicokinetics approach to assess bioavailability of copper, chromium and arsenic to earthworms in contaminated soils

J.J. Kilpi-Koski, Department of Environmental Sciences Faculty of Biological and Environmental Sciences; V. Haili, University of Helsinki / Department of Environmental Sciences Faculty of Biological and Environmental Sciences; O. Penttinen, University of Helsinki / Faculty of Biological and Environmental Sciences; A. Vaisanen, University of Jyvaskyla; C.A. Van Gestel, Vrije Universiteit, Department of Animal Ecology
In Finland there are more than 20,000 contaminated sites including around 200 sites used for wood salt impregnation, often using a copper-chromium-arsenic (CCA) mixture. The remediation of those sites requires insight into the potential risk of the contamiation, which asks for determining bioavailability of the contaminants. In this study soils were taken from an old wood impregnation site, from four different spots with high, medium, and low pollution level, and a control (C) to obtain a gradient of CCA contamination. An uptake-elimination kinetics experiment following OECD guideline 317, using the earthworm *Eisenia andrei*,was performed to assess bioavailability of the metals, which was related to total, water and 0.01 M $CaCl_2$ extractable copper, chromium and arsenic concentrations in the soils. In the low contaminated soil, containing 12.5 mg Cr/kg dry soil, 5.1 mg Cu/kg and 10.1 mg As/kg, no uptake of copper, chromium and arsenic was seen, with earthworm concentrations remaining more or less constant at approximately 7.7, 0.9 and 22 mg/kg body weight, respectively throughout the uptake and elimination phases. The medium and high contaminated soils contained similar Cr (1477-1592 mg/kg) and Cu (642-791 mg/kg) levels, while As concentration was highest in the high contamined soil (850 versu 2812 mg/kg). In both soils, copper and chromium showed very fast uptake and elimination kinetics. For copper, uptake rate constants (k1) were 0.16-0.19 kg soil/kg earthworm/day and elimination rate constants (k2) 2.2-2.4 per day. For chromium uptake and elimination were so fast that it was hard to obtain reliable k1 and k2 values. For both metals, steady level was reached within a day and after transfer of the earthworms to clean soil they reached the background level also within one day. Arsenic showed very slow uptake and elimination kinetics in the medium and high contaminated soils. Steady state was not reached within 21 days of exposure. For arsenic, k1 values were 0.0065-0.011 kg soil/kg earthworm/day and k2 was 0.006-0.012 per day. From these values, a bioaccumulation factor (BAF) of 0.55-1.78 was estimated for arsenic bioaccumulation in earthworms. The results show that in the low contaminated Hartola soils, the CCA metals have a low bioavailability. In the medium and high contaminated soils, however, all metals are bioavailable and taken up by earthworms. It seems the risk of CCA-contaminated soils near Hartola is mainly in the high bioavailability of arsenic.

Modelling of chemical fate and exposure in a regulatory context (II)

EFSA Guidance Document on clustering and ranking of emissions of plant protection products from protected crops (greenhouses and crops grown under cover) to relevant environmental compartments

M. Egsmose, EFSA; T. van der Linden, RIVM
EFSA was asked by the Commission (DG SANCO) to draft an EFSA Guidance Document [3]. This guidance is intended for the risk assessment of plant protection products (PPPs) active substances and their transformation products (metabolites) when emitted from covered crop structures. Guidance is provided for when the same methodology as for open field can be used and be considered representative or conservative, and when special approaches are more appropriate.

266

Progress in regulatory degradation kinetics

J. Ranke, Johannes Ranke wissenschaftlicher Berater
This contribution discusses the potentials and shows examples of using the single first-order reversible binding (SFORB) kinetic model for parent and metabolites. Secondly, an elegant method for the generation of plausible confidence intervals for rate constants and sets of formation fractions based on internal parameter transformations is presented. Definition of kinetic models, forward simulation (prediction) and fitting was performed using the R package mkin.\n While the single first-order (SFO) kinetic model is a one-box model, the dual first-order in parallel (DFOP) model and the SFORB model are best described as two-box models. In spit of the two forms of the parent compound occuring in these models, the pattern of metabolite formation generated from them is exactly the same. However, using the SFORB model makes it possible to use Eigenvalue based solutions, which is significantly faster than using the lsoda algorithm from the deSolve package. Benchmarking results for solving the kinetic models discussed above are given in Table 1.\n\n Model deSolve (lsoda) Eigenvalue DFOP - SFO 0.276 s not implemented SFORB - SFO 0.374 s 0.005 s *Table 1: Benchmarking results in seconds for the different model variants and solution methods* The precision of the Eigenvalue based solution is illustrated by the fact that the lsoda based solutions converge to the eigenvalue based solutions when the absolute and relative error tolerance used in calling lsoda are decreased. For the purpose of leaching simulations, the SFORB model parameters can be converted to the parameters of the kinetic sorption model implemented in the FOCUS-PEARL and FOCUS-PELMO models when linear sorption is assumed. For metabolites, a lack of fit of the SFO model due to biphasic degradation can sometimes be observed in aerobic soil degradation data, and the fits to such data can substantially be improved by using the SFORB model for these metabolites, resulting in lower χ^2 error-levels and possible leading to acceptance of a metabolite fit where the SFO fit would be rejected. The use of of internal parameter transformations for making the assumption of a normal distribution for the parameter estimates viable has been demonstrated earlier. Meanwhile, the calculation of confidence intervals on the basis of these transformations has been implemented, and practical examples, including plausible confidence intervals for formation fractions are demonstrated. \n \n \n

EFSA guidance for evaluating laboratory and field dissipation studies to obtain DegT50 values of active substances of plant protection products and their transformation products in soil

J. Boesten, Alterra / ERA team; A. Boivin, ANSES; M. Egsmose, EFSA; M. Klein, Fraunhofer Institute of Molecular Biology and Applied Ecology; C. Lythgo, EFSA European Food Safety Authority; A. Massey, Chemicals Regulation Directorate HSE
EFSA was asked by the Commission to prepare a guidance of EFSA for evaluating laboratory and field dissipation studies to obtain degradation rate parameters (DegT50 values) of active substances of plant protection products and their transformation products in soil. The EFSA guidance provides guidance for users on how to obtain *DegT50* values when performing risk assessments according to Regulation EC no 1107/2009 of the European Parliament and the Council. The aims of this guidance are: (i) to provide methods to derive the soil matrix *DegT50* from individual laboratory and field dissipation studies, (ii) explain how to determine whether the databases of *DegT50* values from laboratory and field studies can be treated as separate databases or whether they should be pooled, (iii) provide guidance on selecting the appropriate input value for use in exposure modelling. The guidance for the field dissipation studies considers two aspects. The first considers the design of tailored *DegT50* field studies. Such studies need an experimental design that aims to exclude the influence of surface processes and

leaching as far as possible. The kinetic fitting of the experimental results should be carried out following FOCUS kinetics guidance. The second aspect considers the procedure to be taken where surface processes have not been minimised. This procedure consists of decision-making flow charts to derive the most appropriate kinetic model and thus derive the *DegT50*. The underlying principle of these flow charts is that the degradation rate obtained should not include other processes than degradation within the soil matrix. The purpose of the selection of the appropriate input value for use in exposure modelling is to obtain a median *DegT50* for the population of agricultural/ horticultural field soils in the area of use of the substance. The medians of the laboratory and field *DegT50* values are estimated using a geomean estimator. The selection is based on a decision-making flow chart in which it is tested whether the *DegT50* values from the separate laboratory and field databases are statistically different. If yes, the laboratory values are discarded and the field DegT50 values are used provided that at least four field *DegT50* values are available for active substance or three for each metabolite. If no, the guidance recommends pooling all the laboratory and field *DegT50* values. Note: the content of this abstract does not necessarily represent the official views of EFSA.

Which role plays the scenario selection for pesticide risk assessment of soil organisms? – A case study with the vertical distribution model for Collembola FOLCAS

V. Roeben, RWTH Aachen University Institute for Environmental Research / Institute for Environmental Research BioV; M. Ross-Nickoll, RWTH Aachen / Institute for Environmental Research; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; F. Scherr, Bayer CropScience AG / Environmental Modelling; T.G. Preuss, Bayer CropScience / Institute for Environmental Research

This study investigated how scenario selection in exposure assessment may influence the ecological risk assessment for soil organisms. For this purpose the recently developed individual-based vertical distribution model FOLCAS - Folsomia candida Simulation - was used. FOLCAS simulates the dispersal of the soil-dwelling collembolan *Folsomia candida* in an agricultural soil column in order to investigate effects of variations in environmental parameters on population behaviour and distribution in the soil. In addition, the model is able to evaluate the influence of a pesticide application by simulating the exposure of the population as a result of their dispersal including the subsequent effects on reproduction and mortality. The environmental parameters and pesticide exposure data are derived from calculations with the numerical fate model PEARL. FOLCAS was applied to simulate different European agricultural soils in order to evaluate the effect on the dispersal of the population and therefore on the possible exposure to a pesticide under a range of conditions. In addition, different crops were simulated to elucidate the effect of crop selection on the population distribution. The off-market pesticide Lindane was used as a model substance at concentrations within the dose-response range for *F.candida*. Furthermore, recently published European scenarios for assessment of exposure of soil organisms to plant protection products were tested ("EFSA Scenarios"). The results indicate that the exposure of collembolan communities depends on the environmental parameters, the emerging vertical distribution, and the soil properties of the according scenario simulated and the population demography. First tests using the EFSA scenarios showed that winter temperatures in the scenarios are too cold to be able to establish stable populations of *Folsomia candida* given the current literature based parameterization of the model. Based on this study it can be concluded that scenario selection in exposure assessment influences the ecological risk assessment for soil organisms. Study results further elucidate the influence of crop selection by illustrating different effect expressions of pesticides on collembolan populations living in soil. Through linking exposure and effect assessment ecological modeling offers a powerful tool to identify discrepancies and subsequently to take a step toward bridging the gap between exposure and effect assessment in environmental risk assessment.

Importance of exposure dynamics in aquatic ecosystem risk assessment

M. Morselli, University of Insubria / Department of Science and High Technology; M. Semplice, University of Turin / Department of Mathematics; A. Zichella, A. Di Guardo, University of Insubria / Department of Science and High Technology

The goal of ecological risk assessment (ERA) is to quantify the risk that a given chemical would impair the structure and function of natural ecosystems by assessing its environmental exposure and the expected ecological aspects. However, the environmental realism, ecological relevance and methodological accuracy of the currently used exposure and effect assessment approaches have been questioned for years. For example, exposure to chemicals is generally modelled using *steady-state* approaches, which do not account for spatial and temporal variations of emissions and environmental parameters. In this context, the European Chemical Industry Council (CEFIC)-Long-range Research Initiative project “ChimERA: An integrated modelling tool for ecological risk assessment” was started, with the main objective of coupling separate exposure and effect models into a chemical integrated exposure and effect ecosystem model for ecological risk assessment (ChimERA) in aquatic environments. In this work, the development of the dynamic fate and exposure sub-model is presented. The modelling unit, based on the dynamic water-sediment model DynA, now includes other compartments and sub-compartments, such as macrophytes, phytoplankton, particulate organic carbon (POC) and dissolve organic carbon (DOC). Moreover, the sediment compartment was divided in a number of layers to account for the spatial variability of exposure in benthic populations. After a preliminary sensitivity analysis, some simulations were performed to illustrate the effect of the most influential parameters (e.g., chemical emission, POC and DOC concentrations, macrophyte density, etc.) on exposure levels of three selected chemicals. A preliminary scenario was also prepared to include some of the parameters which change over a year cycle (water fluxes, macrophyte and phytoplankton growth, DOC/POC production, etc.). The modelling approach presented in this work, combined with the effect sub-model included in the ChimERA framework, could be a vital tool for the identification of those environmental and ecological conditions where risk is expected to be highest. *Acknowledgement* - The ChimERA project is financed by the Long-range Research Initiative of CEFIC (www.cefic-lri.org) (project code: LRI-ECO19).

Which exposure profile counts? Estimating worst case scenarios based on ecotoxicological relevance

B. Daniels, RWTH Aachen / Institute for Environmental Research BioV; T.G. Preuss, Bayer CropScience / Institute for Environmental Research

Current risk assessment procedures for chemicals in the aquatic environment consider realistic worst case scenarios determined by the highest predicted environmental concentration (PECmax) of this chemical among the calculated exposure scenarios. However, the time-dependent concentration dynamics of the estimated exposure scenarios are not considered in the selection of worst-case scenarios yet. In this study we present a generic concept to compare the ecotoxicological relevance of several different dynamic exposure scenarios and to identify the worst case scenario by applying TKTD models. The TKTD-model GUTS of fourteen different organism-substance combinations with various aquatic freshwater species and chemicals with different modes of action (including fast effects, carry over toxicity and delayed effects) were used to simulate survival rates for different exposure scenarios. In addition, TKTD parameter values were randomly generated and added to the model in order to obtain well-founded and holistically applicable results. The selected exposure profiles were a combination of calculated realistic scenarios and theoretically possible concentration changes over time. We used in total more than 400 different exposure scenarios in variable test replicates. The ecotoxicological relevance of the exposure profiles, characterized by the simulated mortality rate of the different organisms and chemicals, was converted into an ordinal scale (scenario ranking).This ranking was subsequently compared with the respective ranks of the scenarios based on different scenario descriptors (PECmax, AUC, etc.). We showed that the use of the PECmax as a driving descriptor for the impact of an exposure profile is an imprecise and often wrong method to estimate the risk of a scenario. It does not necessarily correlate with the effective impact of the scenarios towards organisms. This can lead to an underestimation of exposure profiles and to the choice of wrong worst case scenarios. However, using the descriptors PECmax and AUC in combination (min(PECmax, AUC)), by selecting the lower of both ranks for each scenario, leads to a protective prediction value for the ecotoxicological relevance of scenarios. With this descriptor the ecotoxicological impact of exposure scenarios can be compared and predicted protectively. This could be another step towards a more realistic link between exposure and effects and leads to a more thorough environmental risk assessment.

Advancements in life cycle impact assessment and footprint method development (II)

271

Combining spatially distributed land and water use impacts to an endpoint of global species extinction and application to a Kenyan case study

F. Verones, Radboud University Nijmegen / Department of Environmental Science; L. de Baan, ETH Zurich IED / NSSI; S. Hellweg, ETH Zurich / Institute of Environmental Engineering

Assessment of ecosystem damages made large progress during past years. However, none of the currently utilized methods on endpoint level take vulnerability of species and global extinction risk of species into account. We used recently developed methods for assessing biodiversity loss from land and water use in terms of “global species-equivalent loss” that account for these issues. Data on mammals were available for both land and water use assessments, while 3 additional taxa (birds, amphibians, reptiles) were included for water use. We discuss different weighting schemes to arrive at a common endpoint. We illustrate the application in a case study of 1 kg of sugarcane, tea and flower production in Kenya. For the land use assessment, characterization factors (CFs) were calculated

for mammals for both occupation and transformation impacts. Flower production had the highest CFs (1.1E-07 species-eq·yr/m^2 for transformation and 5.7E-10 species-eq/m^2 for occupation) because the production region is home to very vulnerable species. Final impacts on biodiversity were 6.7E-09 species-eq·yr/kg for flowers, 2.1E-10 species-eq·yr/kg for tea and 1.5E-12 species-eq·yr/kg for sugarcane. Impacts were for all crops dominated by transformation. For the water use assessment, we assumed that tea and sugarcane were irrigated with surface water, flowers were irrigated with both surface and groundwater. CFs varied between 1.5E-15 species-eq·yr/m^3 for reptiles (flowers) and 9.7E-09 species-eq·yr/m^3 for waterbirds (sugarcane). 3 weighting schemes were applied for aggregating across taxa within water use: 1) all species have equal weight, 2) weighting according to species richness of taxa, and 3) weighting according to average vulnerability of taxa. Results differed substantially for the different weighting schemes. Impacts for sugarcane were between 3.9E-10 – 1.5E-09 species-eq/kg and for flowers and tea between 1.6E-13 – 6.8 E-13 species-eq/kg and 3.1E-10 – 1E-09 species-eq/kg, respectively. For total impacts on mammals, land use impacts contributed between 14% (sugarcane) and almost 100% (flowers) to the total damage. Considering all taxa (with a weighting scheme), the share of land use impacts was between 0.1 – 0.4% (sugarcane) and 99.9 % (flowers). The importance of water use impacts increased due to more taxa and species considered. With the new unit, differences between impacts, due to different species richness and vulnerabilities were revealed.

272

The water accounting and vulnerability evaluation model (WAVE): Considering atmospheric evaporation recycling and the risk of freshwater depletion in LCA and water footprinting

M. Berger, Technische Universitaet Berlin / Chair of Sustaiable Engineering Office Z; R. van der Ent, Delft University of Technology; S. Eisner, Univerity of Kassel; V. Bach, Technische Universitaet Berlin / Chair of Sustainable Engineering; M. Finkbeiner, DaimlerChrysler AG / Chair of Sustainable Engineering

Aiming to enhance the analysis of freshwater consumption along products’ life cycles, the water accounting and vulnerability evaluation (WAVE) model is introduced. On the accounting level, the atmospheric evaporation recycling within drainage basins is considered by means of the basin internal evaporation recycling (BIER). Results show that, depending on the climatic conditions and the size of the basin, up to 38% of evapo(transpi)rated water can return to the originating basin via precipitation. When taking into account the runoff fraction, i.e. the hydrologically effective share of precipitation, 10-33% of evapo(transpi)ration return as blue water in basins in the Himalayas, Alaska, south-east Asia, and the North of South America. In order to allow for an assessment of potential consequences resulting from water consumption, the vulnerability of drainage basins to blue water depletion is evaluated. This vulnerability approach distinguishes the WAVE model from conventional characterization models describing consequences on resources. Rather than “predicting” impacts on freshwater resources, WAVE denotes the risk that water consumption in a certain region will lead to freshwater depletion. This risk of freshwater depletion (RFD) can be determined by multiplying the effective water consumption in each basin with its corresponding water depletion index (WDI). WDI denotes the vulnerability of drainage basins to freshwater depletion based on physical blue water scarcity. In contrast to previous works, water scarcity is measured based on a consumption rather than a withdrawal-to-availability ratio and accounts for the presence of ground and surface water stocks for the first time. In order to consider absolute freshwater shortage in addition to relative scarcity, WDI is automatically set to the highest value in (semi-)arid basins. WDI is at the highest level in many drainage basins located in Central Asia, India, Saudi Arabia, Australia, Northern and Southern Africa, Mexico, the south-west of the USA, and the Andes. In contrast, little or no freshwater resource depletion is caused by water consumption in most basins located in Russia, Canada, Northern Europe, or around the equator. A concept is presented, how this advanced scarcity index can be used as a starting point for assessing impacts on resources, human health, and ecosystems on the endpoint level.

273

Alternatives to GWP in LCA: temperature metrics and explicit time profiles

F. Cherubini, NTNU / Energy and Process Engineering; A. Levasseur, CIRAIG École Polytechnique de Montréal / Chemical Engineering

The Global Warming Potential (GWP) for different time horizons (TH) was introduced by the International Panel on Climate Change (IPCC) in 1990 as an illustrative example of a potential global warming metric. Nevertheless, GWP with TH = 100 years has become the nearly exclusive emission metric used in Life-Cycle Assessment (LCA), as well as in other fields. The main criticisms of GWP regard 1) its lack of clear physical meaning in terms of temperature change, 2) the treatment of time, including the arbitrary choice of a TH, and 3) the fact that GWP is an indicator of cumulative warming which is less suitable for some climate impacts such as those associated to reaching an irreversible tipping point. For instance, because GWP assigns equal weight to emissions irrespective of the policy target and the proximity to it, it is inappropriate in the context of policies aiming at maintaining temperature changes below a given target. A few recent initiatives and research works have addressed some of these issues in the LCA community. However, a critical discussion about global warming characterization in LCA is needed since a wider range of metrics are today available for aggregating the climate impacts of different emissions to common units (e.g., kg CO_2-equivalent). Metrics based on temperature like the Global Temperature change Potential (GTP) evaluates the impact on surface temperature at a given point in time and are therefore more compatible with global policy mitigation targets. To this regard, the new 5th IPCC Assessment Report has produced characterization factors for both GWP and GTP. Here we show, using LCI data from default case studies, the large importance that the choice of a metric may have for the global warming impact category. Climate impacts based on instantaneous temperature changes differ from those based on the traditional GWP, as they are generally smaller in magnitude and shorter in time. Beside normalized indicators, the explicit inclusion of time transparently shows the time dependence of the climate effect of emissions and enhances the understanding and interpretation of the climate impact potential. The role of metrics other than GWP and their additional insights should be further investigated by LCA practitioners, especially when analyses are intended to support policy makers in the identification of the best climate change mitigation strategies.

274

Estimation of Effect Factors for application to marine eutrophication in LCIA

N. Cosme, Technical University of Denmark DTU / DTUMAN QSA; M.Z. Hauschild, Technical University of Denmark / Department of Management Engineering

Marine eutrophication is defined as the set of ecosystem responses to nutrient loadings in the photic zone of marine waters. The nutrients enrichment boosts primary production and subsequent degradation of this organic matter by heterotrophic bacteria in bottom waters results in the consumption of dissolved oxygen (DO). Impacts to ecosystems health and local economy may rise from changed communities’ composition, species interaction, decrease of water quality and depleted DO in bottom waters down to hypoxic or anoxic levels that may affect the survival of benthic species. The impacts of hypoxia on biota depend on the severity, frequency and duration of the exposure to low DO, and both acute and chronic effects can be expected. Exposure to extreme or prolonged hypoxia leads to mass mortalities, but hypoxia also induces many different sub-lethal responses in organisms at the behavioural, physiological and ecological levels. The geographical distribution of relevant benthic, demersal, or benthopelagic species (n=58), available from a dataset of sensitivities of individual species to hypoxia, was found. These were grouped into 5 climate zones - polar, subpolar, temperate, subtropical, and tropical. Species Sensitivity Distribution (SSD) curves were produced to estimate the Potentially Affected Fraction of species (PAF) at different levels of DO. For the application in Life Cycle Impact Assessment (LCIA), the distribution of the sensitivities of individual species to hypoxia is used to estimate the sensitivity to low DO levels of the communities found in each climate zone. The distribution is used to estimate the HC50, i.e. the concentration of DO (intensity of the stressor) affecting 50% of the species above their EC50 level. Characterisation Factors (CF) are used in LCIA to convert emissions and resources consumed into impact potentials for specific impact categories. The CF integrates the Fate Factor (FF), the habitat Exposure Factor (XF), and the Effect Factor (EF). The EF expresses the change of effect due to a variation of the stressor intensity and it is calculated by EF=ΔPAF/(Δ[O2])=0.5/HC50, in accordance to the average gradient method. Preliminary EF results were produced for the 5 climate zones together with a global default. The spatial differentiation obtained for the EF results was found essential to increase the discriminatory power of the model. This approach will be combined with a suitable methodology for the FF and XF.

275

From methodological developments to actual action plans in the industry: example of water availability footprinting applied to electricity production

A. Prieur Vernat, A. Blot, GDF SUEZ / CRIGEN; J. Mertens, Laborelec GDF Suez; E. Marcellan, GDF SUEZ / CRIGEN; E. Favrot, GDF SUEZ

Over the last few years and in parallel with climate change, sustainable water use has been receiving more and more attention. In particular, water use in energy production has become an important issue. Therefore, there exists a need within utility companies to measure their water footprint and identify hot-spots where water scarcity is a potential issue and intervention may be required. The objective of this study is twofold. It aims first to illustrate how the existing water availability footprint methodologies apply to electricity production and discusses the applicability of the three methods and the potential improvements needed in an industrial context. 13 different power plants were modeled to calculate their water availability footprints according to 3 methodologies : Pfister et al., 2009, Boulay et al., 2011 and Frischknecht et al., 2006. All methods have been considered through characterization factors at the watershed level, thus implying modification of the default factors available in Quantis Suite. The model was built-up so that the water footprint can be evaluated separately for: (i) fuel supply chain, (ii) operation of PP, (iii) cooling water, (iv) water demineralization installation and (v) infrastructure building. The results obtained within this study show that, from an industrial

perspective, it remains impossible to put forward one method based on the state of the art, as the ranking amongst power plants and the relative contributions of direct and indirect operations may differ between different methods, even when differences in water consumptions are large, and hence the prioritization of action plans. This is clearly a barrier to the deployment of such methodologies by the industry, as there is a need of robustness of the methods in order that they can be used as decision making tools. This study shows that there are still some gaps to fill before a water availability footprint methodology can be recommended, at least to be applied to electricity production. The main difficulty is to choose amongst available water availability footprints, given that results may be very different and imply different improvement actions. A consensus is thus needed, either to choose one of the methods or to build another one. An analysis based on statistics could be useful to identify, for a given sector or product, the most sensitive parameters of each of the methods, and the common characteristics.

Risk assessment of chemical mixtures: strategies, bottlenecks, and the steps ahead (II)

276

Nutritional modulation of environmental pollutant toxicity: Implications for risk assessment

M.C. Petriello, University of Kentucky / Toxicology; B. Hennig, Univeristy of Kentucky

An emerging body of evidence correlates persistent environmental toxicants, such as dioxins and PCB mixtures, with human diseases like diabetes and atherosclerosis. Many communities that reside in and around Superfund and related hazardous waste sites face daily contaminant exposure risks in addition to the impact of a multitude of other physiological and social stressors. One such confounding stress, sub-optimal nutrition, has now been shown to exacerbate toxicant-induced disease. Toxicants and poor nutrition both promote chronic inflammation and oxidative stress and have been shown to work synergistically to promote a more profound disease phenotype. Interestingly, new evidence now shows that diets focused on healthful nutrition (e.g., diets centered on fruits, vegetables and healthier fats) may be able to counteract the detrimental effects of persistent organic pollutants such as PCB mixtures. We have shown that mice supplemented with the tea catechin EGCG, a polyphenol, are protected against PCB-induced inflammation and oxidative stress by exhibiting a more efficient antioxidant response. Similar results have been seen in mice supplemented with DHA, a long-chain omega-3 PUFA, and subsequently exposed to coplanar PCBs. Although complete remediation of persistent environmental pollutants may be preferred to eliminate their contribution to disease pathologies, this process is extremely time-consuming and cost-prohibitive. Therefore, it is necessary to identify easily available modulators of toxicant-induced disease. Bioactive food components such as polyphenols and omega-3 polyunsaturated fatty acids may act as a sensible means to provide physiological “buffers” against toxicant-related diseases. This new paradigm that the nutritional status of an individual can impact the toxicity of pollutants has important ramifications for risk assessment and exposure sciences. Understanding the nutritional makeup and tendencies of a community will allow scientists to better measure and estimate true risk of a specific pollutant or mixture. As part of the University of Kentucky’s Superfund Research Center, active community engagement aims to educate and inform communities directly impacted by daily exposures to persistent environmental pollutants.Through nutritional education, counseling, and demonstrations we empower individuals to make smarter eating decisions that can help to buffer against chronic exposures to environmental contaminants.

Zounkova, Masaryk University Faculty of Science RECETOX

Thousands different chemicals are discharged into the environment from agriculture, industry, medical facilities, house-holds. Currently, there is an increasing concern for the environmental impact of mixture of compounds since the additive and eventual synergistic effects are unknown and could produce serious adverse effects. Recently, a document from the European Commission on combination effects of chemicals highlighted the need to ensure that risks associated with chemical mixtures are properly understood and assessed. To address this issue, a joint-effort of 16 European and associated research groups participated to an exercise to test a synthetic reference chemical mixture on the own routine bioassays to investigate the chemical mixtures effects. The reference material included class of pesticides, pharmaceuticals, industrial products, heavy metals and polyaromatic hydrocarbons. The mixures were prepared, each compound at Equivalent Quality Standard (EQS) value, the safety limit concentration allowed by the European Water Framework Directive, (WFD).The bioassays proposed by the groups could cover the entire ecosystem from bacteria to fish as well *in vitro* assays providing an unique scenario from ecological risk assessment perspective. The results showed that effects were observed at very low concentration on algal-bacteria composition in a marine microcosm, immobilization in crustacean, fish embryo toxicity and frog embryo development. We conclude that some precaution on the chemical mixture assessment should be taken even in case the individual compounds are present at EQS, the safety limit concentration under European legislation.

278

Ecotoxicological assessment of immersion samples from façade render

E. Vermeirssen, Eawag / Dept of Environmental Toxicology; C. Dietschweiler, University of Applied Sciences; S. Campiche, Swiss Centre for Applied Ecotoxicology; M. Junghans, Swiss Centre for Applied Ecotoxicology EAWAG EPF / Ecotox Centre; A. Schifferli, Swiss Centre for Applied Ecotoxicology Eawag/EPFL; C. Kienle; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; M. Burkhardt, HSR Hochschule für Technik Rapperswil

To protect façade renders from growth of bacteria, fungi and algae, biocides can be added to a render before it is applied onto a façade. A comprehensive protection can be achieved by combining several biocides. During rain events and over time, biocides will gradually leach out and thus have the potential to affect soil or aquatic ecosystems. In this study the leaching behaviour of three biocides (terbutryn, OIT, DCOIT) from three render formulations was evaluated: one render contained free biocides, another encapsulated biocides and a control render had no biocides. The renders were applied onto extruded polystyrene panels and water samples were generated over 9 immersion cycles of the panels in accordance with standard EN 16105. Concentrations of the biocides were measured using LC-MS. The toxicity of the first and ninth immersion samples was determined using bioassays. Toxicity to aquatic organisms was evaluated by assessing inhibition of photosynthesis and algal growth rate, inhibition of bacterial luminescence and inhibition of daphnid population growth. Toxicity to soil organism was assessed by determining avoidance behaviour of worms and reproductive output in springtails. Encapsulation reduced the leaching of terbutryn, OIT, and DCOIT 4-, 17-, and 25-fold compared to free biocides. Generally, the toxicity of water from render containing encapsulated biocides was always lower than that of render with free biocides and toxicity was 4- to 5-fold lower for the ninth immersion day compared to the first immersion day sample for both free and encapsulated samples. For the aquatic organisms, inhibition of photosynthesis was the most sensitive endpoint, followed by algal growth rate, bacterial bioluminescence and daphnid reproduction.

At all tested sample concentrations, none of the samples with biocides caused effects on soil organisms. Results from bioassays matched quite well with expected bioassay responses based on chemical analysis and the toxicity of the individual biocides. It could be concluded that the toxicity of given concentrations on algae is explained by terbutryn whereas the toxicity on bacteria and daphnids is caused by DCOIT and OIT. The results thus indicated that other components in the render did not add to the toxicity of the individual biocides. Overall, the approach combining a standard leaching test with standard bioassays is very promising to evaluate the ecotoxicity of biocides that leach from façade renders.

279

Qualitative environmental risk assessment of photolytic transformation products of Iodinated X-ray contrast media (ICM) Diatrizoic acid

T. Rastogi, Leuphana Universitat Luneburg / Institue of Sustainable and Enviornmental Chemistry; C. Leder, Leuphana Universität; J. Menz, Leuphana University Lüneburg / Institute of Sustainable and Environmental Chemistry; M. Schneider, Universität Lüneburg / Nachhaltige Chemie und Umweltchemie; K. Kümmerer, Institute of Sustainable and Environmental Chemistry

One of the worldwide used genres of chemical for intravascular administration is ICM which heavily contributes to the total adsorbable organic halides load in municipal and hospital effluents. Therefore it is necessary to assess the environmental risk caused by these ICMs. In this study, a combination of analytical methods, *in silico* predictions, biodegradation testing and *in vitro* toxicity screening using luminescent bacteria (modified luminescent bacteria test [LBT]) for initial analyses of the environmental fate and effects imposed by the photodegradation TPs (PTPs) of Diatrizoic acid (DIAT). DIAT was photolytic transformed under UV irradiation. Its PTPs and a degradation pathway were elucidated. DIAT and PTPs were assessed by the USEPA PBT profiler which indicated DIAT as persistent chemical and its photo-TPs as comparatively less persistent and possess no bioaccumulation threat to aquatic organisms. The mixture of PTPs was subjected to standardized OECD 301 biodegradation test assays. The results indicated that a few of the PTPs were comparatively better biodegradable than DIAT itself confirming the *in silico* readily biodegradable predictions of PTPs. These comparatively better biodegradable PTPs were identified. Although, the slight inhibitory effect was observed against the inoculum’s bacteria which indicates that some of the formed PTPs might be toxic to bacteria. However, few PTPs were predicted by *in silico* models to be toxic against environmental bacteria. These predicted toxic PTPs were also identified to be non-biodegradable. LBT assays demonstrated an increase of acute and chronic toxicity against *Vibrio fischeri* for the mixture of PTPs with highest inhibition after 32 and 64 min irradiation. Although these predicted toxic PTPs were formed in low yield but might have additive or synergistic mixture effects in LBT and the inhibition in biodegradation test assays. Furthermore, few photo-TPs were predicted to be active for mutagenicity and genotoxicity which indicates the need for further testing to confirm these predictions. *In silico* predictions and *in vitro* test results were in direct correlation but the formation of free Iodine during photodegradation might be responsible for the inhibition against bacteria in LBT assay which require further testing to confirm. However, the elucidations of the structural formula of TPs are sufficient to collect appropriate data as a basis for an environmental risk analysis.

280

Bioanalytical and Chemical Evaluation of Swimming Pool Water

R.Y. Yeh, Entox; M.J. Farre, The University of Queensland / Advanced Water Management Centre; D. Stalter, The University of Queensland / National Research Centre for Environmental Toxicology Entox; J.Y. Tang, The University of Queensland / ENTOX; J. Molendijk, The University of Queenland / National Research Centre for Environmental Toxicology; B.I. Escher, Helmholtz Centre for Environmental Research GmbH UFZ / Cell Toxicology

The use of chemical disinfectants in swimming pools is vital to prevent pathogens from causing adverse human health effects. However, toxic disinfection by-products (DBPs) are formed from the reaction between disinfectants and organic/inorganic precursors. The aim of this study was to assess the toxicity and presence of DBPs in various swimming pool types in Brisbane, Australia. The combination of chemical and bioanalytical tools was applied to evaluate the toxicological relevance of the known fraction of DBPs compared to the unknown fraction of total contaminants. Further, we assessed one pool fortnightly during 6 months after a complete water exchange. The time series revealed that chlorinated organic compounds were higher concentrated compared to tap water while the brominated compounds decreased over time, indicating a removal and/or volatilisation without reformation. Haloacetic acids (HAAs) were the dominating DBPs with highest concentrations for dichloroacetic acid and trichloroacetic acid (up to 26× higher than the Australian drinking water guideline value of 100 µg/L). Up to 100% of the organic halides (AOX) could be explained by the detected HAAs, which is extraordinary high compared to DBPs in drinking where the knowns often explain less than 50%. Despite the high agreement between AOX and HAAs, HAAs explained only up to 4% of non-specific toxicity (Microtox) and ≤1% of oxidative stress response (AREc32) and genotoxicity (UmuC). This indicated the presence of other contaminants, which contributed to the overall toxicity in the pool water samples. The p53 induction was masked by cytotoxic effects for most of the samples and is hence not further discussed. The bioassay response of pool water was within the range of tap water indicating a comparable level of toxicity. While chlorinated organic compounds are higher concentrated in pool water, the toxicologically more relevant brominated organics decreased over time and were generally considerably lower compared to tap water. Despite their predominating concentrations, HAAs account for < 5% of the bioassay responses, indicating a) a low toxicological relevance of both HAAs in the comlex mixture of the samples and b) the presence of other contaminants, which contributed to the total toxicity. This study demonstrates the necessity of combining chemical and bioanalytical evaluation to provide a comprehensive picture of real-world mixtures for water quality and risk assessment.

Chemical pollution in sustainable management of aquatic ecosystems – challenges and approaches from a Swiss perspective (II)

281

The Swiss water policy for tackling chemical pollution

M. Schärer, U. Sieber, S. Müller, Federal Office for the Environment FOEN; P. Wunderlin, Eawag

Chemicals, often referred as micropollutants, such as pharmaceuticals, personal care products, pesticides, biocides, or endocrine disruptors, are organic trace contaminants present at very low concentrations in the water bodies (at nonagrams or micrograms per liter). Most of these substances are contained in municipal wastewater and discharged into receiving waters, since not sufficiently eliminated by state-of-the-art municipal wastewater treatment plants. Especially, rivers with inadequate dilution of treated wastewater inflows are subject to elevated micropollutant concentrations. These findings suggest that several measures have to be taken in order to further improve water quality: For example, the International Commission for the Protection of the Rhine (ICPR) stated in a recent strategy paper (Report No. 203) that emission into water bodies should be reduced. Moreover, several types of actions are discussed, which are: measures at the source (e.g. adaptation of product registration, optimization of production processes, regulation of use and disposal), decentralized measures, as well as centralized measures in municipal wastewater treatment plants (e.g. implementation of further treatment steps such as ozonation or the application of activated carbon). In Switzerland, 100 out of over 700 municipal wastewater treatment plants will be upgraded with advanced treatment processes in a targeted approach within the next 25 years. In that way, the total micropollutant load in municipal waste water will be reduced by 50 per cent, at estimated total investment costs of about CHF 1.2 billion, which is considered a justifiable cost/benefit ratio. In parallel, further steps will be evaluated, such as measures at the source or reducing diffuse inputs. Latter is currently addressed by several studies providing an overview of current measures, focusing amongst others on the field of agriculture (e.g. development of a national action plan) or urban water drainage.

282

Bank infiltration, river restoration and effects on drinking water: the relevance for Switzerland

D. Radny , Eawag; M. Schirmer, Eawag Swiss Federal Institute of Aquatic Science / Wasser Resources and Drinking Water

Around 80 % of Swiss drinking water is obtained from groundwater. 25 to 30 % of this groundwater is abstracted from aquifers that are hydraulically directly connected to a surface water body, mostly rivers. Here, a large portion of the extracted groundwater is freshly infiltrated surface water. During the percolation of the surface water through the aquifer an improvement of water quality is achieved by a series of physical, chemical, and biological processes (e.g. adsorption, reduction, biodegradation). With this, bank filtration can be seen as pre-treatment measure in the overall treatment chain. Consequently, Swiss regulations defined that the travel time for the subsurface passage from the surface water body to a drinking water well has to be at least 10 days to ensure that most microbial pathogens are filtered out or die off before they can reach the well. This regulation is also basis for the prohibition of river restoration measures next to bank filtration sites. River restoration in general increases river dynamics, environmental heterogeneity, biodiversity, and also the exchange of surface water and groundwater. Swiss legislation requires river restoration actions also as part of flood protection measures. This and the improvement of the ecomorphological status of selected river sections, mainly located in the Swiss plateau, are the main reasons for the decision of the Swiss government to restore river sections of a total length of about 4´000 km in the upcoming decades. These measures will have an impact on the river-river corridor-aquifer system and with this, also on bank filtration sites. To provide clean drinking water also in the future, the impact of numerous restored river sections on the groundwater needs to be investigated. With this an adequate understanding of the underlying hydrogeological and ecological processes can be developed.

283

Artificial groundwater recharge: conflicts between river water quality and drinking water needs?

T. Scheytt, TU Berlin

Naturally occurring recharge of groundwater is a well know process in humid areas. In order to enhance the amount of stored and available groundwater, water may additionally be recharged. Artificial groundwater recharge is a technical measure to increase available groundwater resources while using the natural attenuation capacity of the subsurface passage to improve the water quality. Use of artificial groundwater recharge has rapidly increased in Europe, USA, and in Australia in recent years not only for drinking water use but also as an efficient means of recycling stormwater or treated sewage effluent for non-potable and indirect potable reuse in urban and rural areas. During artificial groundwater recharge, surface water (e.g. from infiltration ponds) or treated sewage water is infiltrated into the aquifer and is extracted after subsurface passage at extraction wells. Artificial groundwater recharge offers opportunities for producing safe drinking water supplies where they do not exist. However, it relies first and foremost on the presence of suitable aquifers and safe sources of infiltration water together with effective water policies. Recently, a major concern in the application of artificial groundwater recharge for drinking water abstraction is the occurrence of persistent organic and inorganic compounds even at trace levels and pathogenic microorganisms. Therefore, research has focused on the removal of these contaminants including pharmaceutically active compounds like primidone, carbamazepine, and sulfamethoxazole and on removal of pathogens. In many places, not only groundwater is limited but also surface water. Artificial recharge of groundwater with river water may limit the amount of river water available for the river ecosystem, for downstream users, for industrial use of surface water including hydropower and for recreational purposes. The quality of the infiltrating water determines the overall quality of groundwater in the long-term which leads to the demand of infiltrating water with best quality only if drinking water is to be produced. Finally, due to climatic change these systems may have to be reevaluated based on the local impacts of climate change.

284

The Swiss strategy abating micropollutants: What can be learned for outside Switzerland?

R.I. Eggen, Eawag

Evolutionary, multigenerational and epigenetic effects of pollutants: providing scientific support to long-term ERA

Cd-resistance in field Gammarus populations: genetic adaptation, transgenerational effect, or selection of phylogenetic cryptic lineages?

A. Vigneron, Irstea / UR MALY Laboratoire Ecotoxicologie; R. Wattier, Université de Bourgogne / Biogeosciences; H. Queau, Irstea centre de Lyon Villeurbanne / UR MALY Laboratoire Ecotoxicologie; T. Rigaud, Université de Bourgogne / Biogeosciences; O. Geffard, a. chaumot, Irstea / UR MALY Laboratoire Ecotoxicologie

We have recently identified a field population of the crustacean *Gammarus fossarum* historically-exposed (geochemical background) to cadmium (Cd) that exhibits a resistance transmissible to offspring. This population constitutes a good case study to investigate mechanisms underlying population's resistance to long-term exposure to contamination that are of deep concern for ERA, especially in the field. In order to gain insights into the determinism of the Cd-resistance observed in this historically-exposed population, we applied quantitative genetic protocols both in two Cd-naive populations and in the resistant one. In addition, because *G. fossarum* is known to constitute a complex of cryptic species with potentially heterogeneous sensitivities to contaminants, we also tested whether this resistance could be explained by the selection of a peculiar phylogenetic group among the *Gammarus* diversity (based on COI genotyping). Our work reveals that the Cd-resistant population does not belong to a specific lineage and sustains that its resistance to Cd is due to transgenerational maternal effect induced by exposure in the field. Whether this transmissible resistance is fixed (phenotypic plasticity) or transitory (flexibility) is still to be investigated to decipher the role of acclimation in population resistance. Also, parental effects seem to be a key endpoint to understand the modification of sensitivities to contaminants in the field, and taking into account this phenomenon is mandatory to improve the relevance of ERA.

Molecular mechanisms behind snail metal sensitivity: Cadmium metallothionein gene transcription involves activation of metal responsive elements

M. Niederwanger, University of Innsbruck; V. Pedrini-Martha, University of Innsbruck / Institute of Zoology; M. Höckner, University of Innsbruck / Biology; R. Kopp, R. Dallinger, University of Innsbruck

Many animal species are able to cope with elevated Cd concentrations in their environment by upregulation of Metallothionein (MT) genes and binding the metal to the expressed MT protein [1]. In vertebrates and other animal species, MT gene transcription is mediated through the binding of the Metal Responsive Transcription Factor 1 (MTF-1) to Metal Responsive Elements (MREs) in the promoter region of the MT gene. Only little information was so far available about Cd-dependent MT transcription activation in terrestrial gastropods. Although their CdMT gene contains putative MREs, they apparently lack the MTF-1 [2], which raises the question of about how they upregulate their CdMT gene under metal exposure. In the present study, Roman snails (*Helix pomatia*) were exposed to elevated Cd concentrations over a period of 14 days, in order to track the accumulation of Cd in the midgut gland and to quantify, concomitantly, the transcription of the *CdMT* gene, as well as the expression of CdMT at the protein level. Low MT transcript copy numbers, low Cd concentrations and accordingly depressed CdMT concentrations were detected throughout the whole experiment in control animals. In contrast to this, Cd-exposed individuals showed increasing Cd concentrations within the midgut gland, along with a transient MT mRNA transcription peak on day 5 of exposure, whereas the respective MT protein concentrations increased from the beginning of the experiment reaching a persistent elevated level until the end of Cd exposure. In order to verify whether the MREs identified in the promoter region of the snail *CdMT* gene might be involved in its Cd-dependent transcriptional activation, DNase I footprinting was applied to control and Cd-exposed individuals. It appeared that the MRE b/c elements in the proximal promoter region of the Roman snail *CdMT* gene are functional as binding sites for transcription factors. Since snails do not possess an MTF-1, the nature of Cd-dependent transcription factors in their *CdMT* gene remains still unknown, suggesting the evolution of a detoxification mechanism in terrestrial gastropods that differs from most other animal species.

Cu and Zn selection leads to adaptation and heterozygote excess in a natural Daphnia magna population without affecting tolerance to novel stressors

J.D. Hochmuth, Ghent University; C.M. Pereira, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology; L. De Meester, Katholieke Universiteit Leuven / Biology; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology; K.A. De Schamphelaere, Ghent University UGent / Environmental Toxicology and Aquatic Ecology

Natural populations can genetically adapt to chemical stress through the process of micro-evolution. As a consequence the allelic constitution of the population is altered and overall population genetic diversity is reduced. We exposed a natural *Daphnia magna* population to a control, a Cu (180μg Cu/L), and a Zn concentration (760μg Zn/L) for 10 weeks under semi-field conditions to assess whether adaptation could indeed occur on such a short time scale. Populations which evolved under Cu and Zn during the microevolution experiment produced significantly more offspring under Cu and Zn exposure than the original population. At the end of the micro-evolution experiment DNA samples were taken fom the original population, as well as from the evolved aquaria populations and microsatellite genotyping was performed using a total of 13 microsatellite markers. We estimated the inbreeding coefficient (*F*), which is a measure of homozygous vs. heterozygous excess, where negative values specify an excess of heterozygotes, while positive values indicate an excess of homozygotes and we observed negative inbreeding coefficients (excess of heterozygotes) in the Cu and Zn adapted populations, while inbreeding coefficients were positive (excess of homozygotes) in the original and control evolved populations. After confirming adaptation to Cu and Zn, we assessed the cost of adaptation, whereby populations evolved under and adapted to either Cu or Zn, may become less tolerant to novel stressors. We compared the tolerance of the metal adapted populations to the original and control evovled populations to temperature and cyanobacteria diet stress (*Microcystis aeruginosa*). We did not detect noticable differences in tolerance to new stressors. We did notice that survival time of the population evolved at 760μg Zn/L was significantly lower relative to the control evolved population at 28°C. Overall our results suggest that adaptation to Cu and Zn leads to an excess of heterozygotes but that such an adaptation comes neither with a cost of tolerance nor a distinctive advantage when the adapted populations are faced with novel stressors.

Does the nutritional status of parental Chironomus tepperi midges influence the sensitivity of its offspring?

V. Colombo, CAPIM; L.A. Golding, CSIRO Land and Water; A.A. Hoffmann, BIO The University of Melbourne; V.J. Pettigrove, The University of Melbourne / Zoology; K. Townsend, University of Melbourne / CAPIM

Environmental stimuli can induce plastic variations in the life history traits of an organism without corresponding alterations in the genome.Such variations can be transmitted to the offspring through the inheritance of factors other than alterations in the DNA sequences (non-genetic inheritance or transgenerational effects).

Nutrition is an environmental factor known to cause generational effects also in humans. The present study considers the effects of parental nutritional status in *Chironomus tepperi* on some life history traits and metal sensitivity of offspring. This study is divided in two parts:\n The first experiment was designed to verify whether transgenerational effects are inducible in *Chironomus tepperi* by varying the nutritional status of the parents. This was achieved rearing the parents in three different feeding regimes (high, standard and low) and the offspring in the same regime (standard). The parental feeding regime "low" was chosen with the purpose of causing stress conditions. The second experiment aimed to evaluate whether the nutritional status of parental *Chironomus tepperi* influenced the sensitivity of offspring to zinc. We tested whether exposing the offspring of stressed parents to a stressor different from that experienced by the parents will reveal an advantage. Therefore the offspring was exposed to a sublethal zinc concentration (0.02 mg/L). Nutrition triggered transgenerational responses in *Chironomus tepperi*. Offspring of starved parents had a shorter larval development time in all treatments (in average 2 days shorter) and lower sensitivity to zinc. The opposite trend was observed in fecundity: offspring of well-fed parents appeared to benefit from the nutritional status of their parents, and produced bigger egg-ropes.
Transgenerational effects triggered by nutrition or nutritional stress are common in *Chironomus tepperi* and potentially in other *Chironomus* species. This can have major implications in ecotoxicology. Depending on the environmental conditions experienced by the parents, offspring may exhibit phenotypic variability and fitness differences. Species sensitivity may vary across populations and over time. This could be the cause of inconsistencies and variability among laboratories or within the same laboratory.

Effects of chronic gamma irradiation: a multigenerational study using Caenorhabditis elegans

A. Goussen, IRSN LRE LECO; B. Goussen, INERIS / Unit METO; C. Della-Vedova, magelis; S. Galas, CNRS / Centre de Recherches de Biochimie Macromoleculaire; C. Adam-Guillermin, IRSN; C. Lecomte-Pradines, IRSN LRE LECO

The assessment of environmental impact of exposure to ionizing radiation (natural and ubiquitous phenomenon enriched by human activities) has become a major concern. However, this environmental risk assessment is currently hampered by the lack of knowledge, and hence, is often based on extrapolation from data obtained for acute exposure. Studies on chronic exposure over several generations are so needed to understand the disturbances related to ionizing radiation and their possible consequences on the population. Regarding this background, we assessed the effects of chronic exposure to ionizing radiation over three generations of the ubiquitous nematode *Caenorhabditis elegans*. In this study *C. elegans* were chronically and individually exposed to gamma radiation (dose rates ranging from 6.6 to 42.7 mGy/h). The evolution of growth and reproduction (here, cumulated number of larvae per individual) of individuals were followed daily. Comparisons within and between the generations of *C. elegans* subjected to different exposure statuses: (i) three generations continuously exposed (F0, F1, and F2) and (ii) parental generation exposed (F0) and the following generations placed in recovery (F1' and F2') were performed. Our experiment showed no significant difference in growth between the control and the exposed individuals whatever the generation and the exposed status. However we observed a decrease in the reproductive ability between F0 and F2 at the highest dose rate (42.7 mGy/h). We also observed significant differences in the same generation subjected to different exposure statuses (exposed (F1) or recovery (F1')). Surprisingly, the non-exposed generation (F1') laid out less number of eggs than the exposed generation (F1). Our results confirmed that reproduction is the most sensitive endpoint affected by ionizing radiation and revealed transgenerational effects from parental exposure in the second generation (F1') and the third generation (F2). Using these results on reproduction, molecular and cellular effects of chronic exposure to ionizing radiations on germline are examined to better understand the mechanisms underlying the observed effects

Fish model species in environmental toxicology (III)

Novel approaches to assess the effects of glucocorticoids in zebrafish embryos

A.O. Hidasi, Eawag Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology; K.J. Groh, Eawag / UTOX Environmental Toxicology; M.J. Suter, Eawag Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology; K. Schirmer, Eawag / Environmental Toxicology

Synthetic glucocorticoids (GCs) are widely used in medicine. These compounds have been detected in the aquatic environment in the ng/L range. GCs mimic cortisol, the natural stress hormone, by acting through the glucocorticoid receptor (GR) and altering related gene expression patterns. Potential adverse health effects of GCs may range from teratogenesis to impairment of stress response, glucose metabolism and immunosuppression. In our work, we use zebrafish embryos to investigate if exposure to a relevant model GC, clobetasol propionate (CP), would result in the aforementioned adverse effects. The respiratory burst assay (RBA) was used to examine whether GCs can have an effect on macrophage functions, namely, their ability to produce reactive oxygen species (ROS) in response to infectious agents. Embryos exposed to 1000 nM CP from 1 to 120 hours post fertilization (hpf) showed significantly reduced amount of ROS produced by macrophages. The outcome of these experiments indicates that GCs are able to cause suppression of the innate immune system in zebrafish embryos. Targeted proteomics analyses were conducted on tryptic peptide digests from 30-40 embryos exposed to 10 or 100 nM CP from 96-120 hpf. The proteotypic peptide targets were monitored using a mass-spectrometry based targeted proteomics technique, selected reaction monitoring (SRM). GR target genes already examined in zebrafish at the mRNA level were selected to monitor their protein products. The targeted proteins have different physiological roles, e. g. immune response, cardiogenesis, myogenesis and osmoregulation. In a pilot experiment, two protein targets, Smyhc1 and Atp2a2a showed compelling changes in expression in exposed samples, thus they are potential protein biomarkers of GC exposure. The described work supports the fact that GCs can have immunosuppressive effects in fish. So far, the initial targeted proteomics analyses revealed two potential protein biomarkers of GC exposure that may be used to develop a sensitive bioassay in order to detect and identify unknown GR-active compounds with effect-directed analysis (EDA) in environmental water samples. Further experiments examining other potential biomarkers are ongoing.

Toxicity of the mycotoxin zearalenone in fish

C. Pietsch, Programm MGU / Environmental Sciences

The world-wide occurrence of mycotoxins including zearalenone (ZEN) in grains and cereals is a major problem leading to contamination of feed for farm animals and fish. Mycotoxins in feed have been shown to posess multifold detrimental effects on fish. Moreover, contamination of fish feed with mycotoxins has been found to occur. Consequently, mycotoxins have become a worldwide interest. Especially ZEN has been shown to act as a typical estrogenic compound showing high estrogenic potencies *via* estrogen receptors of rainbow trout. In fish, the mechanisms of toxicity of ZEN have not yet been demonstrated but effects on reproduction and development have been described. In mammalian systems it has been concluded that it is unlikely that the toxicity of this substance is solely due to its endocrine potential because other mechanisms, such as oxidative stress, could be involved. Generation of oxidative stress is involved in important physiological functions of all aerobic organisms. But it can also lead to disturbances of metabolic pathways, depletions of cellular antioxidants, and damage to macromolecules, including DNA, proteins and lipids. Thus, possible oxidative stress due to exposure to ZEN was analysed in the present study using fish cell lines to show the involvement of this pathway in the toxicity of this mycotoxin even outside mammalian cell systems. *In vivo* experiments were conducted to evaluate the relevance of the findings in whole fish.

Mechanisms of Selenomethionine and Hypersaline Induced Embryotoxicity in the Euryhaline Fish, Japanese Medaka (Oryzias latipes)

A. Kupsco, University of California Riverside; D. Schlenk, University of CaliforniaRiverside / Department of Environmental Sciences

As climate change worsens, the salinity of important spawning grounds in certain water-restrained estuaries, such as the San Francisco Bay, is increasing. Hypersalinity may not have direct lethal effects on adult fish, but osmotic stress may alter detoxification strategies of developing organisms. Although Selenium is an essential micronutrient, it has demonstrated embryo toxicity to fish at high concentrations and occurs in areas impacted by hypersaline conditions. Selenomethionine has been previously shown to cause oxidative stress in Japanese medaka embryos and when combined with hypersalinity decreased embryo hatch. The objective of this study was to examine potential mechanisms for embryo lethality caused by combined stressors in developing euryhaline fish. Because of the difficulties of working with fish from the Delta, Japanese medaka are a good model organism for studying the effects of multiple stressors. Japanese medaka embryos were treated with 50μM selenomethionine alone and with 12ppth salinity for 12 hours then apical endpoints and endpoints for oxidative stress, apoptosis and the unfolded protein response (UPR) were taken. Deformities were increased in selenomethionine treated embryos. However, no increase in lipid peroxidation was observed. Q-PCR was used for measurements of *CASP3A* and *BAX* transcripts. In selenomethionine only treatments expression of apoptotic transcript, *CASP3A*, was up-regulated significantly, and there was a trend towards an increase in *BAX*. Additionally, transcripts for genes regulating the UPR, *BiP*, *IRE1*, *ATF6, ATF4* and *Nrf2*, were measured. Selenomethionine significantly increased *BiP, ATF4*, and *ATF6*. Effects of salinity stress remain unclear. These results indicate embryo lethality may occur through apoptosis and the unfolded protein response.

FISH EARLY LIFE STAGES ASSAYS WITH SEDIMENT CONTACT

EXPOSURE AS A TOOL FOR HYDROPHOBIC COMPOUND TOXICITY ASSESSMENT

F. Le Bihanic, EPOC / Bat B eme etage; C. Clerandeau, EPOC; K. LE MENACH, LPTC; G. Daffe, University of Bordeaux 1, CNRS; H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC; P. Gonzalez, Géochimie et Ecotoxicologie des Métaux dans les systèmes Aquatiques GEMA team UMR CNRS Université Bordeaux; B. Morin, EPOC; X. COUSIN, INRA; J. Cachot, Université Bordeaux / EPOC

Japanese medaka *Oryzias latipes* embryos were incubated onto artificial reference sediment during their whole development until hatching. This sediment was spiked with different environmental concentrations of three PAH complex mixtures extracted from a PAH-contaminated sediment (Seine estuary, France) and two oils (*Arabian Light* and *Erika*). Several endpoints were examined at different developmental stages including mortality and hatching success, morphological abnormalities, larvae locomotion and genotoxic effects (micronucleus and comet assay). We also examined PAH bioavailability, accumulation in tissues and impact on gene expressions by RT-qPCR. Environmental concentrations of the three PAH fractions delayed hatching, induced developmental abnormalities and DNA damage and disrupted larvae swimming activity. Accumulation of PAH was detected in embryos tissues exposed to the *Erika* fraction. *Cyp1A* transcription level was positively correlated to PAH concentration in water and embryo tissues. Significant gene transcription deregulation was observed for several genes involved in cell cycle control, DNA repair (*p53*), vitamin A (*rarα1*) and oestrogen (*cyp19b*) metabolism, respiratory chain functioning (*coxI*) and anti-oxidant defense (*sod Cu*). These changes in gene expression provided clues to better understand mechanisms of PAH mixtures toxicity in fish early life stages. This was not supported by the toxic equivalency approach that appeared not suitable for the toxicity assessment of the three PAH fractions to fish embryos and larvae. The *Arabian Light* and *Erika* petrogenic fractions, with high proportions in alkylated PAHs and low molecular weight PAHs, were more toxic to Japanese medaka early life stages than the pyrolytic fraction. These results were consistent with toxicity observed with the same PAH fraction samples in rainbow trout early life stages. Altogether, these results demonstrate the suitability of the sediment-contact assay with fish embryos for toxicity assessment of hydrophobic pollutants.

Motoneuron and neuromast damage as new endpoints to explain metal toxicity in the zebrafish embryo toxicity test (zFET)

L. Sonnack, Fraunhofer IME Institute for Molecular Biology and Applied Ecology; S. Kampe; E. Muth-Koehne, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Department of Ecotoxicology; N. Henny, Heidelberg University Hospital Medical Microbiology and Hygiene; L. Erdinger, University of Heidelberg; H. Hollert, RWTH Aachen University / Institute for Environmental Research; M. Fenske, Fraunhofer Gesellschaft IME / Ecotoxicology

Metal exposure is still a global environmental problem and can lead to severe damages and development impairments through toxic mechanisms in organisms like fish. Many of these mechanisms of metal toxicity are still not clarified in detail. We are using the zebrafish toxicity embryo test (zFET), which is increasingly being used as a replacement test method to elucidate the potential sites of metal impact. New endpoints extend the scope of the existing assay and allow specifying the toxic action of a chemical. Therefore, metals were tested including new analysis methods for neuromast and motoneuron damage. The lateral line with the neuromasts is directly exposed to the aqueous surroundings, and hair cell excitation is triggered by water movements, influencing rheotaxis and coordination. Additionally, the hair cells of the neuromasts are homologue to the hair cells in the chochlea of mammals. This makes a neuromast damage assay with zebrafish also interesting for hearing research and the screening of ototoxic substances. In this study, wild-type embryos were exposed to the metals copper ($CuSO_4$), cadmium ($CdCl_2$) and cobalt ($CoSO_4$) for 72 hours. The embryo toxicity tests were conducted according to guideline recommendations and morphological endpoints were assessed as described by Braunbeck et al. 2006. Neurotoxic effects were investigated by immunofluorescence stainings of primary motoneurons (PMNs) and secondary motoneurons (SMNs). To quantitatively evaluate the development and damages of neuromasts, an in vivo staining method was applied using the vital dye DASPEI. Additionally, the consequences of metal toxicity and damage were assessed functional by testing the fish behaviour. Hence, a behaviour assay was performed, which analyses the escape reflex after tactile stimulation. The stained neuromasts of the 72 hpf embryos showed a concentration-dependent decrease in fluorescence for all three metals even in the lowest concentrations, 2 mg/l $CdCl_2$ and 0.025 mg/l $CuSO_4$ and $CoSO_4$. For the secondary motoneurons a slight effect increase was noticeable. The results demonstrate that the neuromast cells are generally more sensitive to metal exposure than morphological parameters, the response to tactile stimulation and the motoneuron damage. Therefore, the assessment of neuromast damage promises a valuable new endpoint for metal toxicity in the zFET.

Ecological Consequences of Exposure to Pharmaceuticals: From the Laboratory to the Field (III)

295

Does exposure to environmentally relevant concentrations of an antidepressant affect risk sensitivity of wild birds?

T.G. Bean, A. Boxall, University of York / Environment Department; J. Lane, The Food and Environment Research Agency; S. Pietravalle, Food and Environment Research Agency; K. Herborn, University of Glasgow; K. Arnold, University of York / Environment

Many species of birds forage on sewage treatment works and on fields fertilised with biosolids, attracted by the abundance of invertebrate prey. Many pharmaceuticals can accumulate in such invertebrates. Fluoxetine (FLU) is an antidepressant commonly prescribed to treat anxiety and depression and has been detected in a range of environmental matrices and also soil invertebrates. In order to assess whether behavioural and physiological effects result from foraging on pharmaceutical contaminated prey, we administered wild-caught starlings Sturnus vulgaris with fluoxetine-injected invertebrates over 16 weeks in captivity. Assayed over two days in isolation, anxiety related behaviours (exploration in a novel environment and responses to human disturbance) and activity levels were unaffected by chronic exposure to environmentally relevant concentrations of fluoxetine. Fluoxetine did affect physiological stress responses: As found other species, controls showed a highly variable corticosterone response on day 1, i.e. immediately following the stress of being put into isolation. This was followed by a significant reduction in stress hormone variability on day 2, characteristic of habituation by all birds to the new environment. In contrast, the variance in mean corticosterone levels of the FLU-group did not change from day 1 to day 2. Similarly, controls demonstrated the expected relationship between stress hormones and mass change: the birds showing high corticosterone on day 1 lost more body mass than controls with lower physiological responses to the stress of isolation. However, for FLU- birds, corticosterone did not predict mass change in isolation. Finally, in their home aviaries controls, as expected, fed more at the beginning and end of the day. So as seen in other avian species during winter, controls were strategically trading-off the risk of starvation against the ability to escape predation depending on the time of day. The FLU-group, in contrast, did not change their feeding rate over the day, thus their foraging behaviour showed them to be less risk sensitive to starvation and predation. Our data suggest that exposure to fluoxetine disrupts the relationships between Corticosterone, feeding behaviour and body mass regulation in birds, thus altering risk sensitivity. Further work is needed to determine whether our experimental results could decrease individual fitness resulting in changes to population dynamics.

296

Tissue-Specific Concentrations of Polar Pharmaceuticals and Personal Care Products (PPCPs) in Wild Fish from Wastewater Discharge Area

R. Tanoue, Ehime University / Center for Marine Environmental Studies; K. Nomiyama, Center for Marine Environmental Studies CMES Eh / Center for Marine Environmental Studies CMES; T. Isobe, Ehime University / Center for Marine Environmental Studies CMES; R. Shinohara, Prefectural University of Kumamoto / Graduate School of Environmental and Symbiotic Sciences; S. Tanabe, Ehime University / Center for Marine Environmental Studies CMES

Pharmaceuticals and personal care products (PPCPs) are considered as "pseudo-persistent" contaminants, because of their continuous loading to aquatic environments through the effluent discharge of wastewater treatment plant (WWTP). As a result, exposures and adverse effects of PPCPs on fish are becoming problems of deep concern. In our previous study, a sensitive and accurate isotope dilution method was developed for the simultaneous determination of 19 polar PPCP residues (log K_{ow} = 1.40–5.74; pK_a >3.10; pK_b >4.15) in various biological matrices (e.g., liver, kidney, and brain). The present study elucidated residue levels and bioaccumulation patterns of 19 polar PPCP in the blood, gill, liver, kidney, muscle, and brain of wild fish from wastewater discharge area. Thirteen of 19 target compounds were detected in fish tissues analyzed. Overall, higher concentrations of psychotropic agents were found in brain, liver, and kidney rather than plasma and muscle. Relatively higher concentrations of antibacterial agents were found in liver and gill. In contrast, tissue levels of analgesic agents were comparable with plasma concentrations. Among target compounds found in ambient water, antihyperlipidemic agents, ethenzamide, and warfarin with lower lipophilicity were not detected in any fish tissue analyzed. These compounds may be rapidly excreted, and consequently present at low concentrations in fish tissues. However, high bioaccumulation factors (concentration ratios: fish tissues / ambient water) of diphenhydramine in liver and kidney were found in spite of their relatively low lipophilicity. This result implies that other mechanisms such as differences in biotransformation rates by fish might be involved in the accumulation of polar PPCPs. Moreover, comparing measured fish plasma levels to available human therapeutic plasma levels, it can be suggested that haloperidol (antipsychotic agent) and diphenhydramine (antihistamine agent) impose relatively high risk. The mean brain / plasma concentration ratios of psychotropic agents ranged from 8.4 (carbamazepine) to 12 (diphenhydramine), indicating high transport of these compounds to the brain of fish as it is in human beings.

297

Occurrence of endocrine disruptors and pharmaceutical compounds and bioaccumulation in biofilm, macroinvertebrates, and fish in Mediterranean rivers

B. Huerta Buitrago, Catalan Institute for Water Research ICRA / Department of Water Quality; V. Osorio, M. Gorga, IDAEA- CSIC / Department of Environmental Chemistry; A. Jakimska, Gdansk University of Technology / Department of Analytical Chemistry; N. De Castro, Departament dEcologia; L. Ponsati, Water Institute for Water Research (ICRA); I. Muñoz, University of Barcelona / Ecology; S. Perez, Universidade de Vigo / ECIMAT; M. Petrovic, Catalan Institute for Water Research ICRA; S. Rodriguez-Mozaz, Institute for Water Research ICRA; D. Barcelo, IIQABCSIC / Environmental Chemistry

Pharmaceuticals (PhACs) and endocrine disruptors and related compounds (EDCs) are continuously introduced into surface waters, thus, the likelihood of bioaccumulation of these compounds in exposed aquatic organisms is an ever-increasing issue of concern. The situation is of special concern in Mediterranean regions, where the WWTP effluents may represent a high percentage of some streams flow, particularly under water scarcity. This work describes the presence and bioaccumulation of PhACs and EDCs in aquatic organisms from different trophic levels – biofilm, macroinvertebrates, and fish – collected in four Mediterranean rivers inSpain. Sampling was performed in 5 points in each of four rivers to achieve a pollution gradient. A total of 20 sites were sampled during the summer of 2010 for the analysis of up to 43 multi-class pharmaceuticals and 21 EDCs in aquatic organisms from different trophic levels: biofilm, insect larvae, mussels and fish. Twelve EDCs, out of 18 detected in water and sediment, were also found in biota samples. Bisphenol A, propylparaben, TCEP and triclosan were detected in all the biofilm samples analyzed. TBEP was detected in all the macroinvertebrate samples, and in 95% of the fish samples. These compounds were also some of the most prevalent compounds in water and sediment (detected in more than 70 % samples). Compounds like caffeine and tolyltriazole, although persistently detected in water at considerable concentration in the majority of the sampling points (up to 572.2 ng L^{-1} and 874.9 ng L^{-1}, respectively), were only detected in one biota sample at very low concentration. Twenty PhACs, out of 77 found in water and sediment, were also detected in aquatic organisms. Most prevalent compound in biofilm was the antibiotic azythromycin, found in 44 % of the samples. In contrast, the anti-inflammatory drug diclofenac was the most ubiquitous compound in fish, as it was detected in different fish species and all the river basins. Compounds frequently detected in water, such as acetaminophen and ibuprofen, with concentrations around 150 ng L^{-1} in some sampling sites, were not detected in any aquatic organism.

298

Analyses of pharmaceuticals in fish collected from a subset of urban streams in the U.S. in the U.S. EPA's National Rivers and Streams Assessments

S. Rodriguez-Mozaz, Institute for Water Research ICRA; J.M. Lazorchak, US EPA / Office of Research and Development; B. Huerta Buitrago, Catalan Institute for Water Research ICRA / Department of Water Quality; D. Barcelo, IIQABCSIC / Environmental Chemistry; A.L. Batt, National Exposure Research Laboratory; J.B. Wathen, US EPA / Office of Science and Technology

U.S. EPA' conducted the first statistically based survey of persistent and bio-accumulative contaminants in fish from U.S. Rivers. This national fish survey was conducted under the framework of EPA'sNationalRiversand Streams Assessment (NRSA), a probability-based survey designed to assess the condition of the Nation's streams and rivers. In 2008 and 2009, field teams applied consistent methods nationwide to collect samples of fish commonly consumed by humans at 542 randomly selected river locations (≥ 5th order based on 1:100,000-scale Strahler order) in the lower 48 states during June through October, 2008-2009. Fish were collected at every sampling location and prepared as composite samples, which consisted of five similarly sized adult fish of the same species. Largemouth and smallmouth bass were the primary species collected for the study, accounting for 34% and 24% of all fish composites, respectively. The selected streams were further stratified into 160 urban streams, where a water sample was collected for pharmaceutical analyses in addition to fish. Fifty four pharmaceuticals and 6 metabolites measured in the water samples were used to prioritize 25 sites for fish tissue analyses. Criteria used for selecting sites for pharmaceutical analyses of fish fillets included: nearness to a wastewater treatment plant discharge, broad continental U.S. distribution, low flow data when available, and highest levels of the five pharmaceuticals that could be measured by the analytical methods available for water and fish (carbamazepine, metoprolol, hydrochlorothiazide, sertraline and atenolol). Results indicate that several pharmaceuticals are found in fish fillets in Urban systems and where pharmaceuticals are detected in water. The views expressed in this presentation are those of the authors and do not represent those of U.S.EPA.

Bensodiazepines; bioconcentration and bioaccumulation in various biota and presence i European surface waters.

J. Fick, Umea University / Department of Chemistry; T. Brodin, M. Heynen, Umea University / Department of Ecology and Environmental Science; M. Jonsson, Department of Ecology and Environmental Science; J. Klaminder, Umea University / Department of Ecology and Environmental Science

In a recent study we showed that an anxiolytic drug, the benzodiazepine Oxazepam, alters behavior and feeding rate of wild European perch *(Perca fluviatilis)* [1]. In this study only a single species was investigated but inter-species internal levels, following exposure of a pollutant, may vary due to diverse bioaccumulation rates. This will of course have implications in effluent dominated aquatic environments since not all exposed biota present will be affected at the same exposure levels. In addition, not all species have the mode-of-action targets for pollutants, which are relevant in the case of pharmaceuticals, since the environmental effects would have to be correlated with conserved targets in exposed biota and not with a general toxic effect [2]. Benzodiazepines, for examples, act upon the γ-aminobutyric acid (GABA) receptor and several species have orthologs of this receptor [2]. This study is focused on bioconcentrations factors (BCFs) and bioaccumulation (BAFs) factors of one of the besodiazepines, oxazepam, in Perch, Crucian carp, Sticklebacks, Damselfly larvae. Dragonfly larvae, Caddisfly larvae and Mayfly larvae. By investigating BCF and BAF in several species we can describe the flow of benzodizepines in the food web. What makes this especially interesting is the fact that several of the studied species do not have the GABA receptor and therefore will most likely not be affected at environmental relevant levels and that different species have larges differences in bioconcentrations factors. Damselsfly larvae are, for example, not affected by oxazepam at water concentrations (1.8 microg/L) that affects Perch, even though our studies show that they bioconcentrate 120 times more (compared to Perch). That some invertebrates have elevated bioconcentration factors makes bioaccumulation (BAFs) factors highly relevant to study and we will present results from several predator-prey studies using Perch and Dragonfly larvae as predators and Sticklebacks, Damselfly larvae, Caddisfly larvae and Mayfly larvae as prey. We will also present the results from an EU-wide study of the presence of 13 bensodiazepines in surface water. Four European River catchment systems, River Aire-Calder, Blanice River, River Tiber and the Danube were included (17 rivers and tributaries in 9 countries). 1. Brodin, T, et al. *Science* **339,** 814–815 (2013). 2. Gunnarsson, et al. **42,** 5807–5813 (2008).

From theory to reality – Evaluation of suitable organisms and test systems for the biomonitoring of pharmaceuticals - Literature review

S. Schwarz, Animal Physological Ecology; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology; D. Jungmann, K. Berg, Dresden University of Technology; M. Frey, Steinbeis Transfer Center for Applied Biological Chemistry; J. Oehlmann, Johann Wolfgang GoetheUniversitat Frankfurt / Aquatic Ecotoxicology; M. Oetken, GoetheUniversity Frankfurt / Aquatic Ecotoxicology; I. Ebert, Umweltbundesamt / Pharmaceuticals Department

A vast diversity of human and veterinary pharmaceuticals is frequently detected in aquatic ecosystems. However, the actual effect of these substances on biota is hardly assessable. Since the principle of pharmacovigilance also demands the examination of environmental effects, it is crucial to develop new, effect-based strategies for the monitoring of pharmaceuticals. As a first step, we conducted a survey of recently published literature (2011 to 2013) to gain an overview, which pharmaceutical groups appear to be of highest relevance for biota, and which organism groups and effect endpoints react most sensitively to pharmaceuticals. A database was created from the given information and the studies were evaluated with respect to the reported lowest observed effect concentrations (LOECs), which were subsequently compared to measured environmental concentrations (MECs) in surface waters. Additionally, we investigated the reliability of studies reporting LOECs in close range to the MECs. Overall, 452 studies were examined, of which 232 directly investigated pharmaceutical effects. The most frequently studied organism group were fish, with *Danio rerio* being the most commonly used species, followed by molluscs. It was also shown that a huge variety of different species is applied in the evaluation of pharmaceutical effects, but only few of them are investigated in more than one study. Considering relevant endpoints, behaviour, vitellogenin synthesis, growth, reproduction and histopathological changes were among the most sensitive responses. Based on the effect information extracted from the studies, the analgesic diclofenac, the β-blocker propranolol, the lipid regulator gemfibrozil and the antibiotics erythromycin and sulfamethoxazole were identified as environmentally most relevant pharmaceuticals. Unfortunately, the evaluation also showed that only a minor part of the investigated publications can be considered as fully reliable; most studies included at least some minor flaws. Furthermore, there still appears to be a huge knowledge gap considering the effects of mixtures, and the population relevance of many observed effects remains unclear. For further monitoring strategies, we propose a system based on effect classes rather than leading substances, and want to stress out the crucial need for mode-of-action based testing.

Macro, micro and nanoplastic pollution in the aquatic and terrestrial environments: Sources, fate, exposure

and ecological and toxicological impacts

301

Releasing of hexabromocyclododecane (HBCD) from expanded polystyrene (EPS) buoy in marine water: a field study

M. Rani, Korea Institute of Ocean Science and Technology; M. Jang, Korea Institute of Ocean Science and Technology / oil and POPs reserch group; G. Han, Oil and POPs research group; W. Shim, S. Hong, Korea Institute of Ocean Science and Technology / Oil and POPs research group

Polystyrene is widely used as building insulation material, floating device and in packaging. It is also a major component of debris found to in-land and marine system. To prevent it's burning, HBCD is frequently added as flame retardant. HBCD is an additive, not covalently bonded to the material, leading to the risk of migration out of the product during production, use or disposal. Due to its persistence and adverse biochemical effects, it has been added to the list of global elimination compounds under the Stockholm Convention in May 2013. However, the interesting point is the presence of HBCD in water, oyster and sediment collected from and nearby aquafarms i.e. non-industrial area. EPS buoy, a rich source of HBCD (~70-75 μg/g of EPS), is highly used in Korea for the culture of longline oyster (2 million buoys/year). It may be considered as a cause of HBCD contamination through leaching by sea water. In view of this, it is imperative to carry out a systematic field study on the leaching of HBCD from EPS buoy in sea water. Studies in the field was designed in enclosed-rectangular-glass chambers (50x100x50cm) and mesocosm. A monolayer of detached EPS spherules was dispersed on the surface of water. The leaching of HBCD was investigated by determining the residual HBCD in known amount of EPS collected at different interval of time.Results show that there is an exponential decrease in the concentration of HBCD. Leaching characteristics that fast-leaching initially followed by slow desorption over time were generally observed. Nevertheless, γHBCD was the most abundant isomer followed by αHBCD and βHBCD, of the total HBCD concentration. The lower α/γ ratio (0.22, Fresh EPS: 0.35) of HBCD isomers observed in collected EPS favoured the solubility of αHBCD. Among three conditions investigated in the field for two months (August and September), fastest kinetic was observed in mesocosm followed by sun- and dark-exposed condition highlighting the phenomenon of weathering and degradation. Within 3 days, the percentage of HBCD lost in laboratory and field is 20 and 77%, respectively. In field test, the maximum leaching rates were estimated to reach in range of 53 to 86% (from dark exposure to mesocosm) which were significantly affected by high volume of water, UV light, microorganisms, physical impact and temperature. Results obtained during the study indicate that EPS buoy is a significant source of HBCD in Korean marine environment.

302

Enrichment of additive HBCDs in mussel attached to expanded polystyrene buoy

M. Jang, Korea Institute of Ocean Science and Technology / oil and POPs reserch group; S. Hong, Korea Institute of Ocean Science and Technology / Oil and POPs research group; G. Han, Oil and POPs research group; M. Rani, Korea Institute of Ocean Science and Technology; W. Shim, Korea Institute of Ocean Science and Technology / Oil and POPs research group; S. A, Oil and POPs research group

Expanded polystyrene (EPS) is widely used polymer for varying purposes including insulation materials, packing materials, and aquaculture buoy. Large amount of EPS buoys has been used for aquaculture of oyster and mussels in South Korea leading to a large number being lost or disposed as waste. Floating EPS buoy as marine debri have become a habitat for marine organisms. In our previous study, we detected considerable amounts of hexabromocyclododecanes (HBCDs) in EPS buoy with a median concentration of 40 μg/g. To find evidence on marine debris as a source for toxic chemicals to marine organisms, floating EPS buoy and attached mussels were collected from Jinhae Bay, Korea were chemically analysed. Samples were categorized as follows; EPS buoy, mussel attached to its EPS buoy (Group 1), mussels attached to high density polyethylene (HDPE) buoy (Group 2), mussels attached to non-polymeric substrate (Group 3). The concentration of HBCDs in EPS buoy (μg/g dw)and Group 1 mussel (μg/g lipid weight) were in the range of 0.15-1,580 (mean; 246±571) and 0.074-5.16 (1.3±2.19), respectively. The HBCD concentration among EPS buoys and mussels showed large variations. However, HBCDs in mussel were positively related to HBCDs in EPS they were attached, indicating HBCD level in individual buoy might directly affect the mussels on it. Mussels collected from HDPE buoy (Group 2) and non-polymer substrate (Group 3) accumulated much smaller amounts of HBCDs than that in Group 1 with the concentration range of 0.062-0.097 μg/g lipid weight (mean; 0.07±0.015) and 0.035-0.062 μg/g lipid weight (0.056±0.015), respectively. Although the distance between EPS and HDPE buoys was less than 1m, approximately 5 times higher concentration of HBCDs was detected in mussels from EPS buoy than in HDPE buoy. There were clear changes in α/γ ratio in mussels according to the type of their substrates. In this study, we tried to find evidence on raising questions of contributions of macro- and micro-sized plastic marine debris bioaccumulation to marine life through analysis of mussels attached to EPS substrate collected. The body residues and isomeric profiles of HBCDs in mussel reflect those in their plastic substrates. This result strongly implies that plastic marine debris can be a moving source of toxic chemicals to marine life and can be biomagnified in marine food chain.

303

Microplastic particles in aquatic sediments: New methods for sampling, extraction and quantification

H.K. Imhof, Uni Bayreuth / Animal Ecology I; N.P. Ivleva, Institute of Hydrochemistry IWC / Chair for Analytical Chemistry; C. Laforsch, Animal Ecology I

Although plastic-debris is constantly accumulating in aquatic-environments, the impact on aquatic-ecosystems is not yet fully understood. A first important step in order to assess the consequences of plastic-debris in aquatic-ecosystems is the establishment of a reliable, verified and standardized method to quantify the amount of plastic-particles of all ecologically relevant size classes (down to 1μm).\n In this study we developed a novel density separation setup (Munich Plastic Sediment Separator -MPSS) which allows for a successful separation of mesoplastic particles (20–5 mm), L-MPP (5–1 mm) as well as for S-MPP (Validation of the MPSS was done using the most commonly used plastic types, including two with relatively high specific densities. Identification of the found particles was performed by Raman microspectroscopy (RM). The new method was compared with the "classical density separation setup" comparable to other studies. Moreover we improved the sampling of aquatic beach sediments by combining the advantages of transect sampling and sediment core sampling. This results in a representative sample of one beach segment. With a volume which perfectly fits into the newly developed MPSS. Additionally we suggest certain criteria for transect placement to enable realistic and representative sampling and subsequent quantification of microplastic particles This is to our knowledge, the first study which examined systematically the recovery rates of different separation methods and provides a standardized apparatus for the process of density separation complying all requirements for the extraction of even very small particles (down to several microns) from sediment samples. For the identification and quantification of the plastic particles in sediments, RM can be successfully applied. In combination with other separation liquids the MPSS and RM could also be applied for the separation and identification for any particles down to the micrometer range from a sample with high volume (up to 6 l). It perfectly suits the requirements in handling microparticles and could also be constructed on a smaller scale.\nThe evaluation of the suggested sampling method revealed a representative location for beach transect. The use of sediment cores proved to be useful in combination with the use of the MPSS.

304

Microplastics in field collected and cultured bivalves

L. Van Cauwenberghe, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology; M. Claessens, DuPont de Nemours; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology

Microplastics are present throughout the marine environment, and ingestion of these small plastic particles has been demonstrated repeatedly in a laboratory setting for a wide array of marine organisms. However, as the exposure concentrations of microplastics in these types of experiments is much higher than any reported field concentration, it is difficult to assess the relevance of these results for natural environments. Therefore, we assessed the presence of microplastics in two bivalve species living in natural conditions: both field collected and cultured individuals of *Mytilus edulis*, and farmed *Crassostrea gigas* were investigated. Part of the organisms (all field collected *M. edulis* (N=30), and half of the cultured *M. edulis* (N=36) and *C. gigas* (N=10)) were subjected to a gut depuration to allow them to clear their gut. To examine microplastic presence, the soft tissues were acid digested. Small numbers of microplastics were recovered from the tissue of the species under investigation. In field collected *M. edulis* the average microplastic load (post-depuration) was 0.20 ± 0.30 particles per gram of soft tissue. In cultured *M. edulis* microplastic load (pre-depuration) was 0.36 ± 0.07 particles.g^{-1} of soft tissue. After the depuration period, only 0.24 ± 0.07 particles.g^{-1} were encountered. The same trend was observed in *C. gigas*: without depuration on average 0.47 ± 0.16 particles.g^{-1} were present in the animals, while microplastic concentrations decreased to an average of 0.35 ± 0.05 particles g^{-1} after depuration. It is not surprising that the microplastic load of cultured animals resembles that of field collected animals since they are cultured in natural conditions. As a result these filter feeding organisms are exposed to any pollutant present in the seawater, including microplastics, in the same way as their wild counterparts. Although it is now established that mussels and oysters contain microplastics, this is the fist report so far on microplastics in foodstuffs. Currently, only a preliminary dietary exposure could be estimated. The hazard posed by microplastics needs to be established through in-depth toxicological studies. Due to a lack of dedicated studies, the complexity of estimating particle toxicity hinders a comprehensive assessment of the risks associated with microplastics. Estimations of the potential risks for human health posed by microplastics in food stuffs is not possible.

305

Nanoplastic affects growth of S. obliquus and reproduction of D. magna

E. Besseling, WUR / Aquatic Ecology and Water Quality Management Group Department of Environmental Sciences; B. Wang, University of Maryland Baltimore County / Civil and Environmental Engineering; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group Department of Environmental Sciences

The amount of nano- and microparticles in the aquatic environment rises due to the industrial production of nanoplastic and the degradation of macroplastic into small particles. Little is known about the fate and effects of nanoplastic, while there are lots of speculations about possible effects. In this study, the effects of nano polystyrene on performance of green algae *Scenedesmus obliquus* and zooplankton *Daphnia magna* were assessed. At high doses inhibiting effects on the growth of *S. obliquus* were shown. During chronic tests the suspensions of nano polystyrene were not lethal to *D. magna* but reproduction effects were observed. Interestingly, aqueous vs. dietary exposure to nano polystyrene played an important role in the occurrence of effects on *D. magna*. Thereby this study provides a novel indication about the importance of uptake routes in nano plastic exposure.

Tracing POP-BDE routes through plastic waste streams in the Netherlands

H.A. Leslie, Institute for Environmental Studies VU Amsterdam; P. Leonards, VU University Institute for Environmental Studies / Chemistry Biology; S. Brandsma, IVM institute for environmental studies / Faculteit der aard en levenswetenschappen; B. van Hattum, Vrije Universiteit Amsterdam / Institute for Environmental Studies; M. Janssen, Nat Inst Publ Health Environ / VSP; N. Jonkers, IVAM

There is currently only limited understanding of the dynamics of the distribution and levels of tetra-, penta-, hexa- and heptabrominated BDE congeners (POP-BDE) in waste streams in Europe and worldwide. This study investigated how plastic waste materials that may contain POP-BDE are sorted, separated, disposed of, recycled, landfilled, incinerated and/or exported in the Netherlands. This was coupled to measured concentrations of POP-BDEs in samples taken from four points in the waste streams to study the mass flow of these regulated POPs through the Dutch plastic cycle. A cost-effective, fast 'direct probe' screening method developed at IVM was applied to quickly determine the presence or absence of POP-BDEs. The method makes use of a direct probe coupled to atmospheric pressure chemical ionization-high resolution time-of-flight-mass spectrometry (APCI-HRTOF-MS). The method can be used to screen samples for POP-BDEs in plastic, so that the more laborious solvent extraction procedures are only done when quantifiable amounts are present. In total 90 samples were selected for determination of the POP-BDE concentrations, using gas chromatography with the electron capture negative ionization technique and mass spectrometry detection (GC/ENCI-MS), using a highly sensitive method. This study provides a unique POP-BDE dataset for the relevant plastic waste streams in the Netherlands. POP-BDEs were rarely found in single automotive parts (when detected, it was only in car parts from the USA) or WEEE items. Shredder material (consisting of a large number of shredded items), frequently did contain POP-BDE. The samples in which POP-BDEs were detected confirmed that c-PentaBDE can be found in automotive, whereas the c-OctaBDE pattern is found in WEEE. DecaBDE (not a Stockholm POP) is frequently found in plastic fractions from shredded automotive and WEEE material and recycled plastic pellets. Based on the mass flow analysis, 22% of the POP-BDE in WEEE is expected to end up in recycled plastics. In the automotive sector, 14% of the POP-BDE is expected to end up in plastics recycling, while an additional 19% is expected to end up in second-hand parts (reuse). POP-BDEs were detected at low concentrations in some new products made from recycled plastic (imported products). This also indicates that the legacy of POP-BDEs will be with us for quite some years to come, until the plastics are downcycled to the point that they are sent for incineration.

Recent advances and critical future research directions for poly- and perfuorinated alkyl substances (PFASs) (I)

307

Global emissions, fate and transport of C6-C10 perfluoroalkane sulfonic acids (PFSAs): what we know and what we do not know

Z. Wang, Swiss Federal institute of Technology / Institute for Chemical and Bioengeneering; I.T. Cousins, Stockholm University / Applied Environmental Science ITM; M. Scheringer, ETH Zuerich / Institute for Chemical and Bioengineering; M. MacLeod, ITM Stockhom University / Dept of Applied Environmental Science ITM; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

Long-chain perfluoroalkane sulfonic acids (PFSAs, $C_nF_{2n+1}SO_3H$, $n \geq 6$), especially perfluorooctane sulfonic acid (PFOS), are a group of global contaminants of high concern. These substances are highly persistent, bioaccumulative, toxic, and distributed ubiquitously in the environment, biota, and humans. A recent study estimated a global emission inventory of PFOS and PFOS precursors (PreFOS) and coupled the emission inventory to a global-scale multimedia mass-balance model to assess the global fate and transport of PFOS and PreFOS. That work highlighted the significance of direct industrial sources to the overall distribution of PFOS in the global environment. However, that work also demonstrated that the estimated global emissions of PreFOS are too low by one to two orders of magnitude. Moreover, that study did not realistically represent the recent production of PFOS and PreFOS in China. Furthermore, previous studies focused solely on PFOS and PreFOS, whereas their short- and long-chain homologues have also been produced since the 1960s. To tackle these knowledge gaps, we use new information on PFSA uses and disposal and develop a new global emission inventory of C_6–C_{10} PFSA homologues from 1958 to 2030. Then we use a global-scale multimedia mass-balance model to assess the global fate and transport of these PFSAs in the environment. We estimate that 2700–7000 tonnes of PreFOS and 3600–6000 tonnes of PFOS are emitted between 1958 and 2015. Our new estimates are higher than the previous estimates. In particular, we estimate one to two orders of magnitude higher emissions of PreFOS, which is enough to close the mass balance between emissions of PreFOS and their levels measured in the global atmosphere. Overall, our estimates of the direct emissions of PFOS from production sites and during the product use and disposal phases are much higher than the indirect emissions of PFOS from degradation of PreFOS. Furthermore, we highlight several critical knowledge and data gaps. For example, we estimate that about 800 tonnes of perfluorooctane sulfonyl fluoride (POSF) have been emitted since the 1950s. However, due to a lack of reliable degradation half-life data for POSF in air, it is not possible to estimate the time-resolved historical contribution of this additional source to the environmental levels of PFOS.

308

Occurrence and removal fluxes of Perfluorinated alkyl substances in the tropical and subtropical Global Oceans.

B. Gonzalez-Gaya, Institute of Environmental Assessment and Water Research / Environmental Chemistry; E. Jurado, J. Dachs, IDAEACSIC / Environmental Chemistry; B. Jimenez, CSIC Institute of Organic Chemi / Instrumental Analysis Environment

Perfluorinated alkyl substances (PFASs) are receiving an increasing worldwide attention due to their persistence, toxicity and widespread occurrence. These emerging contaminants have high water solubility and lower lipophilicity compared to legacy persistent organic pollutants, being their global fate and removal processes still uncertain due to their particular chemical characteristics. This study provides the global concentrations of three PFASs families, perfluorinated carboxylic acids, perfluorosulfonates and perfluorosulfonamides, in surface seawater and at deep chlorophyll maximum depth in the global tropical and subtropical oceans. Horizontal and vertical occurrence was evaluated in north and south basins of Atlantic and Pacific Oceans and in the Indian Ocean during the Malaspina 2010 circumnavigation cruise. The Atlantic appeared as the most polluted ocean in our global study; followed by the Pacific and then the Indian Ocean. Mean ΣPFASs concentrations found in the Northern hemisphere were lower than values found in the Southern hemisphere, suggesting differences in emission patterns in both Hemispheres. It is remarkable the high relative abundance of perfluorooctanoic sulphonate (PFOS) and perfluorooctanoic acid (PFOA). Removal fluxes due to vertical turbulent diffusion in the water column and to sorption to biomass and sinking are considered the two main removal processes affecting the superficial concentrations of PFASs as biodegradation has not yet been reported for these compounds. The oceanic sink due to vertical eddy diffusion is given for individual PFASs. Turbulent fluxes were estimated with a 1D diffusion model and using KT (eddy diffusion coefficient) measured simultaneously to the PFASs concentrations during the Malaspina cruise. In addition, the sinking flux (biological pump) can be predicted from the dissolved phase concentrations, the fluxes of organic carbon estimated from measured chlorophyll a concentrations, and reported bioconcentration factors (BCF) for marine phytoplankton. Modeled fluxes suggest that the biological pump is far more efficient in removing PFASs from the surface ocean than the turbulent flux; being the latter only relevant during extreme mixing events. However, both removal fluxes are low (less than 0.01 ng m^{-2} d^{-1} for PFOA and PFOS) suggesting long residence times of PFASs in the surface ocean. Other parameters as sources, vicinity to coast or ocean currents also affect the global distribution of PFASs.

309

Ecodynamics of selected PFASs in the Gironde estuary

G. Munoz, LPTCEPOC CNRS; V. Bocquet, University of Bordeaux; H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC; J. Lobry, J. Selleslagh, Irstea UR EPBX; M.P. Babut, Irstea / Water; P. Labadie, University of Bordeaux / UMR EPOC Equipe LPTC

Over the past 15 years, there has been a flurry of research activities in the analysis of poly- and perfluoroalkyl substances (PFASs) in water, sediments and wildlife, due to their persistent, bioaccumulative, and toxic properties. However, little is known about their ecodynamics, especially in estuarine ecosystems. In this work, the Gironde estuary was selected as the study site because of its ecological value: it

is home to the largest assemblage of migratory amphihaline fish in Western Europe. Water, sediment and a wide range of biota samples were collected at selected locations in this estuary. Biota samples included benthic invertebrates, zooplankton (copepods, mysids), shrimps, and several fish species – grey mullet, meagre, seabass and sole. The contamination of biota was therefore assessed for top predators but also for several taxa at the bottom of the food web, whose PFAS contamination remains poorly documented. In view of the high number of values that fell below detection limits, statistical treatments taking into account non-detects were implemented, leading to more accurate calculation of descriptive statistics, correlations, and differences among groups. The relationship between the contamination of biota and that of abiotic compartments was quantitatively assessed: bioaccumulation factors and biota to sediment accumulation factors were calculated. Biomagnification factors (BMF) and trophic magnification factors (TMF) were also determined to quantify PFAS transfer within the food web. In addition, a specific statistical modelling approach is currently implemented to evaluate the relative influence of trophic position and biometric characteristic on PFAS bioaccumulation in key fish species (common sole and spotted seabass).

310

Temporal Trend of Perfluoroalkyl Compounds in the Atmosphere at Dalian, China: Evidence of Unknown PFC?

W. Liu, School of Environmental Science and Technology Dalian University of Technology / School of Environmental Science and Technology; H. Zhang, Dalian University of Technology; C. Chen, Liaoning Provincial Meteorological Bureau; B. Gao, K. Meng, W. Tang, Dalian University of Technology

The level and profile of perfluoroalkyl compounds (PFAAs) in the atmosphere indicate their local distribution and the global transportation. However, there are still only a limited number of studies to determine atmospheric concentrations of PFAAs.Dalian is a coastal city located in Liaoning Province, northeast of China. The city, as well as other regions in Liaoning, has been reported of higher PFAAs concentrations, in water, sediments, aquatic organisms, and even human serum, than most of other regions in China, by both our previous studies and other researches. Therefore, the environmental risk of PFAAs in this area has attracted extensive concern of both the scientists and the public. The purpose of the present study is to trace the trend of PFAAs levels and profiles in the atmosphere in this region. Particulate matters were collected at Dalian, in 2006-2013, and the PFAAs concentrations were reported. Three perfluorosulphonates (C4, 6, 8) and eight perfluorocarboxylates (C5-12) were dected by HPLC-MS/MS, where internal standard calibration was employed for quantification. Furthermore, the unknown PFC was analyzed, to evaluate the impacts of the replacement in fluorine chemistry on the environmental pollution.

311

Factors Impacting Groundwater Fate and Transport of Perfluoroalkyl Acids at AFFF-impacted Sites

J.L. Guelfo, Shell Projects and Technology / Soil Groundwater; E.R. McKenzie, Civil and Environmental Engineering; C.P. Higgins, Colorado School of Mines / Civil Environmental Engineering

The recent implementation of soil and drinking water regulatory guidance values for some perfluoroalkyl acids (PFAAs) reflects growing concerns regarding the presence of these persistent and bioaccumulative chemicals in the environment. Because of their unique properties, PFAAs have a wide variety of uses including aqueous film-forming foams (AFFF). AFFF is used to extinguish hydrocarbon fuel fires by fire departments, the hydrocarbon industry, and the military. Concentrations of PFAAs in groundwater have been measured in the ng/L - µg/L range at fire training facilities where AFFF was repeatedly used in training exercises. These sites may also be impacted by co-contaminants including non-aqueous phase liquids (NAPL). Where co-contaminants are present, site conditions may also be impacted by previous remedial efforts such as in situ chemical oxidation. Thus, the present work invesitages the transport and reaction processes for 10 PFAAs in the subsurface by evaluating batch sorption and 1-dimensional column transport in the presence and absence of co-contaminants and chemical oxidants. Batch sorption experiments demonstrate that sorption of smaller PFAAs does not follow a chain-length dependent trend with sorption of perfluorobutanoate(PFBA) similar to that of perfluorooctanoate (PFOA). The primary impact of NAPL was an increase in isotherm linearity leading to a concentration-dependent impact to sorption Preliminary results suggest that sodium persulfate may increase PFAA sorption due to decreases in system pH in the presence of this oxidant. Column breakthrough of PFAAs yielded column sorption partitioning coefficients (K_d) values smaller than those measured in equilibrium systems, indicating a potential for nonequilibrium transport. Lastly, Flow interruption experiments verified that nonequilibrium tranport was caused by rate-limited sorption of some PFAAs. PFAA breakthrough curves were modeled to obtain rate constants on the order of 10^{-7} to 10^{-5} min^{-1} that can be incorporated into a 2-site sorption model to describe nonequlibrium, advective PFAA transport. These results demonstrate a need for additional studies of the fate and transport of PFAAs, in particular research that further explores the impact of co-contaminants and oxidants in advective scenario.

312

Prediction of Partition Coefficients of Per- and Polyfluoroalkyl Substances and Organosilicons using Polyparameter Linear Free Energy Relationships

S. Endo, Helmholtz Centre for Environmental Research UFZ / Department of Analytical Environmental Chemistry; K. Goss, Department of Analytical Environmental Chemistry

Per- and polyfluoroalkyl substances (PFAS) have received an increasing attention over the past decade. PFAS have characteristic partitioning properties such as relatively high volatility and hydrophobicity compared to the hydrocarbon-based analogues. These properties occur due to the very weak van der Waals (vdW) interaction properties of PFAS. Such characteristic vdW interaction properties are partially shared by organosilicon compounds, another compound class of recent environmental interest. Property estimation models that are calibrated only with hydrocarbon-based compounds can give rise to large errors in estimated values of PFAS and organosilicons, because the latter compounds are out of the model application domains. In this study, polyparameter linear free energy relationships (PP-LFERs) were evaluated for their accuracy to predict environmentally relevant partition coefficients of neutral PFAS and organosilicon compounds, using fluorotelomer alcohols (FTOHs) and cyclic volatile methyl siloxanes (cVMS) as test chemicals. Literature data for octanol–water, air–water, octanol–air, and organic carbon–water partition coefficients of FTOHs and cVMS were used for model validation. To amend the data set, olive oil–water and liposome membrane–water partition coefficients of FTOHs were determined. The results show that, in most cases, the PP-LFER predictions for FTOHs and cVMS are within 1 log unit of the experimental data. In general, a recently proposed form of PP-LFER that uses molar volume (V) and the log hexadecane-air partition coefficient (L) as descriptors for non-specific interactions provided more accurate predictions than the traditional forms of PP-LFERs. The traditional PP-LFERs even caused > 2 log-unit errors for predictions of air-water partition coefficients. A further optimization of descriptors and parameters resulted in high agreement between experimental and PP-LFER-calculated partition coefficients (RMSE < 0.2 log units), if the newer form of PP-LFER was used. The results of this study indicate that the newer form of PP-LFER that uses V and L has significant advantages over the former PP-LFERs to describe and predict the partitioning behavior of PFAS and organosilicons.

Usage, fate and risk of carbon based nanomaterials

313

Strong sorption of PCBs to carbon nanotubes, fullerenes, nanoplastics and micorplastics. Effects of salinity and sediment organic matter.

I. Velzeboer, Wageningen University; C.J. Kwadijk, IMARES; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group Department of Environmental Sciences

With the presence of carbon-based nanoparticles and microplastics in the environment, implications for the fate and effects of traditional hydrophobic chemicals are considered. Therefore, a comparative study was done on the sorption of 17 PCBs to 2 carbon nanoparticle types: multiwalled carbon nanotubes (MWCNTs) and fullerene (C_{60}), 2 types of plastics: micrometer sized polyethylene (micro-PE), nano-polystyrene (nano-PS) and a natural sediment. To increase environmental realism and assess the effects of salinity and sediment organic matter (OM) fouling, multi-solute sorption isotherm experiments at 10^{-5} to 10^{-1} µg L^{-1} were performed in fresh- and seawater, with and without the presence of sediment. Sorption to the 'bulk' sorbents OM and PE dominated by linear hydrophobic partitioning with OM and PE having similar sorption affinity where sorption to MWCNTs, C_{60} and PS was non-linear. PCB sorption to MWCNTs and C_{60} was 3-4 orders of magnitude higher than to OM and PE. Sorption to 70 nm PS was 1-2 orders of magnitude higher than to 10-180 μm PE, which was related to the higher surface-volume ratio of nano-PS. OM and salinity effects varied among sorbents with the largest OM fouling effect observed for the high surface sorbents (MWCNTS, nano-PS), and salinity decreasing sorption for sediment and MWCNTs, but an increasing sorption for the polymers nano-PS and PE. The exceptionally strong sorption of (planar) PCBs to C_{60}, MWCNT and nano-PS in combination with their capability to penetrate membranes may constitute an unforeseen risk.

314

Biological Uptake and Depuration of Radio-labeled Graphene by Daphnia magna

E.J. Petersen, National Institute of Standards Technology; L. Mao, State Key Laboratory of Pollution Control and Resource Reuse / School of the Environment

Graphene layers are potential candidates in a large number of applications. However, little is known about their ecotoxicological risks. One critical factor is the extent to which graphene bioaccumulates in organisms and spreads through food chains. However, this topic has not been investigated yet, largely because methods have not been available to readily quantify it in complex environmental or biological systems. In this study, graphene was synthesized by means of graphitization and exfoliation of sandwich-like $FePO_4$/dodecylamine hybrid nanosheets, and ^{14}C was incorporated in the synthesis (see Figure 1). Carbon-14-labeled graphene was spiked to artificial freshwater and the uptake and depuration of graphene by *Daphnia magna* were assessed. After exposure for 24 h to a 250 μg/L solution of graphene, the graphene concentration in the organism was nearly 1% of the organism dry mass. These organisms excreted the graphene to clean artificial freshwater and achieved roughly constant body burdens after 24 h depuration periods regardless of the initial graphene exposure concentration. Addition of algae and humic acid to water during the depuration period resulted in release of a significant fraction (>90%) of the accumulated graphene, but some still remained in the organism. Accumulated graphene in adult *Daphnia* was likely transferred to the neonates. The uptake and elimination results provided here support the environmental risk assessment of graphene and the graphene quantification method is a powerful tool for additional studies.

Prediction of sorption of organic compounds by multi-walled carbon nanotubes using poly-parameter linear free-energy relationships

T. Hüffer, University of Vienna / Department of Environmental Geosciences; F. Metzelder, University of DuisburgEssen / Instrumental Analytical Chemistry; T. Schmidt, University of DuisburgEssen

The interpretation and prediction of molecular interactions between organic compounds (OC) and carbon-based nanomaterials (CNM) is of major importance to understand the phase transfer processes in environmental matrices. Sorption of OC by CNM has already been studied to some extent; however, time consuming batch experiments in combination with the variability of OC make it impossible to determine all distribution coefficients (K_d) in laboratory experiments. The correlation between K_d values of OC and their physicochemical properties (e.g., K_{ow}) is common practice in environmental chemistry; however, for the prediction of sorption these correlarions are only valid for the compound class and solvent/sorbent phase, which were used for model development. These disadvantages may be overcome by the use of poly-parameter linear free-energy relationships (ppLFER), which incorporate the contribution of individual molecular interactions by properties of the sorbate and the sorbent in a single equation [1]. Recently, a ppLFER model was reported for sorption of aromatic compounds by MWCNTs [2]. However, not all terms of the ppLFER were considered in the development process, which may be necessary for a comprehensive discussion of the relevant interactions. In addition, the derived phase decriptors depend the calibration range of the compound set used for ppLFER development. Thus, the aim of this work was to derive a ppLFER for sorption of multi-walled carbon nanotubes (MWCNTs) in order to investigate the contribution of individual molecular interactions to overall sorption. To this end, individual sorption isotherms of 37 compounds were experimentally determined in batch experiments. The sorbates covered a broad range of substance classes, e.g., non-, mono, and bipolar aliphatic and aromatic compounds. The here presented data set extends literature data by the incorporation of aliphatic compounds, which leads to an overall better prediction of sorption, especially for aliphatic compounds. The results showed that the development of a ppLFER equation allowed a precise prediction of sorption of OC by MWCNTs. The contribution of individual molecular interactions to overall sorption was evaluated, by which the sorption properties of MWCNTs could be characterization using the ppLFER approach. Nanotraces in the nanoworld – Occurrence of fullerenes in environmental samples

J.A. Sanchís, IDAEACSIC / Environmental Chemistry; L.F. Silva, Centro Universitário La Salle; M. Farre, IDAEACSIC; D. Barcelo, IIQABCSIC / Environmental Chemistry

Fullerenes are carbon based nanomaterials in a hollow-spherical shape which, during the recent years, have been extensively studied. While some relevant aspects of their behaviour, fate and their ecotoxicity effects start to be well understood, their quantification in real environmental samples is still an analytical challenge, mostly because of their extremely low concentration levels. In comparison with other emerging contaminants, very few works have reported the occurrence of fullerenes in the environment although characterizing their concentrations in several environmental compartments is an important task for properly assessing the real environmental risks of fullerenes. In this work, several types of environmental matrices (river water, wastewater, soils and sediments) have been analyzed by HPLC, with buckyprep columns, coupled with an atmospheric photoionization source to a high resolution mass spectrometer with a hybrid quadrupole-orbitrap analyzer. This instrumentation offers unique sensitivity and selectivity and the method performance allows the detection of fullerenes in the low pg/L order in water samples. Surface water and sediments samples from two river basins from Barcelona under high anthropogenic pressure have been analyzed. As expected, the release of wastewater effluents is observed to increase the concentrations of unfunctionalized fullerenes in some hot spots. These results and the possible origins of fullerenes will be further discussed. Finally, the occurrence of fullerenes in soils has been studied. Fullerenes have been reported to be emitted from combustion and industrial sources and, in previous works, they were detected in ppq-ppqt concentrations in atmospheric particulate and soils from Saudi Arabia, near oil refinery plants. In the present work, we report the results of the analysis of soils located near fossil combustion power station in Brazil.

Effects of co-exposure of single walled carbon nanotubes and ethinyl estradiol on estrogen receptor binding, activation, and downstream responses in fish

J.H. Bisesi, University of Florida / Environmental and Global Health; B. Castillo, University of Florida / Applied Biology Program; C.M. Lavelle, Physiological Sciences; L. Ferguson, Pratt School of Engineering / Department of Civil and Environmental Engineering; N.D. Denslow, University of Florida / Physiological Sciences; T. Sabo-Attwood, University of Florida / Department of Environmental Global Health Center for Environmental and Human Toxicology

Single walled carbon nanotube (SWCNT) use in manufacturering has led to concerns that these materials may become contaminants of environmental concern. Previous research in our laboratory has shown that SWCNTs are not acutely toxic and are not readily taken up through intestinal exposure routes. But the potential for interaction with other environmental contaminants has lead our laboratory to consider other mechanisms of toxicity for these materials. For example, researchers have found that SWCNTs will readily bind ethinyl estradiol (EE2), a potent synthetic estrogen, potentially decreasing its bioavailability. Inadquate removal during wastewater treatment has led to measureable concetrations of EE2 in final treated wastewater effluent and receiving waters. Fish exposed to EE2 at environmentally relevant concentrations have been shown to exhibit reproductive disruption and evidence of similar effects in the wild suggest that EE2 may be causing reproductive toxicity in the environment. The objective of the current study was to examine the interaction and effects of SWCNTs and EE2 mixtures using a number of *in vitro* and *in vivo* molecular techniques. Fluorescence polarization binding assays and luciferase reporter assays were used to characterize the effect of SWCNTs on the binding and activation of the estrogen receptor (ER) by EE2, respectively. To compare *in vitro* and *in vivo* responses, largemouth bass were gavaged with EE2 and EE2/SWCNTs mixtures. Livers were analyzed for nuclear ER and VTG gene expression levels using qPCR as well as differential protein profiles using iTRAQ LC-MS/MS based proteomics techniques. SWCNTs decreased in vitro binding of EE2 to the estrogen receptor. Luciferase reporter assays showed that in addtion to binding, activation of the estrogen receptor by EE2 is also decreased in the prescence of SWCNTs. The *in vivo* gavage study is currently underway to determine if our *in vitro* responses translate to transcript and protein effects in whole organisms. Results from this study will help increase our understanding of how SWCNTs will interact with the complex mixture of contaminants in our environment as well as natural hormones in organisms.

318

Sorption behaviour of carbon-based nanomaterials: effects of dispersion and aging

M. Kah, University of Vienna / Department of Environmental Geosciences; X. Zang, University of Vienna; T. Hueffer, T. Schmidt, University of DuisburgEssen; T. Hofmann, University of Vienna / Environmental Geosciences

Understanding the interactions between organic contaminants and carbon based nanomaterials (CNMs) is essential for evaluating the materials' potential environmental impact as well as the potential efficiency as superior sorbents. Although a great deal of work has been published on the subject, sorption data remain limited in terms of compounds, concentrations, and conditions investigated. A passive sampling method was developed and validated [1] to address a number of important knowledge gaps on a series of carbon nanotubes [1,2] and fullerenes (C60) [3]. The presentation will combine the results obtained for a series of PAHs and over a range of dispersion scenarios that CNMs may undergo during their life cycle. We considered both intentional dispersion events (e.g., sonication, addition of surfactants) and environmental aging events (e.g., presence of oxygen, natural organic matter, irradiation). Sorption isotherms across a wide range of concentration and extensive characterization of the CNMs systems were combined in order to support mechanistic interpretations of the results. Overall, the series of studies shows that the effects of dispersion and aging cannot be neglected when studying interactions of organic contaminants and CNMs (i.e. discrepancies of orders of magnitude were observed in some cases). We also demonstrate that adaptation of classical experimental set up is necessary to generate reliable data, and evaluate the potential applications and environmental impact of CNMs. [1] Kah M, Zhang XR, Jonker MTO, Hofmann T. 2011. GERDA: A new exposure approach for pesticide inputs into surface waters via surface runoff, erosion and drainage in Germany

M. Bach, University of Giessen; D. Grossmann, German Federal Environment Agency; D. Guerniche, RLP AgroScience GmbH; U. Hommen, Fraunhofer IME; M. Kaiser, German Federal Environment Agency; M. Klein, Fraunhofer Institute of Molecular Biology and Applied Ecology; R. Kubiak, RLP Agroscience; A. Mueller, Federal Environment Agency / IV; T.G. Preuss, Bayer CropScience / Institute for Environmental Research; S. Reichenberger, Footways SAS / FOOTWAYS S.A.S.; K. Thomas, Institute for Agroecology; M. Trapp, RLP AgroScience IfA / Institute for Agroecology

The German national registration procedure currently uses the model EXPOSIT 3.01 to evaluate the surface water exposure from pesticides input with runoff, erosion, and drainage. To adjust the German national exposure and risk assessment procedure to the FOCUS surface water approach and furthermore to enhance some of the its limitations and shortcomings the German Federal Environment Agency (UBA) has launched in 2011 the development of GERDA (GErman Runoff, Erosion, and Drainage risk Assessment) which probably will replace EXPOSIT in future. The concept and the main components of the GERDA project are presented. The models PRZM and MACRO are still used to assess the edge-of-field pesticide losses. Instead of TOXSWA, GERDA uses the model STEPS-1-2-3-4 to calculate PEC hourly time series in the receiving water body. A 30-year time series is applied to assess PECsw/PECsed, in contrast to only 12 or 16 months in FOCUSsw. The ecotox effects of different concentration profiles has been captured and ranked by TK/TD modeling. Results show that both maximum PEC and the AUC (area under curve), are highly rank-correlated to the modeled ecotox effects. Thus both descriptors are used to create cumulative distribution functions (CDFs) which allow identifying scenarios protective for a specific proportion of the landscape. A reliable *a priori* assessment of the "worst-case-ness" of soil-climate combinations is not possible. For a specific soil-climate scenario, defined by a weather time series and a bundle of soil properties, the percentile of the edge-of-field loss calculated by PRZM and MACRO, respectively, can not be derived from the cumulative distribution functions (CDFs) for a soil properties and/or climate variables. To select soil-climate scenarios in a rigorous, statistically based manner, 350000 PRZM and 90000 MACRO simulation runs for soil/climate/crop/substance-combinations, covering the entire arable land area in Germany, were used to calculate long-term PECsw time series. The time series were ranked according to the calculated PECsw to create area-weighted CDFs for Germany. Details on the derivation of the specific national soil-climate scenarios (soil classification and climate zone clustering) have already been presented. This approach facilitates the identification of soil-climate scenarios with a given cumulative probability with respect to ecotoxicological effects and the spatial representativity of the selected soil-climate scenarios.

320

GERDA: A new software tool for pesticide exposure assessment for surface waters in Germany

S. Reichenberger, Footways SAS / FOOTWAYS S.A.S.; M. Bach, University of Giessen; D. Grossmann, German Federal Environment Agency; D. Guerniche, RLP AgroScience GmbH; U. Hommen, Fraunhofer IME; M. Kaiser, German Federal Environment Agency; M. Klein, Fraunhofer Institute of Molecular Biology and Applied Ecology; R. Kubiak, RLP Agroscience; A. Mueller, Federal Environment Agency / IV; K. Thomas, Institute for Agroecology; M. Trapp, RLP AgroScience IfA / Institute for Agroecology

The EU regulation (EC) No1107/2009 calls for a harmonization of the various national pesticide exposure and risk assessment approaches between EU member states. The German Federal Environment Agency (UBA) therefore launched a project (FKZ 3711 63 427) to harmonize the German national exposure assessment procedure for surface waters with the FOCUSsw scenario approach used at the EU level for approval of active substances. Within the project the exposure assessment tool GERDA (German Erosion, Runoff and Drainage Assessment) has been developed which takes into account the full range of agro-pedo-climatic conditions in Germany. GERDA produces 30-year PECsw/sed time series for i) drift and drainage inputs and ii) drift, surface runoff and erosion (and potentially lateral subsurface flow) inputs into surface water. Pesticide losses from the field via tile drains (and lateral subsurface flow) are simulated with MACRO 5.2, while pesticide losses via surface runoff and erosion are simulated using PRZM 4.51. Furthermore, GERDA includes the option of simulating vegetated filter strips with the model VFSMOD. Pesticide fate in surface water is calculated with the model STEPS. GERDA includes 12 climate scenarios, all 102 agriculturally relevant FOOTPRINT soil types (FSTs) for Germany and 49 different crops. The GERDA package includes 1296 spatial cumulative distribution functions (CDFs) of worst-case-ness corresponding to unique combinations of i) pathway: drainage or surface runoff, ii) Koc, iii) DT50 in soil, iv) application month, v) crop seasonality and vi) descriptor variable: median (annual PECsw,max) or median (annual area under the curve). The user first creates or selects a project and then chooses the desired cumulative area percentage of worst-case-ness. GERDA then determines internally the relevant 4-16 CDFs and reads off the soil/climate combinations corresponding to the selected percentage. The user can now launch the PRZM and MACRO simulations. Once the results of PRZM and MACRO are available, VFSMOD (if applicable) and STEPS can be run. For each STEPS simulation, the GERDA user can view a summary report containing an echo of the inputs and the registration-relevant outputs. Moreover, a 30-year hourly time series of PECsw/sed is stored which can be used for e.g. TKTD modelling. GERDA constitutes a major scientific improvement in comparison to FOCUSsw. The spatially probabilistic approach of GERDA enables informed regulatory decisions on a national level.

321

Losses of glyphosate and AMPA by runoff in a typical residential area: monitoring and a conceptual model

T. Tang, VITO NV / Unit RMA; A. van Griensven, Vrije universiteit Brussel / Dept Hydrology and Hydraulic Engineering; P. Seuntjens, J. Bronders, VITO Flemish Institute for Technological Research / Unit RMA; N. Desmet; W. Boenne, VITO Flemish Institute for Technological Research / Unit RMA

Runoff from urban hard surfaces may be an important source of pesticides in urban streams. To investigate the behaviour of pesticide runoff from hard surfaces, a monitoring campaign was conducted in a typical Belgian residential area (9.5 ha) between 15 May and 10 August, 2013. The campaign yielded a relatively high-resolution dataset of rainfall, flow and concentrations of glyphosate and its major degradation product - aminomethylphosphonic acid (AMPA), as well as detailed information from surveys with residents on glyphosate application and the characteristics of the studied area. On the other hand, a new conceptual model will be proposed based on an extensive literature review, taking into account the spatial characteristics of the residential area. Here, we will first present the results from the monitoring campaign and then the model concept for simulating urban pesticide runoff. According to our surveys and measurements, less than 0,3% of applied glyphosate was detected at the outlet of storm drainage. Twelve rainfall events were analysed to generalize the glyphosate behaviours during runoff. Unsurprisingly, glyphosate losses during individual events are associated with a wide range of factors, including the application rate, the interval between application and rainfall event and the potential location of application. Meanwhile, a few factors are identified as non-determinant. For instance, the flow rate is found to have no correlation with the concentrations of glyphosate and AMPA. Yet, the wide range of influencing factors indicate monitoring alone is not sufficient to quantitatively explain the complex pesticide runoff processes. Therefore, a conceptual model will be proposed that considers hydrology-driven processes and non-hydrological processes. It will utilize the grid-cell as the spatial unit and user-defined time-step, therefore, taking proper spatial and temporal variability into account. This conceptual model will be incorporated into an existing dynamic distributed hydrological model. The resulting model, in its simple form, will be applicable in regulatory processes for tailor-made applications.

322

Feedback from ANSES on the use of FOCUS Surface Water tools for Southern zonal risk assessment

A. Boivin, E. FARAMA, a. conrad, A. Duboisset, V. Poulsen, ANSES

Risk assessment of surface water contamination for the approval of active substances at European level is conducted with the European FOCUS (FOrum for the Coordination of pesticide fate models and their USe) exposure models. The objective of these tools is to determine whether a safe use for aquatic organisms can be identified in a European area. However, although initially established for European assessment, the FOCUS tools are now used in several European countries for aquatic risk assessment for preparations. This presentation gives feedbacks on ANSES experience on the use of FOCUS Surface Water exposure models in the framework of zonal dossiers. Risk assessment in France is performed considering all FOCUS Surface Water scenarios defined in Step 3, except D1 scenario. They cover the variety of agro-pedo-climatic conditions, and are used to identify acceptable or unacceptable risks for aquatic organisms, including mitigation options when appropriate. Key parameters of the active substances for describing the processes to be taken into account in the exposure models are usually considered to be the degradation rates and adsorption coefficients. However, some other input parameters have a very significant impact on the Predicted Environmental Concentrations in surface water (PECsw), as for example the Freundlich coefficient and the wash-off factor. In addition, parameters related to the application pattern are also very sensitive. Given that the FOCUS Surface Water models only consider a sixteen-month assessment period, the PECsw values are event driven and very related to the choice of the application window. This last point is considered as an important limit for the interpretation of the model outputs. Taking into account several years of repeated applications as done for PEC groundwater calculations would improve the robustness of aquatic risk assessment.

323

Proziris – a new tool to support pesticide registration at the national and zonal levels

M. Burns, I. Dubus, Footways SAS; S. Reichenberger, Footways SAS / FOOTWAYS S.A.S.; J. Pires, H. Tripault, B. Grand-Perret, S. Briand, H. Dubus, Footways SAS

EFSA has recommended for national assessments to be undertaken to better evaluate the environmental risks of crop protection products: "... the FOCUS scenarios are limited to demonstrating safe use in a significant area in the EU… For national assessments, all crops and the entire potential use area must be considered." At the same time, EU Regulation 1107/2009 requires zonal risk assessments to be undertaken. Therefore, there is an urgent need for a tool able to perform leaching and surface water risk assessments for all agriculturally relevant areas of the EU. \nA multi-lingual web-based risk assessment platform has been developed to support pesticide registration at the national and zonal scales. The system connects a web interface with a supercomputer dedicated to pesticide fate modelling. The input interface allows users to specify the assessment details including i) geographical extent (country or zone), ii) crop, iii) pesticide application date(s) and rate(s), iv) physicochemical characteristics of active substance and metabolites, and v) eventual mitigation measures. Spatially-distributed pesticide fate modelling is undertaken using European-level datasets for soils SGDBE) and land cover / land use (CAPRI). The modelling is undertaken for 10 years using the PRZM 4.51 (surface runoff, erosion) and MACRO 5.2 (leaching, drainage, lateral subsurface flow) models based on the FOOTPRINT Soil Type approach. Spray drift input into surface water is calculated with the Ganzelmeier-Rautmann drift functions. Proziris is able to simulate mitigation measures for spray drift (drift-reducing nozzles, minimum distances) as well as for surface runoff and erosion (grassed buffer strips). Two options are available for buffer strips: a) reduction efficiencies as a function of width, b) dynamic simulation with VFSMOD. All pesticide and water fluxes into surface water bodies are fed into a recoded version of the STEPS model which calculates hourly PECsw, PECsed and PECporewater time series. The obtained PECsw/sed/pw and leaching time series are post-processed automatically to yield all relevant endpoints. The results of an assessment are provided to the user via the web output interface both in non-aggregated and in aggregated form (spatial CDFs, maps). Due to its spatially distributed and spatially probabilitistic approach, Proziris provides a much better accuracy and protectiveness than approaches with only a small number of scenarios like FOCUS.

Sorption and bioavailability of organic chemicals: mechanisms and applications in innovative remediation

324

Interaction of amines with natural soil studied with nitroxyl spin probes

M. Matthies, University of Osnabrueck / Institute of Environmental Research; O. Alexandrova, J. Klasmeier, University of Osnabrueck / Institute of Environmental Systems Research; H. Steinhoff, University of Osnabrueck / Physics

The environmental risk of organic xenobiotics released to soils is controlled by their transformation, sorption and binding processes. However, the molecular mechanisms of reversible and irreversible interactions of xenobiotics with soil constituents are only partly understood. We present a new approach of using stable electron spin probes to investigate the interactions of typical functional groups of xenobiotics with the molecular environment of natural soil. We used the nitroxyl spin labels TEMPO (2,2,6,6-Tetramethylpiperidin-1-oxyl), amino-TEMPO (4-amino-2,2,6,6-Tetramethylpiperidin-1-oxyl) and anilino-NO (2,5,5-Trimethyl-2-(3-aminophenyl)pyrrolidin-1-oxyl), which differ in their hydrophobicity and reactivity to soil organic matter. A significant broadening of the ESR-signals of anilino-NO incubated with luvisol soil indicates a strong restriction of the reorientational motion of the spin probe, which could not be observed with the other two spin probes. The same signals could be detected with the natural humic acid leonardite, which suggest a strong binding to soil humic substances, i.e. covalent binding. The unchanged signals of soil organic radicals rules out radical coupling and suggests a nucleophilic addition reaction as the covalent binding mechanism. Sequential desorption from incubated soil with increasing water volume revealed an almost exponential decrease of the percentage of all three spin probes remaining in the soil. The fractions of TEMPO and amino-TEMPO almost completely diminished with increasing volume of percolate, whereas those of aniline-NO approximated a stationary level of 6% remaining in soil. We conclude that large fractions of all three spin probes are weakly bound to soil with low binding energy, because they can be extracted by an excess of water. For anilino-NO, results indicate an additional fraction to be irreversibly bound to soil. This finding supports the conclusion from the ESR-spectroscopic analysis of the interaction of the spin probes. Our work clearly demonstrates for the first time the large benefit of using spin probes to investigate the interaction of xenobiotics with natural soil via their specific functional groups.

325

Including organic mixture's influence on dioxins and furans' bioavailability for toxic impact assessment in a life cycle context

E. Taing, CIRAIG / CIRAIG Department of Chemical Engineering; C. Bulle, CIRAIG Polytechnique Montreal / Chemical Engineering; L. Deschenes, Ecole Polytechnique de Montreal / Genie Chimique

Polychlorodibenzo-p-dioxins and -furans (PCDD/Fs) are never produced on purpose but as undesired impurities of chlorinated compounds. The pentachlorophenol (PCP) pole-treating oil contains traces of PCDD/Fs and it has been proven that PCDD/Fs migrate deeper in the soil due to the oil's influence, which modifies the PCDD/Fs sorption behavior between soil and water in contaminated sites around PCP treated poles. In the generic context of Life Cycle Assessment (LCA), any interactions between co-contaminants are not included to characterize (eco)toxic impacts. Therefore the main objective of this study is to understand to what extent (eco)toxic impacts of PCDD/Fs would change by including the oil's influence on PCDD/Fs' fate in an LCA context. 2,3,7,8-tetrachlorodibenzodioxin (TCDD) was chosen as a proxy of the PCDD/F mixture. Based on literature, it is assumed that 1) the oil carries the PCDD/F in its environmental distribution in the same proportions, 2) the oil's degradation releases the PCDD/Fs, 3) they are considered as emitted from the compartment where the oil is degraded instead of being emitted in the initial emission compartment. The influenced TCDD's Characterization Factors (CF) are obtained from the influenced Fate Factors and by ignoring the oil's influences on PCDD/Fs' exposure and effects. The toxic impacts of the Canadian overall PCDD/F emissions in 2001 were then obtained. The approach led to a significant increase of potential toxic impacts when PCDD/Fs are emitted into soil only. The application of these CFs on the overall PCDD/F emissions in Canada in 2001 did not result in a high increase because the important change in CF did not overtake the small quantity of PCDD/Fs emitted into soil by poles compared to the overall emission. This work remains exploratory but represents a first attempt to integrate the contaminants' interactions in a LCA context and led to significant increases for TCDD's CFs for an emission into soil. However as the volatilization of PCDD/Fs through organic phases represents an important mechanism, it is recommended to lead studies on this topic to confirm or invalidate this approach.

326

Positioning activated carbon amendment technologies in a novel framework for sediment management

D. Kupryianchyk, Norwegian Geotechnical Inst; M. Rakowska, Wageningen University; M. van Veggel, Martens en van Oord; J. Harmsen, Alterra WageningenUR; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group Department of Environmental Sciences

Contaminated sediments can pose serious threats to human health and the environment by serving as a source of persistent toxic chemicals to humans or aquatic organisms. Amendment of contaminated sediments with strong sorbents like activated carbon (AC) is a rapidly developing management strategy. To date, much attention has been paid to the technical and ecological features and implications of sediment remediation with AC. The present work provides an evaluation of sediment remediation with AC as a sediment management option, in comparison with traditional remediation techniques in use, also covering the main factors related to their full-scale application. First, a summary of AC treatment technology based on recent reviews and the latest literature was provided. This included the effectiveness and ecological safety of the use of AC in natural systems. Then, a qualitative overview of (dis)advantages of current alternatives to remediate contaminated sediments was presented. Finally, this information was used to provide a novel framework for the supporting decisions concerning sediment remediation and re-use.

327

Changes in organic contaminant availability following biochar/activated carbon amendment for enhanced phytostabilisation of contaminated soils

A. Brennan, University of Strathclyde / Department of Civil and Environmental Engineering; C. Switzer, University of Strathclyde

The potential role of biochars and activated carbons in remediating contaminated soils has been suggested many times before but a greater mechanistic understanding of the effects of amendment on contaminant availability and plant establishment is required before full scale field application. Previous work suggests plant establishment can be enhanced by amendment and contaminant availability can be reduced but the heterogeneous nature of different biochars means that this is not always the case. In order to further understand how biochar and activated carbon can enhance soil phytostabilisation and what their effect on PAH availability is, a 90 day outdoor pot trial with Lolium multiflorum (Italian ryegrasss) in coal tar contaminated soil was carried out. A total of 9 treatment and control scenarios were set up (n=5 per treatment) as follows: 1)soil control 2)soil + plant 3) soil + plant + NPK; treatments 4-6 and 7-9as 1-3 except with 1% maize biochar addition and 1% granular activated carbon addition respectively. On the hypothesis that the different treatments would significantly affect PAH uptake to plants and soil porewater PAH concentrations compared to controls, PAHs concentrations were assessed in the soil, soil porewater and plants across treatments. Polyoxymethylene (POM) samplers were used to assess porewater concentrations and predict plant uptake. Activated carbon amendment significantly reduced all PAH concentrations in porewater and plants while variable effects were observed for the biochar

amendment.

Investigating biochar and activated carbon effects on microbial community structures in petroleum hydrocarbon contaminated soils
G. Mangse, Newcastle University / School of Civil Engieenering Geoscience; P. Meynet, Newcastle University / CEGS; R. Davenport, Newcastle University / School of Civil Engineering and Geosciences; D. Werner, Newcastle University / Civil Eng and Geosciences
Organic compounds tend to persist in the environment and may become a serious cause for concern because of their detrimental effects to humans and the environment. It is therefore imperative to consistently develop effective approaches for the remediation of these compounds from the environment. A recently developed novel technique for the remediation of organic compounds is the use of sorbents to amend contaminated soils and sediments. Sorbents have the capacity to adsorb organic pollutants from the environment because of their porous nature. At the same time, sorption of organic pollutants reduces bioavailability of the pollutants to indigenous microorganisms present in soils and sediments. Because of these antagonistic effects, the net effects of sorbents on biodegradation of organic pollutants cannot be easily predicted. It is therefore necessary to gain a better understanding of the trade-offs which may or may not exist between sorption of organic compounds form the soil and biodegradation by soil microorganisms. In the current study, we investigated the effects of biochar and activated carbon on microbial community structures in volatile petroleum hydrocarbon contaminated soils. Previously uncontaminated gravelly sand was amended with 2% biochar (d.w.) and 2% activated carbon (d.w.) respectively. Soils (amended and unamended) were packed into three separate glass columns and a vial containing a mixture of 12 volatile petroleum hydrocarbons (VPHs) was connected to each column via a curved glass tube to serve as a non-aqueous phase liquid (NAPL) source. Soil pore respiration was monitored for a duration of 430 days after which glass columns were taken apart. Soil bacterial DNA was extracted from three sections of each column and the V4 and most of the V5 regions of 16S rRNA gene of DNA isolates were PCR amplified using barcoded 515f and 926r primers. Amplicons were sequenced on a pyrosequencing Roche 454 GS FLX + System and sequences analysed using the Quantitative Insights Into Microbial Ecology (QIIME) tool kit. The major bacterial taxa (relative abundance >1.5) identified include Deltaproteobacteria, Alphaproteobacteria, Clostridia and Bacilli all of which have been previously implicated in petroleum hydrocarbon degradation. Sorbent amendment also had a detectable effect on the relative abundances of bacterial communities between the treatments ($p< 0.05$).
Keywords: Bioavailabilty, VPHs, pyrosequencing, biodegradation

Tools for the evaluation of remediation process in Microbial Electroremediating Cell (MERC).
K. Boltes, University of Alcala / Chemical Enginnering; J. Rodrigo, A. Esteve Nunez, University of Alcala
We presents the techniques using to evaluate Microbial Electroremediating Cell (MERC), a novel tool recently propose by this authors, based on Microbial Fuel Cell, for in situ soil remediation. Our results support the concept of electrogenesis-stimulated bioremediation, which consist in stimulating the microbial oxidation of the pollutant by supplying an anode as extra electron acceptor. For evaluating MERC, we have design a special set up which allow to assay polluted soil samples under different conditions to evaluate the relevance of biological process and physicochemical process (pollutant sorption in soil and electrode materials; electrochemistry mediated transformations). Using differents techniques we confirm MERC as an interesting and efficient methodology which offers the possibility of a) monitoring the in situ pollutant biodegradation using environmentally-friendly tools, and b) stimulate native populations, overcoming the availability in electron acceptor that typically limits biodegradation of organic pollutants, without a sever modification of the soil.

Advancements in life cycle impact assessment and footprint method development (III)

330
Chemical footprint assessment: presentation of method and application to a case study involving different spatial scales
M.L. Diamond, University of Toronto / Department of Earth Sciences; A. Bjorn, Technical University of Denmark / Department of Management Engineering; M. Birkved, Technical University of Denmark; M.Z. Hauschild, Technical University of Denmark / Department of Management Engineering
Expressing Life Cycle Impact Assessment (LCIA) results as footprints is gaining increasing attention by scientific and political communities alike. Footprint assessments have the potential to improve our ability to communicate environmental impacts to stakeholders since footprints are expressed in units more intuitive than those of traditional LCIA impact categories. Furthermore some footprint methods, such as the ecological footprint, can be compared with a carrying capacity, which qualifies them as indicators relevant to environmental sustainability assessment. Footprint methods related to land use, water use and carbon emissions are well established, but as of now, no operational chemical footprint (ChF) indicator exists. We present a newly developed ChF method for quantifying the combined ecotoxicological impact in freshwater from emissions within a territory. In this context a ChF is defined as "the occupation of a (theoretical) fresh water volume needed to dilute a chemical emission to the point where it causes no damage to ecosystems in the volume during its presence". $HC5_{NOEC}$, the concentration at which a maximum 5% of modeled ecosystem species are affected, is used as a safe reference concentration. This allows for the conversion of the USEtox output [PAF.m^3.day] into a ChF [km^3]. Results can be compared to the availability of surface freshwater at the relevant spatial scale. We tested the feasibility of the method by applying it to an inventory of the chemical emissions within Europe in 2004. We found that the ChF of several large European cities exceeded the carrying capacity of surrounding freshwater bodies by more than 10 times, although the carrying capacity of all European surface freshwaters on average was close to non-exceedance. This observation illustrates the inhomogenous distribution of surface freshwater and chemical emissions within the European continent and the importance of focusing territorial ChF assessments on cities and their surrounding freshwater bodies. This method of calculating ChF for freshwaters has the benefit of being easily communicated to decision makers and furthermore, is relevant for environmental sustainability assessment because it directly relates to the environment's carrying capacity. The weakest link in the assessment is knowledge of emission inventories at the spatial scale of cities to small regions.

Great ideas – greater difficulties in their modelling: when LCIA hits a dead-end. A tale of ecotoxic struggle, with a silver lining.
C.E. Raptis, Institute of Environmental Engineering; R. Juraske, ETH Zurich; S. Hellweg, ETH Zurich / Institute of Environmental Engineering
Existing aquatic ecotoxicity effect models employed in life cycle impact assessment (LCIA) inadequately address the need to characterise complex chemical mixtures, such as industrial effluents, since the former have been developed explicitly for emissions of single chemicals. Effluent emissions form part of the lifecyle of numerous products, so there is great motivation to find meaningful ways of characterising the effect these effluents have as a whole, avoiding the need to make rough estimations based on approximations of the comprising individual chemicals. One such meaningful way of quantifying the relative ecotoxic potential of industrial effluents would be via organic sum-parameters, such as TOC, COD, or BOD. These measures of bulk organic content are widespread and easy to measure, so characterising their ecotoxic effect would equate to bypassing the need to estimate their composition. Based on whole effluent toxicity (WET) test results, the idea is to roughly 'split' the effluent into two parts, the organic and the inorganic fraction, and then deduct from the toxicity of the whole effluent the toxicity of the inorganic fraction. If the mixture toxicity principle of concentration addition is valid for these two *groups* of chemicals, then we can expect the remaining toxicity to be attributable to the organics, and we can assign this to a measure of organic content, e.g. TOC. We now have a way of estimating the measure of ecotoxicity for TOC, which will make it comparable to individual chemicals, namely its EC50. With results for several aquatic species, we can then calculate an effect factor for TOC (EF_{TOC}). The elegance of this idea lies in its overall simplicity in the way we think of effluents, and in the way it promises to gives us a means of characterising the bulk of the effluents. However, this overall simple framework is actually made up of difficult and data-intensive steps, which require several assumptions to be made. In this work we present these steps in detail, and our effort to extract something useful for LCIA from the results. LCIA method development often hits a dead-end, despite great ideas and even greater efforts, but there is a silver lining, because if not in LCIA, the results obtained can be applied to other fields.

332
Development of characterization factors for metals in coastal seawater
M.Z. Hauschild, Technical University of Denmark / Section of Quanlitative Sustainability Assessment DTU Management Engineering; Y. Dong, Department of Management Engineering; R.K. Rosenbaum, National Research Institute of Science and Technology for Environment and Agriculture Irstea / UMR ITAP
Metal ecotoxicity Characterization Factors (CFs) in coastal seawater were not developed in USEtox for Life Cycle Impact Assessment (LCIA), due to lack of appropriate ecotoxicity data and inadequate consideration of metal bioavailability in seawater. Taking into account the speciation behavior of metals in seawater and using effect data exclusively for marine organisms, two sets of spatially differentiated CFs were developed for the metals Cd, Co, Cu(II), Ni, Pb and Zn in coastal seawater. One set of CFs ($CF_{sw\text{-}sw}$) addresses the direct metal emission to coastal seawater while the other set ($CF_{fw\text{-}sw}$) represents the ecotoxicity potential of metals in coastal seawater caused by metal emission to freshwater followed by transport to the seawater compartment, taking into account the fate of metal in freshwater and in the estuary. CF is the product of three factors: Fate Factor (FF), Bioavailability Factor (BF), and Effect Factor (EF). The multimedia fate model of USEtox was used to calculate the FF. WHAM 7.0 was used to model metal speciation underlying the BF. Free Ion Activity Model (FIAM) was used to model EF. The results showed that for a given metal, FFin seawater was higher than in freshwater, due to longer residence time of the water in the coastal seawater than in freshwater. The difference between FF in seawater and freshwater was smaller since the difference in water residence time was partially neutralized by metal removal in estuaries. Metal BFs in seawater were similar or slightly higher than in freshwater due to the lower DOC and SPM concentration in seawater. For most metals, EFs were lower in seawater than freshwater, due to lower sensitivity of seawater biota to metals. As a general observation, $CF_{fw\text{-}sw}$ was lower than $CF_{sw\text{-}sw}$ due to metal removal in freshwater and estuary, but the difference was modest for most metals. For Pb , seawater CF were up to 1-4 orders of magnitude higher than freshwater CF. But for the other metals, seawater CFs were similar to freshwater CFs, indicating that the higher FF and BF in seawater were largely counterweighed by the lower EF for these metals. The variation of CFs in different coastal seawaters were up to ca. 2-3 orders of magnitude for one metal, indicating the importance of using spatial differentiated CFs. Compared with USES-LCA default $CF_{sw\text{-}sw}$, the new $CF_{sw\text{-}sw}$ were at least 3 orders of magnitude lower for all metals except Pb, of which USES-LCA $CF_{sw\text{-}sw}$ fall within the range of this study. This implied that for some metals, ecotoxicity CFs in coastal seawater might be overestimated in previous LCIA methods.

Confronting Health Effects of Particulate Matter in LCIA
T.E. McKone, University of California / Sustainable Energy Systems Group; P. Fantke, Technical University of Denmark / IER; O. Jolliet, University of Michigan / School of Public Health
Ambient particulate matter (PM) is one of the most important environmental stressors contributing to the global human disease burden. However, there a lack of guidance on how to include health effects from PM exposure in the health footprint for life cycle impact assessment (LCIA). A task force was initiated to build a PM health impact framework and factors based on scientific consensus. Existing literature was reviewed and expert input was collected and discussed in an initial Guidance Workshop. Key scientific questions and challenges for quantifying health effects from PM exposure have been discussed and initial guidance and recommendations for the upcoming impact quantification process were developed. Preliminary recommendations address the general assessment framework, aspects to determine intake fractions (iF), and aspects to determine exposure-response factors (ERF) along with disease severity: These recommendations include: (1) the 2011 framework proposed by Humbert et al. (doi:10.1021/es103563z) provides an assessment starting point; (2) iF can be used as exposure metric with breathing rate linking ambient concentration and intake; (3) disability-adjusted life years without age-weighting and discounting can be used as a health metric; (4) population archetypes can account for aspects influencing intake fractions; (5) spatially-differentiated iF should be established for all archetypes with geographic differentiation further discussed; (6) emission-weighted iF are needed in all cases where emission and/or exposure conditions are unclear; (7) the 2010 Global Burden of Disease Study provides a useful starting point for calculating health effects; (8) compared to all-cause mortality, cause-specific mortality can provide a more informative basis an LCIA metric but age- and cause-specific disability weights need further analyses; (9) the need remains to discuss whether and how to consistently integrate non-linear exposure-response into LCIA; and (10) $PM_{2.5}$can be used as indicator of the health risk associated with PM inhalation exposure. There is not sufficient evidence-based justification to differentiate between different primary/secondary PM sources or between different particle sizes regarding toxicity. Our study constitutes a first step towards arriving at recommendations for how to account for health effects of emissions of primary PM and secondary PM precursors in LCIA. However, a range of inconclusive aspects requires further analysis.

334
Using machine learning for human toxicity and freshwater ecotoxicity characterization of chemical emissions
A. Marvuglia, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTEResource Centre for Environmental Technologies CRTE; M. Kanevski, M. Leuenberger, University of Lausanne / Centre de recherche en environnement terrestre CRET; E. Benetto, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE
Toxicity characterization of chemical emissions is a complex task which usually proceeds via multimedia models attached to models of dose–response relationships to assess the effects on targets. Different models and approaches are available, but all require a vast amount of data on the properties of the chemical compounds being assessed, which are hard to collect or hardly available (especially for less common or newly developed chemicals). An example of such models is USEtox™, a consensual model for the characterization of human toxicity and freshwater eco-toxicity. The final aim of this work is building a data-driven model for chemical characterization from a limited amount of substance-specific data, complementary (and not alternative) to the existing assessment models. By focusing on Usetox™, and more specifically on the modelling of the fate factor (FF) from continental urban air to urban air ($FF_{airU,airU}$), for which data are available, this work makes a step ahead in that direction by pursuing two main objectives: 1) performing for the first time an extensive exploratory data analysis (EDA) of the input space containing substance-specific properties at the aim of detecting particular patterns in the data manifold; 2) exploring the modelling efficiency (for predicting toxicity) of a set of algorithms based on linear partial least squares (PLS) regression and on non-linear approaches: kernel PLS (KPLS), adaptive general regression neural networks (GRNN) and random forests (RF). The database available in USEtox™ wasused in this study. For the sake of simplicity, only the organic compounds have been taken into account here, to facilitate the development and testing of the approach pursued here, while not affecting the consistency of the outcomes and their applicability to the other compounds. Four main explanatory variables (degradation rate in air, degradation rate in water, Henry law coefficient at 25°C and partitioning coefficient between octanol and water) were identified in the input space. They are, therefore, the most important variables which have to be assessed with a high degree of accuracy. Current research efforts are addressing other parts of the model affected by important data gaps, e.g. to the calculation of human health effect factors. The presentation will focus on the results from non-linear algorithms and on the added value of the data-driven model for the LCA community as a whole and the toxicity assessment practice in particular.

Monitoring the efficiency of risk mitigation measure protecting the environment from pesticide exposure and effects

Feedback from MAgPIE workshop - Environmental risk mitigation measures in risk assessment and management for P
V. Poulsen, ANSES; A. Alix, Dow Agrosciences / Risk Management
A European workshop under the auspices of SETAC and European Commision was organised in order to provide European regulatory authorities a toolbox of risk mitigation measures designed for the use of Plant Protection Products for agricultural purposes. During the two workshops (one in Rome and one in Madrid) and due to their work in-between, stakeholders provided, for groundwater, surface water, in-field terrestrial and soil organisms, and off-field terrestrial organisms: - A summary of existing risk mitigation measures used in the different countries for regulatory purposes, - An analysis of these risk mitigation measures according to: their effciciency, their potential use in risk asessment, their practicallity of implementation for farmers, their practicallity of implementation from a regulatory point of view, - A collection of voluntary initiatives and stewardship programmes, - Feedback on experiences in risk management, - Identification of needs for adaptation/proposal of new S phrases, - Identification of needs for further developpements. For each compartment of the environment, participants prepared a common risk mitigation toolbox in which member states could chose the tools being most appropriate for their specific legal and agro environmental conditions whilst ensuring the same level of protection as in the rest of Europe. Proceedings are in preparation and are intended to be finalized in 2014. They will reflect the state of the art of environmental risk mtigation measures for plant protection products, and provide analyses of these measures according to the discussions among all participants. They will therefore provide risk managers and risk assessors with an efficient toolbox. A website will contain all suitable information to be shared by stakeholders, and to be communicated to farmers in order to help them implementing the most relevant measures at a local scale.

336
Groundwater protection measures for use of Plant Protection Products
A. Sapiets, Syngenta / Syngenta; P. Sweeney, Syngenta; J. Dyson, Syngenta International AG / Sustainable Agriculture and Stewardship
The response of groundwater residues to the introduction of mitigation measures can extend to decades, therefore a combination of fate and behaviour data, local hydrogeological conditions and modelling is commonly required to help design appropriate best management practices for Plant Protection Products (PPP). Mitigation measures can be categorised according to the process or behaviour they are designed to address for example: the field setting (intrinsic soil properties and climatic conditions), the built environment (presence of drinking water abstraction wells), farmer practice and choices and finally the chemical characteristics of the PPP. Relevant mitigation measures may include the exclusion of vulnerable zones with shallow groundwater and porous soils, control of irrigation and using the most appropriate PPP application rate, timing and technique. Currently there is no model routinely used in the PPP regulatory process that describes the potential for residues to be found in groundwater below one metre depth. However real-world monitoring has clearly shown that a combination of important environmental processes, actual farmer use rates and an assessment endpoint in shallow groundwater (The number of mitigation options available to minimise the potential for PPPs to be transported

to groundwater is limited. Additionally a long timeframe is unavoidable for the evaluation of trends indicating satisfactory outcomes from groundwater related best practices. There is, therefore, a pressing need for agreed and validated methodologies to model the effect of such mitigation options within the regulatory process.

Monitoring long-term trends of pesticides in surface waters
J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides; B. Lindstrom, M. Larsson, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; M. Gönczi, SLU / Centre for Chemical Pesticides
Environmental monitoring of pesticides in Sweden started during the mid-80s as short term, research based investigations of possible occurrence of pesticides in streams and rivers. However, during the last decade the monitoring program has expanded substantially. Much effort was directed towards including relevant parameters to enhance interpretation possibilities. Parameters collected include detailed pesticide use data within the catchments, continuous flow measurements, precipitation and soil data. Water sampling is performed continuously with automatic samplers at the catchment outlet. Information on pesticide use enables us to adapt the analytical programme, aiming at including ca 90% of the total volume applied in the catchment area. Results from the programme are e.g. used to assess the success of national legislation and risk management programmes. Some overall results will be presented, including results from one catchment reflecting long-term (20 y) changes in pesticide concentrations due to increased awareness amongst the farmers. Detected concentrations will be compared with the EU EQS and Swedish threshold values for pesticides. This comparison is performed using a Pesticide Toxicity Index (PTI). Results from pesticide monitoring programmes generate information that help researchers, industry and regulators to better understand the pesticide-environment relationship. Results generated can also be used to ensure that the environmental behaviour of pesticides is in accordance with regulatory intentions and applications done with the use of best management practices. This forms the basis for better communication of appropriate practices for minimising possible negative impacts from pesticide use on the environment.

Risk management for pollinators: regulatory context, overview of risk management tools and perspectives
A. Alix, Dow Agrosciences / Risk Management; C. Garrido, IBACON; M. Miles, Bayer CropScience UK / Analytical Chemistry and Environmental Sciences; E. Johansen, Washington Dept of Agriculture; B. golla, Institute for Strategies and Technology Assessment
Risk mitigation measures dedicated to pollinators are of increasing importance for environmental protection in the area of the use of pesticides in crop protection. The question raises multiple exchanges between European authorities, and many initiatives have been undertaken in order to develop, implement and account for risk mitigation measures in the risk assessment procedures. The Organisation for Economical Co-Operation and Development (OECD) has undertaken surveys aiming at collecting risk mitigation practices in OECD countries. In May and November 2013, a European workshop under the auspices of SETAC and European Commission was organised in order to provide European regulatory authorities with a toolbox of risk mitigation measures designed for the use of Plant Protection Products for agricultural purposes. This presentation will illustrate the outcome of the work undertaken by these organisations in the inventory and review of the risk mitigation measures developed and implemented to protect managed and wild bees in agricultural landscape.

340
Plant protection products in surface water: how inputs can be reduced on-farm
O. Daniel, Agroscope ACW; L. Buehler, Agroscope
Agriculture aims at keeping the input of plant protection products (PPP) into surface water to a minimum. Measures to reach this goal are a sophisticated authorisation process, restraints bound to the authorisation such as distances from edge of field to surface water, restraints from agri-environmental schemes such as a 6 m buffer strip, periodic control of the spraying equipment and training of the farmers. Nevertheless, PPP are found in surface water at both, concentrations below and above regulatory thresholds. Agricultural structures, soil and topographical properties vary in Switzerland within a very small scale. Therefore, it is believed that a further minimisation can be achieved by on-farm and intra-parcel measures. We present a categorisation tool which considers erosion potential, soil properties and connectivity to surface water. Each parcel of a farm is categorised with respect of being a potential PPP source, contributing to the transport of PPP (run-off, infiltration) and the connectivity (surface: run-off, sub-surface: drainage) to surface water. Connectivity is affected by physical barriers, the type of neighbourhood parcel, drainages in plain areas, drainages in sinks, gullies in streets and vegetated buffers. Information on the parcels was taken from various GIS maps (e.g. erosion potential), local maps (drainage, parcel plan) and orthofotos. This information was cross-checked and supplemented with information gathered from an interview with farmers and a field inspection. A pilot study with three farms came to the result that: a) hot spots for PPP inputs into surface water can be localised, and the potential of PPP input into surface water can be categorised. b) identification and categorisation allow to prioritise and allocate suitable measures for a reduction of PPP inputs in surface water. c) it has to be distinguished between potential and actual inputs into surface water. In the farms studied several measures to reduce PPP transport, such as an adequate crop rotation, direct drilling and ecological compensation areas, have been implemented by the farmers already.

Environmental OMICs: high-throughput strategies to decipher mechanism of response to stressors (I)

341
Mechanisms of response to Cu and Ag materials: gene expression profile in Enchytraeus crypticus
S.I. Gomes, University of Aveiro / Department of Biology CESAM; J.J. Scott-Fordsmand, Aarhus University / Department of Bioscience Terrestrial Ecology; M.J. Amorim, Universidade de Aveiro / Department of Biology and CESAM
High-throughput gene expression tools help understanding the mechanisms of toxic-mediated responses. Further, to establish the link between alterations in critical macromolecules (e.g. genes, proteins, metabolites) and their possible biological implications at higher levels (survival, reproduction) represents one of the major milestones. Such data can be integrated e.g. via the Adverse Outcome Pathways (AOPs) approach, improving risk assessment. The aim of the present study is to investigate the mechanisms of toxicity for Cu (copper) and Ag (silver) materials using the high-throughput tool for the soil worm *Enchytraeus crypticus* (Oligochaeta), a 4x44K custom Agilent microarray. Testing was done based on reproduction effect concentrations (EC_{20}, EC_{50}) using 3 and 7 days of exposure. Results indicated specific mechanisms of response for the different materials tested. Cu-salt exposure affected mechanisms related with calcium homeostasis and activated the chemosensory system of the enchytraieds. Energetic metabolism was affected differently depending on the copper forms. For Ag, results showed that one of the materials caused a more differentiated transcriptomic profile than the others. Commonly across all Ag forms were the effects on cell cycle control associated with impairment of DNA repair mechanism. The study of gene expression pointed at differences in gene responses to the various Cu and Ag forms tested, information that is notoriously absent in experiments focussing on the standard effect endpoints survival/reproduction. The analysis of Adverse Outcome Pathways (AOP) was a promising approach to integrate effects from various levels and provide input for risk assessors. **Keywords:** High-throughput, mechanisms of response, (nano)materials, soil;

342
Arabidopsis thaliana defense mechanism to Ag- and TiO2-nanoparticles, and carbon nanotubes exposure from transcriptomics analysis
S. Garcia-Sanchez, University of the Basque Country / Department of Physiology; S. Cristobal, Linköping University / Department of Cl and Exp Medicine Cell Biology
There are increasing concerns about the putative impact of released nanoparticles (NPs) on the environment and their toxicity for living organisms. Since plants represent by far the largest interface between environment and biosphere, they will be the first barrier for nanoimpact. The study of detoxification and plant defense mechanisms displayed upon NPs exposure might be of major relevance and transcriptomics could provide information of the regulatory network involved in this process. Here we used the model plant *Arabidopsis thaliana* to study the changes of plant transcriptome associated to NPs exposure. By using Agilent expression microarrays we performed transcript profiling on more than 30k genes in the plant genome. We compared the expression patterns associated to NP exposure with those produced by biotic (infection with biotrophic or necrotropic pathogens) or abiotic (salt, draught or mechanical) stress. These stressors are naturally produced as a consequence of environmental or biological changes and plants manage to survive their deleterious effects by activating the expression of an arsenal of defense-related genes. We found that exposure to NPs caused mild changes in gene expression when compared to the mayor effects of the biotic or abiotic stress tested here. Principal Component Analysis indicates that the main component in transcriptome changes is related to necrotrophe fungal infection, followed by draught and other abiotic stress, whereas exposure to Ag and TiO2 NPs (10, 20, 40 or 80 nm) or carbon nanotubes cluster together in the last position of PCA. Significance Analysis of Microarrays defined a set of 278 gene-probes for which differential expression is verified upon exposure to all the types of NPs tested

here. Many of them are also key regulators of the pathways that are triggered during plant immune and stress responses.

343
Adverse outcome signalling pathways of dioxin-like compounds in Danio rerio
E. Oliveira, IDAEA CSIC / Environmental Chemistry; S.R. Mesquita, Center of Marine and Environmental Research CIIMAR / .; M. Casado, Environmental Chemistry; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; C. Barata, CSIC / Environmetal Chemistry; B. Pina, IDAEACSIC / Environmental Chemistry
Zebrafish embryos constitute a convenient model for studying effects of environmental stressors on development. Among these stressors, dioxin-like pollutants are especially relevant because of their ubiquity among environmental compartments and their known toxic effects (oxidative stress, genotoxicity, cardiotoxicity, and others) in many animal species, particularly in vertebrates. The study performed allowed to detect the transcriptional responses of *Danio rerio* embryos at sublethal concentrations of three compounds with recognized dioxin-like activity, two PAHs (Benzo[k]fluoranthene, and Benzo[a]pyrene) and the natural compound β-Naphtoflavone. A total of 2201 unique genes (out of 15,883) appeared as differentially affected ($p < 0.001$) by at least one of the treatments. Cluster analysis separated data from β-Naphtoflavone treated samples from the PAH treated ones. A defined cluster of genes showed a common pattern of variation for the three treatments, including an enhanced expression of the cytochrome P450 superfamily and other stress- related genes, corresponding to the well-known activation of the regulatory AhR by dioxin-like compounds. Another interesting group of genes was those whose transcripts were only affected upon a long (5 days) longer exposure to Benzo[a]pyrene, a known mutagen. This group included many mitochondrial genes and other ones related to apoptosis or to cell death. We consider that these data suggest a novel mechanism of embryonic toxicity for B[a]Pyr, which compromises the cellular energy process and that may be related with other well known effects of B[a]Pyr, like cardiotoxicity or edemas. The analysis performed here may contribute to distinguish between different modes of action for pollutants that may share some targets in the cell (in this case, the aryl hydrocarbon receptor) but that, at the same time, differ in their toxic effects at the systemic level. Zebrafish embryos thus demonstrate their suitability for predicting the potential for developmental toxicity of environmental air/water samples. Our goal is to use this transcriptomic data to evaluate the toxicity of PAH-rich environmental samples from different origins (atmospheric, aquatic) and composition.

344
Using transcriptomics to evaluate the impacts of paper mill effluent, androgens, and progestins on a potential bioindicator organism, the eastern mosquitofish (Gambusia holbrooki)
E.K. Brockmeier, University of Florida / Physiological Sciences; P.D. Scott, Griffith University / School of Environment and Smart Water Research Centre; F.D. Leusch, Griffith University Smart Water Research Centre / School of Environment and Smart Water Research Centre; N.D. Denslow, University of Florida / Physiological Sciences
OMICs technologies have the potential to enhance the usability of bioindicator organisms in the field, with molecular changes providing insights into a toxicant's mode of action. Recently, progress has been made in developing a custom microarray for the eastern mosquitofish (*Gambusia holbrooki),* a potential bioindicator organism for endocrine disruptors. This species has a wide freshwater distribution and steroid-driven secondary sexual characteristics, and this non-model organism is now a viable bioindicator candidate. In this study, we describe the use of this custom microarray to evaluate the impacts of paper mill effluent and progestin exposures on *G. holbrooki*. Fish were collected from the Fenholloway River, a paper mill impacted site which has historically contained masculinized female mosquitofish, in addition to a reference site along the Econfina River. Liver samples of four female *G. holbrooki* were analyzed by microarrays and these data were compared to microarray data of female mosquitofish exposed to a potent androgen in the lab. Microarray analysis revealed a set of 62 genes that were similarly expressed between the paper mill and androgen exposed mosquitofish, with commonalities in biological pathways also demonstrating a similarity between the impacts of androgens and paper mill effluents. Due to the high presence of natural progesterone at the paper mill-impacted site, additional microarray analysis was conducted to determine the modes of action of synthetic progesterones on mosquitofish. One such chemical, levonorgestrel, also causes masculinization in fish, so we evaluated the ability of this chemical to elicit androgenic impacts on a transcriptional level. Female *G. holbrooki* exposed to 100 ng/L of levonorgestrel had biological processes that were modulated in a pattern similar to androgen-exposed *G. holbrooki,* indicating that both androgens and progestins may be working to disrupt specific metabolic processes. These data are supportive of an androgenic exposure at the paper mill impacted site and indicate that there are overlaps between the impacts of androgen and progestin exposures. This study was a successful implementation of microarray technologies for evaluating the mode of action of chemical exposures occurring in the field at a paper mill impacted site as well as for providing new insights on the biological effects of progestin exposure.

345
Gene expression meta-analysis reveals a gene set that acts in a dose dependent manner suitable for effect based screening
T. De Boer, Vrije Universiteit / AGCI; T. Janssens, Biodetection Systems BV; D. Roelofs, Vrije Universiteit / Inst of Ecological Science; N.M. van Straalen, Vrije Universiteit Amsterdam / Inst of Ecological Science; J. Legler, VU University / Institute for Environmental Studies
The incorporation of genomic techniques into environmental risk assessment is a slow and challenging process since it is difficult to separate effects caused by chemicals from effects caused by confounding factors. Gene expression analyses tend to give very large, complicated datasets that will not supply the straightforward answers sought by ERA. It is therefore thought that smaller sets of genes that act as biomarkers and asses effects rather than compounds may be more suitable. To assess effect responses we performed a meta-analysis on 13 different gene expression studies in the springtail Folsomia candida that all assess different chemicals at EC10 and EC50 and compared these to the control group. 135 genes were significant over all exposures in both EC10 and EC50 as compared to the control. Gene Ontology analysis on these genes revealed many significant GO terms in detoxification . In a case study with increasing concentrations of phenanthrene and cadmium, 30 genes showed a significant monotonic increase or decrease of expression with increasing concentrations of phenanthrene and 9 genes showed this significant effect with cadmium. We present a set of 38 genes that were significant over all exposures and showed a significant monotonic response to either phenanthrene or cadmium.

346
Linking toxicity and adaptive response pathways across the transcriptome, proteome and phenotype of Chlamydomonas reinhardtii exposed to silver
S. Pillai, Eawag Swiss Federal Institute of Aquatics; R. Behra, Eawag / Department of Environmental Toxicology; H. Nestler, Eawag Swiss federal Institute of Aquatic Science and Technology; M.J. Suter, Eawag Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology; L. Sigg, K. Schirmer, Eawag / Environmental Toxicology
Understanding mechanistic and cellular events underlying a toxicological outcome allows the prediction of impact of environmental stressors to organisms living in different habitats. A systems based approach aids in characterizing molecular events, and thereby the cellular pathways, that have been perturbed. However, mapping just adverse outcomes of a toxicant falls short of describing the stress or adaptive response that is mounted to maintain homeostasis on perturbations and may confer resistance to the toxic insult. Silver is a potential threat to aquatic organisms due to the increasing use of silver-based nanomaterials, which release free silver ions. The effects of silver were investigated at the transcriptome, proteome and cellular level of *Chlamydomonas reinhardtii*. The cells instigate a fast transcriptome and proteome response, including perturbations in copper transport system and detoxification mechanisms. Silver causes an initial toxic insult, which leads to a plummeting of ATP and photosynthesis and damage due to oxidative stress. In response, the cells mount a defense reaction to combat oxidative stress and to eliminate silver via efflux transporters. From the analysis of the perturbations of the cell's functions, we derived a detailed mechanistic understanding of temporal dynamics of toxicity and adaptive response pathways for *C. reinhardtii* exposed to silver.

Soil Biodiversity and Ecotoxicology (I)

Earthworms responses to pesticide stress: adaptation strategies and soil implications
N. Givaudan, University of Southern Denmark / UMR CNRS ECOBIO; C. Wiegand, University of Southern Denmark / Biology; D. Renault, Université de Rennes / UMR CNRS ECOBIO; B. Le Bot, EHESP; S. Llopis, F. Pallois, F. Binet, Université de Rennes
The repeated application of pesticides in modern agriculture has led to chronic contaminations of cropped soils. The persistence and toxicity of several of these chemicals raises concern about adverse effects on non-target organisms of the soil biota such as earthworms (Lumbricidae). Although earthworm populations numbers are reduced in intensively cultivated soils, the persistence of certain species such as *Aporrectodea* spp in cropped soils suggests that adaptation processes to residual pesticide pollution can occur. We selected five fields exhibiting different chemical and farming histories within a joint agricultural area (acidic loamy-clay soils) and ranging from conventional cultivated to organic pasture. We investigated whether earthworm (*A. caliginosa and A. chlorotica)* responses to chemical exposure depend on the pesticide pressure in the soil they originate from by comparing pre-exposed populations (conventional farming) and naïve ones (organic farming). We thus analysed earthworm responses to environmentally realistic concentrations of two model pollutants in terms of

detoxication enzymes, metabolome, and burrowing behaviour. Soil pesticide analysis revealed 9 molecules in low levels in the three contaminated fields, amongst them atrazine, despite its ban in France since 2003. Basal activities of soluble glutathione-S-transferases and catalase were higher in *A. caliginosa* directly sampled from the fields with increasing pesticide pressure in the soil. Pesticide stress was reflected in the energy reserves of *A. chlorotica* in the conventional fields. Upon exposure to an environmentally realistic concentration of the fungicide epoxiconazole, GST activity was significantly increased in the pre-exposed populations (i.e deriving from conventional farming) after 7 and 28 days, and this was associated with changes in their metabolome after 28 days. A clear cut-off of metabolic profiles was observed only in the pre-exposed population between fungicide-exposed earthworms and the control group, with an increase in several of the metabolites and in particular amino-acids. There was also a higher burrowing activity leading to faster disappearance of the pesticide in the soil containing the pre-exposed earthworms. By contrast, these responses were not observed with the earthworms from the organic field. These findings demonstrate a physiological adaptation to pesticides in pre-exposed earthworms having possible consequences for the ecosystem level in terms of soil bioturbation.

Impact of Biosolids on Structural Endpoints of Soil Fauna

A. Coors, ECT Oekotoxicologie GmbH; J. Roembke, ECT Oekotoxikologie GmbH; R.M. Schmelz, University of A Coruña / Dep Animal Biology; K. Waszak, P. Lorenz, ECT Oekotoxikologie GmbH; M. Edwards, G. Wilkes, Agriculture and AgriFood Canada; E. Topp, Agricultural and AgriFood Canada; D.R. Lapen, Agriculture and AgriFood Canada

Biosolids, i.e., sewage sludge after appropriate treatment such as anaerobic digestion, is applied to agricultural land worldwide. Due to its high content of complex and readily biodegradable organic matter as well as its content of nutrients such as nitrogen and phosphorus, biosolids improve soil fertility and quality similar to an amendment with other organic fertilizers. Yet, there are not only beneficial effects but also concerns about negative effects of biosolids amendment that relate, among others, to the contamination of groundwater and soil with biosolids-associated metals and organic pollutants. The present study investigated short-term and long-term effects of biosolids amendment on the soil fauna groups of nematodes, enchytraeids and earthworms at two field sites in Canada. The soil parameters organic matter and soil texture differed significantly between the control and the biosolids-treated parts at both field sites. But the difference was apparently not correlated with the biosolids treatment, which allowed assessing the biosolids effect independently from the influence of soil texture and organic matter content. The total abundance of the soil fauna groups nematodes, enchytraeids, and earthworms did not indicate an adverse long-term impact of biosolids application, but clearly illustrated the expected abundance-enhancing short-term effect resulting from the addition of organic material. Yet, the species composition within these groups indicated differences between biosolids-amended and not-amended parts of the fields in the long-term that appeared not to be dependent on other soil parameters such as organic matter content and soil texture. This study may thereby allow identification of indicator species for biosolids amendment or, more general, organic matter amendment in the past.

A new approach for the evaluation of soil toxicity due to atmospheric fall-out

S. Sforzini, Universita Del Piemonte Orientale Amadeo Avogadro / Department of Sciences and Technological Innovation DiSIT; M. Boeri, D. Governa, L. Oliveri, University of Piemonte Orientale; A. Maffiotti, Regional Environmental Protection Agency of Piedmont ARPAP; G. Digilio, University of Piemonte Orientale; A.G. Viarengo, Universita del Piemonte Orientale / Department of Sciences and Technological Innovation DiSIT

In the last decades the presence of toxic chemicals in the air has been considered a major environmental problem, both at ecosystem level and for human health. Air quality is often a major determinant of the level of the toxic chemicals that accumulate into the top soil. Our aim was to investigate the effects of the air pollutant fall-out on the soil. Field experiments were carried out using passive samplers consisting of plastic containers with a microperforated bottom containing OECD standard soil. The containers were maintained for three months in areas with different levels of anthropogenic pressures (Site 1: uncontaminated rural area; Site 2: botanic garden; Sites 3-5: areas close to a road with heavy traffic and industrial pollution). Soils were analysed for chemical content and toxicity. For this purpose, we utilised the social amoeba *Dictyostelium discoideum* and the earthworm *Eisenia andrei*, which are suitable for testing elutriate and soil toxicity respectively. Different endpoints such as mortality and reproduction as well as a battery of biomarkers (e.g., lysosomal alterations, ROS production, mitochondrial functionality and genotoxic effects) were studied. In soils from sites sampled close to a road with heavy traffic, high concentrations of toxic chemicals such as PAHs and heavy metals were detected. The biological results indicated that the soil elutriates have no effects on the different parameters evaluated in *D. discoideum*. The assessment of OECD soil toxicity by the earthworm *E. andrei* indicated in Sites 3-5 minimal effects at the organism level; however, more severe changes at the molecular/cellular level were found. In this context, a strong decrease in lysosomal membrane stability and mitochondrial functionality was observed in coelomocytes of exposed worms. Furthermore, a significant increase of oxidative stress as well as of lysosome/cytoplasm ratio in the chloragogenous tissue was also measured. Of relevance are the genotoxicity data; a significant increase in the level of oxidative DNA damage and micronuclei frequency was demonstrated. Worms incubated in the soil from Site 2, maintained in the botanic garden, showed only minimal increase of lipofuscin content. The role of PAHs contamination in causing toxic and genotoxic effects was confirmed by immunohistochemical results showing intense PAH-related fluorescence staining in tissues of worms exposed to soils placed in Sites 3-5.

Evaluation of the risk for soil organisms under real conditions

A. Toschki, Research Institute gaiac; U. Hommen, Fraunhofer IME; M. Klein, Fraunhofer Institute of Molecular Biology and Applied Ecology; W. Koenig, Federal Environment Agency UBA; S. Pieper, German Federal Environment Agency UBA / Plant Protection Products; C. Possberg, Institute for Environmental Research RWTH; J. Roembke, ECT Oekotoxikologie GmbH; M. Ross-Nickoll, RWTH Aachen / Institute for Environmental Research; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; C. Possberg, RWTH Aachen University / Institute for Environmental Research Biology V; B. Scholz-Starke, RWTH Aachen University Institute for Environmental Research / Institute for Environmental Research BioV; M. Hammers-Wirtz, Research Institute gaiac

It has been questioned in the last years if the risk assessment of Plant Protection Products (PPP) in soil addresses properly the relationship between pesticide exposure and effects on soil organisms. Thus, it is necessary to develop a new approach especially regarding the estimation of environmental concentrations within the soil profile. Two different outdoor studies and one indoor study were conducted by means of Terrestrial Model Ecosystems to measure and analyse the fate and effects on soil organisms (oribatid mites, collembolans, earthworms) of three different PPP with different physico-chemical properties (Lindane, Imidacloprid, Carbendazim) over time. Different soil layers (0-1 cm for pesticides only, 0-2,5 cm, 2,5-5 cm, 5-10 cm, 10-20 cm), were separately analysed and summarising results are shown for different soil arthropods (collembolans, oribatid mites, earthworms) and pesticides. The results of the presented study led to concrete recommendations that are given for risk assessment concerning exposure and risk of soil organisms under realistic conditions.

351

Impact of no-till versus conventional maize plantation in soil mesofauna: a TME experiment

G.G. Rieff, Department of Soil Science Laboratory of Soil Microbiology Agronomy UFRGS; T. Natal da Luz, University of Coimbra / Department of Life Sciences IMAR CMA; R. Schmelz, ECT Oekotoxikologie GmbH Flörsheim am Main Germany and Dep Animal Biology Plant Biology Ecology University of A Coruñna Science Faculty; E.L. Saccol, Department of Soil Science Laboratory of Soil Microbiology Agronomy UFRGS; J.P. Sousa, University of Coimbra

The use of different strategies in crop cultures affects soil mesofauna differently [2], which may interfere indirectly with soil productivity. No-till cropping constitutes a way of growing crops without disturbing the soil through tillage, preserving the soil structure (increasing water retention in the soil) and soil organic matter (nutrients) and decreasing soil erosion. On the other hand, conventional cropping includes soil tillage to remove weeds, shaping the soil into rows for crop plants and furrows for irrigation, which contributes to organic matter losses, degradation of soil aggregates and disruption of soil communities. Understanding the impact of these different cropping systems (no-till *vs.* conventional) in soil mesofauna and investigating the ability of soil communities to recover may provide important information to optimize cropping strategies to protect soil biodiversity and, consequently, preserve soil productivity. Aiming to fill this gap of knowledge, a terrestrial model ecosystem (TME) experiment was performed over two months using soil cores collected in a pasture area. The test treatments were: undisturbed soil with maize (control), mobilized soil with maize (conventional tillage); mobilized soil with maize and insecticide (conventional tillage with insecticide); undisturbed soil with herbicide and maize (no till); undisturbed soil with herbicide and insecticide (no till with insecticide). Soil samples were collected before soil mobilization (T0), after mobilization or herbicide application (T1) and 4 (T2) and 8 weeks (T3) after maize planting or maize planting and insecticide application. In each TME soil sample from 0-5 and 5-10 cm top layer were collected and collembolan and mite communities were identified and enchytraeids abundance was determined. Results suggest that soil mobilization (conventional cropping) affects collembolan and mite communities, making them more susceotible to insecticide application. Although in no-till cropping the insecticide application showed toxic effects especially to mite communities (in 0 to 5 cm top layer), there was a recovery of these communities at the last sampling date (after 8 weeks insecticide application; T3). In general, mite communities were more affected at surface soil layers (0 to 5 cm top layer) than collembolan communities. The

enchytraeids (at least in terms of abundance) showed low sensitivity towards the different cropping systems.

352

Species composition of a soil invertebrate multi-species test system determines the level of eco-toxicity

V. Sechi, Soil Quality; A. D'Annibale, K. Maraldo, Aarhus University; A. Johansen, Aarhus University / Environmental Science; R. Bossi; J. Jensen, Aarhus University DMU / Department of Bioscience; P. Krogh, Aarhus University

Abstract: Invertebrate interactions like predator-prey relationships, competition for resources, mutualism and commensalism play an important role in the biogeochemical cycling of carbon and plant nutrients in soil. Besides direct impact on individual organisms, insecticides may also have detrimental effect on these crucial species interactions and, hence, the entire food-web in the soil. Despite of this, studies on how contaminants affects the structure and functioning of food webs in terrestrial ecosystems are very scarce. A soil multi-species (SMS) test system, consisting of a limited number of soil invertebrate species, with well-defined ecological roles, provides the basic characteristics of the soil ecosystem and enable us to study specific ecological topics, e.g. functional redundancy and species diversity. The aim of this study was to test the performance and validity of such a SMS test system by exposing invertebrate species and the microbial community to the insecticide α-cypermetin. In addition, we evaluated how two alternative worm species would affect the sensitivity of the SMS system. In this way two different faunal communities were constructed, each with three trophic levels and including five species of springtails and the predator mite *Hypoaspis aculeifer*. They only differed concerning the added oligochaete species, which was either juveniles of the earthworm *Eisenia fetida* or adults of the enchytraeid *Enchytraeus crypticus*. After 8 weeks, the EC50 was 0.76 mg kg^{-1} for enchytraeids and ranged between 2.7 and 18.9 mg kg^{-1} for collembolans, showing higher sensitivity than previously observed with single species. *E. fetida* had a positive effect on the majority of the species, apparently reducing the negative insecticide effect. *E. fetida* influenced the species sensitivity and decreased the degradation of the insecticide due to the organic matter incorporated as earthworm food. Changes observed in the community structure and function illustrates the strength of a SMS test system as an ecotoxicological tool compared to single species tests. **Key words**: Soil multi-species experiment, Chemical fate, Insecticide, Species interactions, Bioturbation.

Characterizing the role of pesticides impacting surface water ecosystems in multiple stressed environments

U.S. McKnight, Technical University of Denmark DTU / Environmental Engineering; J.J. Rasmussen, Aarhus University / bioscience; B. Kronvang, Aarhus University / Department of Bioscience; P.J. Binning, P.L. Bjerg, Technical University of Denmark DTU / Environmental Engineering

Groundwater and surface water resources are increasingly under pressure from global exploitation and anthropogenic impacts, such as contamination by chemicals. In response, the European Water Framework Directive requires member states to evaluate all types of contamination sources within a watershed in order to assess their direct impact on water quality. The clear linkage between these two systems requires assessments of "good" chemical and ecological status to include an evaluation of the contribution of toxicants entering surface water via the groundwater pathway. Pesticides are among the most harmful class of compounds impacting surface waters, particularly since they have been so widely used to control the occurrence of pests and weeds in urban and agricultural landscapes. In order to properly identify and subsequently mitigate the impacts to surface water ecosystems, a better understanding of the sources and types of pesticides expected in surface waters becomes essential. Here we (i) assess current trends for pesticide concentrations in surface water and compare them to the historical use of pesticides in Denmark (using sales data), (ii) investigate the importance of groundwater as a pathway for pesticide impacts to ecosystems, and (iii) quantify the impact of sediment-bound pesticides affecting stream macroinvertebrates. Notably, sediment-bound pesticides have long been disregarded as an important source of ecotoxicity, due predominantly to an assumed reduction in bioavailability. Results show that there is little correlation between pesticide findings in streams and estimated current use of pesticides. Chemical toxicity analyses identified sediment-bound insecticides such as chlorpyrifos and hexachlorobenzene as the primary source for ecotoxicity in the studied streams. The presence of the groundwater pathway, however, indicates that stream sampling during base-flow conditions can provide valuable information about the long-term fate of pesticides in groundwater. Ideally, integrative approaches should be developed with monitoring strategies simultaneously involving chemical analyses, ecotoxicological tools and the study of population/community responses in order to obtain a more holistic picture.

354

Comparing Single species Toxicity Tests to Community-Level Effects of Excess Total Dissolved Solids Doses Using Model Streams

J.M. Lazorchak, US EPA / Office of Research and Development; C.T. Nietch, US EPA / Water Supply Water Resources Division; B. Johnson, US EPA; B. Ramakrishnan, EPA Experimental Stream Facility; P. Weaver, The McConnell Group, c/o U.S. EPA; D. Macke, US EPA Test Evaluation Facility; K. Daniels, US EPA / Water Supply and Water Resources Div; S. Decelles, The McConnel Group c/o U.S. EPA; D. Brown, U.S. EPA / Water Supply and Water Resources Division; H. Haring, The McConnell Group; C.A. Impellitteri, US EPA / Water Supply and Water Resources Division

From 2011-2013, model stream chronic dosing studies (42 d) were conducted with three different total dissolved solids (TDS) recipes. The recipes differed in their relative dominance of major ions. Each was dosed to continuous flow-through model streams at the USEPA's Experimental Stream Facility (ESF), in Milford, OH. The community-level model stream dosing designs were also paired with single-species exposures conducted at both the bench scale using the whole effluent testing (WET) format and a new ex-situ exposure format. Single species exposure sensitivities were compared to whole community adult insect emergence response. We consider the latter a metric of whole community growth/development response. The mayfly, *C. triangulifer*, tested in the WET or in the ex-situ format was more sensitive to excess TDS regardless of the TDS composition than the other standard test organisms used; *C. dubia, H. azteca, and P. promelas*. Sensitivity of *C. triangulifer* tended to decrease in the ex-situ format, while the mayfly's sensitivity in the ex-situ exposure condition reflected that derived from mayfly emergence at the community scale. The combined exposure approach is designed to lend community-level context and more dynamic, field-like exposure conditions to help validate and evaluate endpoints obtained from more traditional single-species methods conducted in isolation at the bench-scale. Caddisfly emergence appeared generally as sensitive to the TDS exposures as mayflies, although less sensitive when the excess TDS is dominated by salts of Cl^-. Insects of the dipteran family Chironomidae dominated the total emergence response. Chironomids were less sensitive to excess TDS compared to the Ephemeroptera and Tricoptera taxa when the TDS was dominated by Cl^- salts and $NaHCO_3$ but appeared more sensitive when the excess TDS was a mixture of SO_4^{2-} salts and HCO_3^-. These results help to validate inferred sensitivities of stream insects to excess TDS from single-species exposures, qualifying existing State-level TDS targets for water quality protection, while also supporting the use of *C. triangulifer* WET tests for assessing exposures to excess TDS. The views expressed in this presentation are those of the authors and do not represent those of U.S.EPA.

Site recovery in the Zn-Pb mine of Olkusz, Poland, as shown by changes in the soil properties, nematode communities and plant tolerance

M. Polek, Laboratoire sol végétation; A. Kostecka, W Szafer Institute of Botany Polish Academy of Sciences; E. Dmowska, O. Wisniewska, Museum and Institute of Zoology Polish Academy of Sciences; J. Gobat, University of Neuchâtel; P. Vollenweider, Swiss Federal Institute for Forest Snow and Landscape Research

This study focuses on environmental recovery on mining waste heaps of varying age, situated near Boleslaw and Olkusz in Southern Poland. The soil pollution with heavy metals (HM) in this area is one of the worst recorded in Europe with Zn concentration frequently exceeding 10'000 mg kg^{-1}. Bioindicators of food web complexity (e.g. nematode communities) and colonization by pioneer plant species are important signs of recovery at HM-contaminated sites. In Olkusz, metallicolous populations of the pseudometallophyte *Biscutella laevigata* L. (Brassicaceae) have evolved high HM-tolerance but do not hyperaccumulate HM. Here we combine nematode counting and identification, plant physiological and chemical analyses, and measurements of soil physical and chemical properties to pursue two principal objectives: 1) to document former Zn-Pb mining site recovery and reclaiming by natural ecosystem communities, 2) to analyse allocation–based Zn-tolerance in foliage and its variation as a function of site age. Preliminary results indicate slow site recovery, which appears to happen independently of site age. For instance, soil profiles show missing or weak incorporation of organic matter and the nematode communities at all study sites are still poorly developed. The nematode community structure indicates stressful environmental conditions with i) degraded food web structure, ii) high C:N ratio and iii) decomposition pathways dominated by fungi. Moreover, the average Zn concentration in above-ground and root organs of *B. laevigata* exceeded 1'000 mg kg^{-1}. This level of contamination may impede the development of herbivore communities. Further insights into the tolerance strategies of *B. laevigata* are expected from ongoing analyses on Zn microlocalisation in foliage. From the above results we conclude, that adaptations of local populations to a toxic environment, soil evolution ensuring successful vegetation colonization and metal-enriched dust immissions, rather than site age, likely determine the dynamics of environmental recovery at Olkusz.

356

Can soil communities and decomposition process in boreal forest recover from lead derived stress at a shooting range?

S. Selonen, University of Helsinki / Department of Environmental Sciences; M. Liiri, R. Strommer, University of Helsinki / Department of Enviromental Sciences; H. Setala, University of Helsinki / Department of Environmental Sciences
An ecosystem-scale research was conducted in a shooting range area to study the fate and effects of lead on pine forest ecosystem and the recovery of the system 20 years after abandonment of the shooting range. Bioaccumulation, leaching and vertical distribution of Pb in soil, as well as decomposer communities and litter decomposition were compared between two contaminated sites (active [NC] and abandoned [OC] shooting ranges) and a control site, each site locatingin the same forest. The total Pb pellet burdens at the contaminated sites were similar, reaching up to 4 kg m^{-2}, and the shooting activity had lasted for approximately 20 years at both sites, but occurred 20 years earlier at OC. Total Pb concentrations at the shooting ranges were extremely high, and Pb also accumulated in the biota. The vertical distribution of Pb in the organic soil horizon differed between the shooting range sites, Pb concentrations at NC being higher in the upper fermentation (F) layer than in the lower humus (H) layer and at OC vice versa. Leaching of Pb was greatest in late autumn, being twice as high at OC than at NC. All faunal groups (total number of enchyraeid worms, microarthropods and nematodes) except protozoans were affected negatively by Pb, and the effects were most pronounced in the autumn. Also nematode and microarthropod community structures were affected. In the whole organic soil layer, the negative effects of Pb were less abundant at OC than at NC, especially among microarthropod taxa. Contradictory, in H layer the effects were stronger at OC, enchytraeid worms being completely absent. Pine needle litter decomposed at a lower rate at NC than at OC. The decreased total Pb concentrations in the top soil, decreased toxicity of the organic soil layer and the enhanced litter decomposition rate at the abandoned shooting range (OC) – when compared to the active shooting range (NC) – indicate an on-going recovery process at the abandoned shooting range. In boreal forest soil with low decomposition rate and intensity of soil mixing due to the scarcity of earthworms, a less contaminated top soil layer is gradually formed when shooting activity is ceased. This layer can provide habitats for decomposer biota and promote the recovery of soil functions. However, at the same time the dissolution of Pb from the pellets deeper in the soil increases the toxicity of humus and leaching of Pb posing risk to the ecosystem and groundwater quality.

357
Co-occurrence patterns as a response of interaction network of terrestrial microbial communities to atmospheric pollution and seasonal variations
C. Meyer, B. Karimi, Laboratory of ChronoEnvironment; N. BERNARD, University of Franche-Comte / Laboratory of Chrono-Environment
The ability of ecological systems to continue to deliver the ecosystem services on which human well-being ultimately depends is being increasingly compromised by anthropogenic activities. Traditional holistic works are restraint to food-web ecology while co-occurrence patterns provide a good tool for revealing networks with all interactions among organisms. Microbial communities provide a particularly favorable model to study the community structure, its link to ecosystem functionning and its response to environmental conditions through time. In this study, we evaluate the impact of chemical (particles or gaseous) pollutions on interactions among microbial genera and ecosystem functionning by co-occurrence networks modelling for microbial communities associated to bryophytes under three different polluted conditions (rural, urban and industrial) over an 8-month period. A first result of this study is the change in the community structures linked to the seasonal variations (autumn vs. spring) but not obviously among sites. The genus richness varies significantly among the sites (25 in average at rural site, 20 in average at polluted sites). Our result suggests the diversity is more affected by the pollution stresses whereas the structure of community is essentially sensitive to seasonal variation. The network models and indices calculation showed an evolution of the complexity of the relationship among microbial genera through time and seasons. We observed a modification of the interaction quality between nodes (e.g. negative to positive or positive to negative) and a modification of the genera centrality, according to the type of pollution. The addition of environmental conditions in the co-occurrence patterns indicates which the co-occurring assemblages of organisms prefer or avoid and the inclusion of chemical stress measurements may link groups of organisms with particular functions.
Co-occurrence analysis provides an essential view of the real-world ecosystem response to anthropogenic stresses. Key words : ecological interactions, modelling, microorganisms

358
Seasonal variation in effects of different land-uses on stream ecosystem structure and function
D. Englert, Institute for Environmental Sciences / Institute for Environmental Sciences; J.P. Zubrod, Institute for Environmental Sciences University of KoblenzLandau / Institute for Environmental Sciences; R. Schulz, University of KoblenzLandau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment
Stream ecosystems are impacted by a variety of anthropogenic stressors originating e.g. from agricultural activity, urban areas and wastewater treatment plants. As a result, the structure of aquatic communities as well as associated ecosystem functions (e.g. leaf litter breakdown) may suffer from this contamination. Therefore, the present study assessed alterations in structural (invertebrate community composition) and functional (microbial and invertebrate mediated leaf litter breakdown as well as *in situ* bioassays with *Gammarus fossarum*) endpoints along a low order stream in Southern Germany during winter 2010/11 and summer 2011. This stream is gradually impacted by viniculture, urban area and motorway runoff as well as wastewater release. Microorganism mediated leaf litter breakdown was – possibly due to elevated nutrient concentrations – significantly increased by up to 270% at sites downstream of the city, motorway and wastewater treatment plant during winter but unaffected in summer. At the same sites, macroinvertebrate mediated leaf mass loss was significantly reduced during winter (up to 100%) and summer (up to 44%) compared to the reference site. This effect may be explained by changes in the macroinvertebrate communities, especially by the reduced abundance of a key leaf shredding macroinvertebrate, i.e. *Gammarus*. This reduction may be triggered either indirectly (altered food quality) as indicated by a significantly reduced fungal biomass (up to 58 and 70% during winter and summer, respectively) associated with leaf material, which may have influenced the physiological fitness of shredders. On the other hand, direct ecotoxicological effects of water contamination are also conceivable as gammarids exposed *in situ* exhibited a significantly (up to 55%) reduced feeding rate downstream of the urban area, the motorway (both only during winter) and the wastewater treatment plant (during both seasons). Such reactions in feeding are indicative for a reduced reproductive output in the long run. Finally, this study urges that besides water pollution arising from agricultural activity and wastewater release, the influence of (seasonal) pollution from urban areas should be adequately considered in the future to achieve the "good ecological status" required by the EU Water Framework Directive.

Biodegradation and Environmental Fate of Chemicals - Regulatory Acceptance of Non-Standard Tests

359
Revisiting the evaluation process of biodegradation of chemical substances: the ProbaBio probability concept.
F. BRILLET, M. DURAND, University of Nantes; A. MAUL, University of Metz; T. Gerald, University of Nantes / Microbiology
For the registration of a chemical substance, the European REACH regulation requires, *inter alia*, the evaluation of its biodegradability. A large set of test methods is available since 1992. However, biodegradation results for molecules published in literature, show intra and inter laboratory incoherencies linked to the microbial community variability. Indeed, if biodegradation is achievable from the growth of specific microbial degraders with a substance as the sole source of carbon, the result of the test depends largely on the initial density of degraders. If these species are relatively rare in an environment the likelihood of inoculating a test with sufficient specific cells becomes a matter of probability. It seems then possible to reach a probability of the environmental persistence of an organic compound. In the alternative ProbaBio approach developed in this study, the persistence is not only regarded as a simple intrinsic substance property, but also as the potential presence of specific degraders in various environmental samples (activated sludge, river water and sediment, soil and sea water) to degrade a chemical under realistic exposure (incubation temperature, biomass density at time zero and temporal shifts due to potential seasonal influences). A miniaturized O_2 sensing platform has been developed for a high throughput screening to qualify the biodegradation event of readily to persistent molecules (5700 tests). Results show the probability, represented as environmental biodegradation fingerprints, of five molecules to be degraded according to the environments and its conditions. The ten environments tested have not the same potential of biodegradation. Incubation temperature impacted directly the fate of the biodegradation tests in two ways, (a) the time window required in ready biodegradability tests (RBT) cannot be reached at lower temperature (12°C) and (b) the pass level was reached only at 25°C excluding from the RBT standards the same molecules at 12°C. Moreover, there was a seasonal effect on the biodegradation tests results, thus, some molecules were biodegradable in summer and not in winter. The biomass density at time zero plays the same effect as the temperature. To determine the link between all this parameters, all the tests have been statistically treated. This approach is a new proposal to improve our knowledge about the difficult task of biodegradation assessment.

Enhanced Regulatory Assessments within REACH
T.J. Martin, Newcastle University / School of Civil Engineering and Geosciences; A.K. Goodhead, Newcastle University / Civil Engineering and Geosciences; J.R. Snape, Astrazeneca UK Ltd / AstraZeneca Global Environment; R. Davenport, Newcastle University / School of Civil Engineering and Geosciences
Chemical compounds are ubiquitous within the aquatic environment, causing concern over human health and the environment. The principal elimination process for their removal is microbial degradation, the prediction of which plays an important role in risk assessment. Historically, ready biodegradability tests (RBTs) have formed the core protocol for developing regulatory guidelines. Recently, however, regulatory concerns have developed at a faster rate than standard tests with an increased emphasis placed on approaches to identify Persistent, Bioaccumulative and Toxic (PBT) chemicals. RBTs are notoriously variable, producing a large number of false negatives. The Registration, Evaluation, Authorisation and restriction of CHemicals (REACH) was introduced in 2007 to streamline chemical legislation within the European Union (EU). REACH stipulated the same data requirements for new and existing chemicals, necessitating the development of reliable and reproducible screening tests capable of accurately prioritising chemicals for further testing. A series of enhancements and modifications to existing biodegradation screening tests (BSTs) were proposed as a result of a workshop on biodegradation and persistence hosted by the European Centre for Ecotoxicology and Toxicology of Chemicals, which were adopted in principle within REACH to enable a more effective prioritisation on persistence. The proposed enhancements of increasing test duration, test volume and cell concentration were investigated. The present study assessed methods for the concentration of bacterial cells in aqueous environmental samples. Analysis of scientific and practical criteria were used to inform the selection of the most suitable concentration method for investigations into the effect of volume and cell concentration in activated sludge and marine BSTs and the subsequent development and validation of enhanced BSTs using activated sludge (AS) and marine inocula. Enhancements in AS BSTs were found to significantly reduce variation between replicates ($P < 0.01$), with coefficients of variation as low as 0.34% when using larger test volumes and higher cell concentrations. Enhanced marine BSTs failed to significantly reduce variation between replicates and suggested the requirement for further work, perhaps focusing on investigating pathways and mechanisms of adaptation. The application of molecular techniques and use of predictive models to facilitate future chemical assessments is also discussed.

361
Repeat of previously conducted ready biodegradability studies following current regulatory guidance, and its effect on persistence assessment
R. Menon, Afton Chemical Corp / HSES
The performance of ready biodegradability studies on poorly water-soluble chemical substances has been recognized as problematic for several years. ISO (International Standards Organization) came out with guidance for the preparation and treatment of poorly water-soluble organic compounds for the subsequent evaluation of their biodegradability (ISO, 1995). However, studies continue(d) to be conducted not utilizing this guidance. Ready biodegradability studies conducted in the 1990s (and in some cases, after as well) often also used test substance (TS) concentrations several times the water solubility limit, ignoring the fact that the TS was not really bioavailable to the bacteria at these concentrations, and reported no biodegradation. Often, these studies were done to the OECD 301C guidelines which arguably, stipulate the most stringent conditions to test ready biodegradability. Using results from such studies as such, to evaluate persistence from such studies, for PBT (persistence, bioaccumulation and toxicity) assessment under REACH, meant that there was a very high probability that the substance would get a 'P' label, whether it deserved it or not. Since the ISO guidance was published, there has been significant research in this area by many workers (Handley, et al: 2002, van Ginkel, et al: 2008, etc.). ECHA (European Chemical Agency) too has included this consideration for biodegradability testing of poorly water-soluble substances in their endpoint specific guidance (ECHA, 2012). Using favorable conditions to make the TS more bioavailable has shown to improve biodegradability for such 'difficult-to-test' substances and is being accepted by regulatory authorities, as more representative of what occurs in natural environmental systems. This presentation will include a case study of a substance with very low water solubility, that was deemed to be P or vP based on a 1996 Japanese study that showed very little to no biodegradability. TS concentrations used in this study were almost two orders of magnitude higher that the known water solubility. When the study was repeated in 2011 using 'modified' conditions to make the TS more bioavailable, the TS showed up to 46% biodegradation.

362
Considerations when using OECD 301 tests to assess 'degradation' of hydrocarbon products
G. Whale, Shell Health; J. Dawick; C. Mead, Harlan Laboratories Ltd / Ecotoxicology dept
Degradation of organic chemicals in the environment influences exposure and, hence, it is recognised as a key parameter for estimating the risk of long-term adverse effects on biota. The OECD Guideline 301 A-F tests are used to assess the ready biodegradability of organic chemicals. The results of these tests are used extensively both within a regulatory context (i.e. chemical hazard assessment) and by industry to support marketing claims on product biodegradability (i.e. 'green credentials'). However, a fact that is often overlooked is that these stringent tests were developed as relatively simple and inexpensive methods to screen organic chemicals for ultimate biodegradation over a period of 28 days. In the OECD 301 A-F series of aerobic tests, the biodegradation of a high concentration of the test substance (in the range of 2 to 100 mg/L) is measured by non-specific parameters such as loss of Dissolved Organic Carbon (DOC), or the extent of respiration increase (O_2 uptake measured as Biochemical Oxygen Demand (BOD) and CO_2 evolution) over time. These OECD 301 tests have several limitations, particularly when used to assess the biodegradability of complex and/or poorly water soluble substances. In this presentation we provide an overview of some of the recent experiences encountered with the conduct and interpretation of OECD 301B and F tests undertaken on complex hydrocarbon products. We also discuss some additional steps which can be taken to improve the conduct and reporting of such studies when used to assess the biodegradation of hydrocarbon products such as fuels and lubricating oils.

363
Improved test system to determine chemical degradation in laboratory water/sediment systems – experimental results
D. Hennecke, Fraunhofer IME Institute for Molecular Biology and Applied Ecology / Ecological chemistry; A. Bauer, P. Shresta, Fraunhofer IME Institute for Molecular Biology and Applied Ecology; T. Junker, ECT Oekotoxikologie GmbH; K. Fenner, ETH ZürichEawag
The OECD 308 guideline on "Aerobic and Anaerobic Transformation in Aquatic Sediment Systems" has been used since 2002 extensively in different legislative frameworks. However, several shortcomings have been identified and discussed over the years on the guideline: the combination of degradation and sorption, which makes it impossible to locate where and how degradation occurs; the unrealistic water-sediment ratio of 3:1 which often result in high levels of non extractable residues (NER) and huge anaerobic areas in the sediment. Thus, a derivation of a compartment specific degradation half-live is hardly possible from OECD 308. In the last years the OECD 309 guideline for biodegradation in aerobic natural waters, became more important. It is run at low sediment concentrations under fully aerobic conditions as a laboratory shake flask test. With concentrations between 0.01 and 1 g suspended solids (SS)/L it might potentially exhibit several advantages over OECD 308 for determining biodegradation. Against this background, the aim of the Cefic-funded project LRI-ECO18 is to understand the value and information content of the existing OECD 308 and 309 protocols and to develop an improved testing strategy to obtain robust degradation in water/sediment systems. In combination with a data analysis approach, an experimental approach is used to enable disentangling sorption from (bio)degradation and clearly distinguish between aerobic and anaerobic conditions. A suite of four different water/sediment systems is used to investigate the behavior of four chemicals with varying sorption properties and biodegradability: (1) OECD 308 standard protocol (water:sed ratio = 3:1, not stirred); (2) OECD 308 modified protocol (water:sed ratio = 10:1, stirred water phase); (3) OECD 309 modified protocol (water:sed ratio = 100:1, stirred system); (4) OECD 309 standard protocol (water:sed ratio = 1000:1, stirred system). The presentation will focus on experimental methods and the current status of data determination including first results and conclusions about the influence of the experimental setup on substance degradation. The variation of the test systems might help to improve the experimental setup and to overcome some of the criticism on the current OECD 308. In combination with advanced parameter estimation techniques the Cefic project will provide a tool to better understand the processes at the water-sediment interface.

364
Estimating transformation rate constants from OECD 308 data – Opportunities and limitations of existing data
M. Honti; K. Fenner, ETH ZürichEawag
The OECD guideline 308 for the testing of transformation in aquatic sediments is an integral part of environmental risk assessment of chemicals. The results of these studies are generally used to derive half-lives in water phase ($DT_{50,w}$) or in the whole experimental system. However, both of these values depend heavily on the loosely standardised system geometry. Moreover, $DT_{50,w}$ lumps diffusion and transformation rates together. Overall, none of these indicators seems to be well suited for assessing actual transformation rates or – in general – the persistence of chemicals. In the Cefic-funded LRI-ECO18 project we used Bayesian parameter estimation with four different model versions that represent the experimental system with different hypotheses about degradation and diffusion in the sediment. The models were calibrated to existing data for 25 pesticides and pharmaceuticals. Available information was used to support model calibration in form of parameter prior distributions. All 3 model versions explicitly describing diffusion in the sediment could fit the data well, which indicated that experimental data do not provide evidence about the depth-dependence of degradation in the sediment. As a consequence, calibrated sediment degradation rate constants differed strongly by model version, whereas degradation rate constants in water could be estimated more robustly. Degradation half-lives in water, $DegT_{50,w}$, as derived from the calibrated degradation rate constants were significantly longer than the disappearance half-lives $DT_{50,w}$ estimated from the raw data.

Identification and prioritisation of hazardous emerging pollutants (I)

Despite the extensive efforts to attain a good quality status for all European river basins, in the majority of cases this goal has not been achieved. There are strong indications that toxic chemicals are significantly responsible for this failure although the quality status of rivers could not be related to the chemical status defined by 41 priority and other pollutants. This may be due to the enormous complexity of chemical pollution with more than 100.000 chemicals in daily use and mixtures of tens of thousands of chemicals in typical environmental samples. Thus, this paper presents a novel conceptual framework to provide solutions to the contamination problems associated with legacy, present and future pollutants in European water resources, developed by the European Collaborative Project SOLUTIONS. This framework integrates models and tools for identification, prioritisation, assessment and abatement of hazardous emerging pollutants with respect to ecosystems and human health. The framework is designed as the basis of a user-friendly decision support tool that helps to identify trains of models and tools for the identification of River Basin Specific Pollutants and of appropriate abatement options. This approach is demonstrated in large trans-European case studies in the Danube, Rhine and several Iberian river basins. First results of pollutant identification and prioritisation in the largest SOLUTIONS case study, based on the Joint Danube Survey 3 organised by the ICPDR, will be presented and discussed along with concepts developed and open research questions raised. The new data and information on emerging pollutants will be compiled in an extensive knowledge base linked to the European integrated data platform on chemical monitoring data (IPCheM).

An innovative and comprehensive study to identify relevant emerging contaminants in French surface waters

F. Botta, V. DULIO, F. Lestremau, S. ANDRES, INERIS; S. Ait-Aissa, INERIS / Ecotoxicology Unit; F. Brion, N. Creusot, C. Feray, W. Sanchez, INERIS; F. Alliot, M. Chevreuil, ecole pratique des hautes etudes UMR SISYPHE; M. Devier, University of Bordeaux / UMR CNRS EPOCLPTC; P. Labadie, H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC; C. Cren, Insitut des Sciences Analytiques UMR TRACES Team; E. Vulliet, Institut des Sciences Analytiques UMR TRACES Team; D. Amouroux, LCABIE IPREM / UMR CNRS; M. Monperrus; A. Morin, INERIS

As part of the implementation of the National Action Plan on Micropollutants in the Aquatic Environment, the French Ministry of Ecology a large national screening study took place in 2012 in France. INERIS was charged with the design and technical implementation of this project for surface water. For the selection and prioritisation of the watch list compounds the National Expert Group for prioritisation of substances (CEP) decided to adopt the criteria of the NORMAN methodology for prioritisation of emerging substances.That methodology uses a decision tree that first classifies chemicals into six categories, on the basis of the existing knowledge gaps and the actions to be taken to fill them. The priority within each category is then ranked on the basis of specific indicators, which allows a score to be calculated. For surface water three campaigns were performed on water matrix and one in sediments at about 159 sampling points. Grab sampling was applied on all sites. In addition, passive samplers (POCIS) were deployed in 20 rivers in order to allow the implementation of bioassays. Sampling was carried out according to AQUAREF's (National Reference Laboratory for Aquatic Environment) technical specifications and a unique courier was selected for transport of samples to the laboratories. The analytical work for a given group of compounds was performed by one single laboratory in order to ensure data comparability. Four academic laboratories were selected for chemical analyses. 170 substances were finally selected for chemical analysis in water and sediment.The benefits of this innovative approach for identification of relevant emerging contaminants are i) a unique prioritisation scheme (NORMAN Network) applied at French national level for substance and site selection; ii) Information on occurrence, source and variability for 170 substances (50 000 robust analytical data items) ; iii) an efficient method for data collection, validation and exploitation thanks to a unique data collection template and an exhaustive set of metadata; iv) the application of effect-based tools to classify 20 sites of various quality; to characterise site contamination a panel of *in vitro* and *in vivo* bioassays were deployed as well as biomarkers to assess impacts of pollutants in wild population of fish.The results contributed to the selection of substances to be integrated in the national river basins monitoring programmes.

367

How much risk can be covered by monitoring prioritized substances in surface waters? A complete pesticide screening example

C. Moschet, Eawag / Uchem; I. Wittmer, Eawag; J. Simovic, Eawag / Uchem; M. Junghans, Swiss Centre for Applied Ecotoxicology EAWAG EPF / Ecotox Centre; A. Piazzoli, ETH; H. Singer, Eawag Aquatic Research; C. Stamm, Eawag / Uchem; J. Hollender, Eawag / Environmental Chemistry

Synthetic pesticides have been used in agriculture and in urban areas for many decades. The risk that pesticides can pose to surface waters was recognized a long time ago and subsequently critical substances were banned and/or listed as priority pollutants, for example in the European Water Framework Directive (WFD). Because new pesticides are entering the market every year and pesticide application varies regionally, river basin specific pollutants should, according to the WFD, be additionally selected. However, when pesticides are prioritized and only the selected substances are monitored, there is always the chance to miss potentially important substances. The goal of our study was to perform a complete analytical pesticide screening in five agriculturally influenced rivers during the main pesticide application period, assess the associated risk for the aquatic environment, and compare it with selected subsets of pesticides which are regulated (WFD) or selected for monitoring in Switzerland. The analytics were done using solid phase extraction (SPE) liquid chromatography coupled to high resolution tandem mass spectrometry (LC-HRMS/MS, QExactive). By using a combined target and suspect screening method, 86% of all registered synthetic organic pesticides (310) could be detected in low concentrations (0.5-10 ng/L). In addition, for 10 highly toxic pyrethroids, a GC-MS/MS method was set up using polydimethyl-siloxan (PDMS) passive samplers. In the complete analytical screening, 30-40 substances were detected per sample and the sum of pesticide concentrations was on average 2 to 4 μg/L. The sum of individual risk quotients following the concept of concentration addition for plants and invertebrates exceeded the critical value by a factor of 4-6 and 2-3, respectively. It was found that only 50% of the detected substances would be measured when a subset of only 30-40 pesticides is investigated, but that the sum of pesticide concentrations was not strongly influenced. Applying the mixture toxicity approach (sum of individual risk quotients), the scenarios would on average (whole investigation period in the five rivers) miss 30-40% of the total risk. This number, however, varies between the different rivers. Thus, if priority substances are selected carefully, they can in most cases (in medium sized rivers) sufficiently cover the risk of surface waters. However, to really assess the complete exposure of pesticides, a full chemical screening is essential.

368

Are carboxylic acid metabolites from alkylated PAHs a new class of potential contaminants in marine waters?

L.M. Malmquist, University of Copenhagen / PLEN; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change; E. Sørensen Boll , University of Copenhagen / Department of Plant and Environmental Sciences; J.H. Christensen, University of Copenhagen

Concentrations of alkyl substituted PAHs in crude oils are much higher than concentrations of nonsubstituted PAHs, and certain C1-C4 alkyl substituted PAHs are highly toxic. In spite of this knowledge, only little attention regarding ecotoxicological fate and effects of these compounds have been given in research. We have previously shown that the benthic invertebrate Nereis diversicolor metabolize 1-methylpyrene in sediment exposure setups more than five times faster than its non-alkylated relative, pyrene. In addition, we showed that this rapid metabolism primarily results in production of the water-soluble aromatic acid, 1-pyrenecarboxylic acid (90% of the total metabolites). Here we show that also methylated phenanthrenes and chrysenes exposed to N. diversicolor generate aromatic acids as main metabolites. In addition, we show that metabolism is faster for alkylated PAHs than for their relative non-alkylated PAH. Our results suggest that metabolism of crude oil spilled to benthic environments in general results in a build-up of water-soluble aromatic acids.

Occurrence, risk assessment and prioritization of emerging pollutants in Mediterranean (Iberian) rivers

M. Kuzmanovic; A. Ginebreda, IDAEACSIC; M. Petrovic, Catalan Institute for Water Research ICRA; D. Barcelo, IIQABCSIC / Environmental Chemistry

Introduction Worldwide contamination of aquatic systems with numerous chemicals is one of the key environmental problems. One approach for identifying dangerous compounds is screening of the environment for a large set of chemicals together with an assessment of the potential toxicity.Within the project SCARCE-Consolider project an extensive sampling at 77 sites from four Iberian river basins was undertaken. This work presents a synthesis and critical evaluation of levels for 244 organic emerging contaminants in water and provides a basis for assessing the risk towards ecosystem for each river basin. This also allows providing a prioritization list of these contaminants in Iberian rivers that can be relevant from the regulatory point of view. **Results** The most frequently detected chemicals were of industrial origin, followed by personal care products parabens, degradation products of industrial detergents, some pharmaceuticals such as azitromycin, and pesticides chlorphyriphos and diazinon. In the highest average concentrations were found: nonylphenol monocarboxylate, tolyltriazole, tris(chloroisopropyl) phosphate found at average concentrations above 100 ng/L. Llobregat river was the most contaminated, showing clear and significant increase in concentrations downstream the river being the sites near the mouth of the river the ones with the highest contaminants load. In the Ebro river basin several hot spots can be identified especially where treated wastewaters are discharged into the river or its smaller tributaries. Of studied river basins, Jucar showed to be the least contaminated. At majority of sampling sites pesticides contribute to the major extent to the overall risk, with the exception of lower Llobregat where significant contribution from perfluorinated compound and smaller from pharmaceuticals is observed and several points at Guadalquivir with significant contribution from EDCs of industrial origin. In terms of individual compounds posing the highest risk highlighted were prochloraz, diuron and triclosan. **Acknowldegment** The authors wish to acknowledge the financial support provided by the Spanish Ministry of Science and Innovation through the projects SCARCE (Consolider-Ingenio 2010 CSD2009-00065) and CEMAGUA (CGL2007-64551/HID) HID), and the Generalitat de Catalunya (Grup Consolidat de Recerca: Unitat de Qualitat de l'Aigua i Sòls, 2009SGR965). Forensic ecotoxicology in a multi-stressed Mediterranean river: unravelling major toxic effects of phytotoxins in a superfund site in Ebro River (NE, Spain)

C. Rivetti, IDAEA CSIC Barcelona; R. Giaggio, IDAEA CSIC Barcelona / Department of Environmental Chemistry; S. Lacorte, IDAEACSIC / Environmental Chemistry; M. Casado, Environmental Chemistry; S. Diez, CSICIDAEA / Environmental Chemistry; C. Barata, CSIC / Environmetal Chemistry

Assessing and identifying toxic compounds in multi-stressed rivers in the field require the combination of toxicity assays and chemical analytical/fractionation methods. Among the existing procedures, TIE (Toxicity Identification Evaluation) approaches are among the most accepted ones but many times are unsuccessful in detecting causal-toxic compounds within complex samples. Lack of success often occurs when toxic effects are associated to a minor compartment fraction of the sample (i.e. suspended material within water samples), effects are sublethal, toxicity is due to low amounts of highly toxic compounds and/or when toxic compounds are very polar. Here we present data on a long term study performed to determine the toxic components present in the suspended material fraction of the water column. The study was conducted in the lower part of Ebro River (NE, Spain) at the Flix superfund reservoir site during an unusual prolonged period of high water flow with an increase two to five fold (January to June 2013). Flix reservoir is heavily contaminated with organochlorine and mercury wastes deposited in the sediment from a chlor-alkali industry operating for more than 50 years. The study aimed to assess how water flow increases would affect the re-suspension of toxic sediment wastes into the water column. Chemical compounds of suspended material were extracted with a battery of non polar and polar solvent and analysed by GC-MS/MS. Mercury content was also determined for all sites. Post exposure feeding *Daphnia magna* rates were used to asses toxic effects of whole water samples and of the filtered water and re-suspended solid fractions. Organochlorine and mercury residues in the water samples increased from upstream to downstream locations. Conversely, toxic effects were greater at the upstream site than at and downstream of the superfund Flix reservoir. A further analysis of the suspended solid fraction identified a toxic component eluted within the 80:20 methanol:water fraction. Characterization of that toxic component fraction by LC-MS/MS identified three different candidate phytotoxins coming from the bottom sediment upstream and re-mobilized when opening the reservoir dams. This study provides evidence that, in real field situation under the action of multiple stressors, measured contaminant residues not always agree with toxic effects.

Recent advances and critical future research directions for poly- and perfuorinated alkyl substances (PFASs) (II)

371

Substitution of prioritized poly- and perfluorinated chemicals to eliminate diffuse sources (SUPFES)

P. Leonards, VU University Institute for Environmental Studies / Chemistry Biology; H. Andersson, IVL Swedish Environmental Research Institute Ltd; U. Berger, Stockholm University; I.T. Cousins, Stockholm University / Applied Environmental Science ITM; P. Gillgard, Swerea IVF AB; G. Peters, Chalmers tekniska högskola; S. Posner, Swerea IVF AB; J. Weiss; C. Jonsson, Swerea IVF AB

Fluorinated substances have important technical applications in consumer products, e.g. in textiles where they are used for oil and water repelling properties. The aim of the SUPFES project is to help industry find alternatives that can replace poly- and perfluorinated chemicals (PFASs) which are harmful to the environment. Within the project a number of scientific and industrial partners collaborate to assess the risks with different chemicals and make sure that the new alternatives provide desired functionality. PFASs have important technical applications in consumer products, e.g. in textiles where they are used for oil and water repelling properties. However, some PFASs are long-lived and accumulate in the environment. In several independent studies they have been found to cause adverse effects on animals' development and negative changes in humans' immune systems. The substances have been found in the blood of humans, mammals, sediment and water in very remote areas such as the Arctic. Some PFASs are already banned under UN regulations (e.g. PFOS) and regulated in the European chemical legislation REACH (e.g. PFOA). A unique consortium has been established in connection with the SUPFES research project, consisting of: Swerea IVF, Chalmers University of Technology, VU University Amsterdam, Stockholm University, Käppala wastewater treatment plant and outdoor retailer Haglöfs. The SUPFES project will test the hypotheses that emissions of these chemicals are mostly generated as diffuse emissions, i.e. as small and large emissions throughout the whole life of the product, and that textiles are an important source of these emissions. Alternative chemicals will be tested on functionality, leaching behaviour, toxicity and a life-cycle assessment will be performed.

372

Perfluorinated alkylated substances in freshwater fish on Svalbard

M. Garsjo, Norwegian University of Life Sciences UMB / Chemistry Biotechnology and Food Science; R. Kallenborn, Norwegian University of Life Sciences / Arctic Technology; D. Huertas Lopes, Institute of Environmental Assessment and Water Research; D. Herzke, Norwegian Institute for Air Research

Perfluorinated Alkylated subsances (PFASs) were analysed and quantified in Arctic char (*Salvelinus alpinus*), from the lake Linnévatnet in Svalbard in order to investigate levels and distribution of this substances in a typical Arctic freshwater system. In many high Arctic region, Arctic char is the only resident fish species in freshwaters, and therefore favourable as biomonitoring species also for this project. During the fieldwork in March 2013 (N=6, liver and fillet samples) and September 2010 (N=13, fillet samples) Arctic char were caught and kept frozen until analyses of PFAS. The analyses were conducted at the Norwegian Institute of Air Research (NILU) in Tromsø. Principal component analysis (PCA) was used to investigate the relationship between the samples and the PFASs. The results confirmed that perfluorobutanoic acid (PFBA) and perfluorohexanoic acid (PFHxA) were the most abundant contaminants detected in all samples. In 2010, PFBA in fillet samples showed the highest concentrations (in ng/g w.w). The fluortelomer 6:2FTS showed highest concentration in the liver samples from 2013. The short-chained PFASs compounds (4-6 carbons) contributed to 78 % of ΣPFAS in the 2010 measurements, while the long-chained PFASs (7-13 carbons) together accounted for 56.8% of the ΣPFAS in 2013. In general, the concentrations were relatively low. However, there was a decrease in levels of PFASs in fillet samples from 2010 to 2013, while the highest levels were mainly detected in liver samples from 2013. This is consistent with previous studies indicating that PFAS bind to protein in the blood and bioaccumulate in the liver. Because of the location of the lake Linnévatnet and the low concentrations of PFASs, long-rang atmospheric transport is the main pathway for these contaminants instead of local sources. Based on previous studies, perfluorooctanoic sulfonate (PFOS) and perfluorooctanoic acid (PFOA) were expected to have higher concentrations and to be the dominating contaminants, but this was not the case in the present study. Detecting levels of PFASs in Svalbard, which are being used in production of perfluorinated products in Asia, give reasons for further research and to investigate temporal trends and distribution of these contaminants in the European Arctic.

373

Accumulation and elimination of perfluoroalkyl substances (PFASs) by the insect (Chironomus riparius) larvae (Diptera, Chironomidae) exposed to sediment

D. Bertin, Irstea; P. Labadie, University of Bordeaux / UMR EPOC Equipe LPTC; B. Ferrari, Swiss Centre for Applied Ecotoxicology; J. Garric, Irstea Lyon / Groupement de Lyon; H. Budzinski, University of Bordeaux / UMR EPOC

Equipe LPTC; M.P. Babut, Irstea / Water
Long chain perfluoroalkyl acids or sulfonates and a few precursors have been found in different media of the Rhone river downstream of Lyon (France). Although most of these compounds are considered as bioaccumulative, the exposure pathways of aquatic biota and the accumulation kinetics remain poorly understood. The objectives of this study are (i) to assess the accumulation and depuration kinetics of C_9 to C_{14} carboxylic acids (nonanoic PFNA to tetradecanoic, PFTeDA), C_8 to C_{10} sulfonates (perfluoro-octane, PFOS to perfluoro-decane PFDS) and 3 precursors, in a benthic invertebrate species, the midge *Chironomus riparius*; (ii) to test the concentration dependency of PFASs accumulation. Chironomids are an important food source for other species; their life cycle involves a larval stage in contact with sediment and use to feed on detrital carbon food source. Natural sediments from a deposition site along the Rhône river (France) downstream of an industrial site releasing amounts of PFASs were collected with a Van-Veen grab, sieved at 2 mm, pooled in polypropylene jars and stored at 4°C. Chironomids were exposed at their optimum temperature (21°C). Two series of experiments were conducted, dealing with uptake and depuration respectively. PFASs were analysed in water, pore water, sediment and organisms by LC-MS/MS. The accumulation of all tested perfluoroalkyl substances (PFASs) is measurable already at the first intermediate time (two days). Transfers from sediment to surface or pore water as well as chironomid larvae can be demonstrated. Biota to sediment accumulation factors appear lower than those published for *Lumbriculus variegatus* ([1,2]). These results allow to draw a conceptual model of PFASs distribution in abiotic compartments, and to determine the pathways and dynamics of accumulation by chironomids. Tentative uptake and depuration rates were calculated on the basis of the uptake experiment and a partition model ([1,3]). Experimental depuration rates will be presented, and the perspectives to develop a complete kinetic model will be discussed. ([1]) Higgins, C. P., McLeod, P. B. et al. (2007). 374
Life-traits analysis for evaluation of long-term effects of perfluorinated compounds (PFASs) on Chironomus riparius (Diptera, Chironomidae) under a multi-generational approach
L. Marziali, IRSACNR Brugherio; F. Stefani, National Research CouncilWater Research Institute; A. Fumagalli, F. Rosignoli, Italian National Research Council Water Research Institute CNRIRSA; S. Valsecchi, Water Research Institute Italian National Research Council IRSACNR; M. Rusconi, Water Research Institute Italian National Research Council / Water Research Institute; R. Bettinetti, Università dellInsubria; S. Polesello, Water Research Institute CNR / Water Research Institute
A multi-generational test with *Chironomus riparius* was performed in order to assess long-term effects on life-traits of selected perfluorinated compounds, i.e. PFOS, PFOA and PFBS. These persistent contaminants are widespread in aquatic ecosystems and may cause long-term toxicity. Among aquatic invertebrates, *Chironomus* was shown to be sensitive to PFOS at low concentrations (NOEC = 21,7 μg/l, 20-d growth of *C. tentans*, MacDonald et al., 2004), possibly due to interaction with hemoglobin. Based on this result, in this study *C. riparius* larvae were exposed for 10 generations to 10 µg/l solutions of PFOS, PFOA and PFBS, i.e. at the maximum values found in Italian freshwaters. For each generation, the following life-traits were estimated: survival (emergence ratio), growth (weight of IV instar larvae, weight of male and female adults, length of male and female pupal exuviae), development (development rate, mean emergence time), and reproduction (number of egg ropes per female, number of eggs per egg rope, number of hatching eggs per rope). Comparison between treatments and control were performed for each generation. No effects on survival were found. Treatments showed reduced growth, with significant differences for PFOS and PFOA. Development was affected by PFOS and PFOA, with anticipated or delayed emergence. Reproduction traits showed no significant differences between control and treatments. PFOS showed effects mainly in the early generations, possibly inducing adaptative response of the population. PFOA showed effects in all generations, possibly inducing physiological response. PFBS affected only the last generations, i.e. the most stressed by the lab breeding conditions. These pre-exposed populations will be used for a final test on tolerance induction to 100 μg/l PFOS and 200 μg/l PFOA. Results show that PFASs can induce long-term toxic effects in aquatic communities at low concentrations, with different mode of action.

375
Are fluorinated alternatives to long-chain perfluoroalkyl carboxylic acids (PFCAs), perfluoroalkane sulfonic acids (PFSAs) and their precursors safer than the substances they replace?
M. Gomis, Stockholm University / ITM; Z. Wang, Swiss Federal institute of Technology / Institute for Chemical and Bioengeneering; M. Scheringer, ETH Zuerich / Institute for Chemical and Bioengineering; I.T. Cousins, Stockholm University / Applied Environmental Science ITM
Long-chain perfluoroalkyl carboxylic acids (PFCA) and perfluoroalkane sulfonic acids (PFSA) are persistent, bioaccumulative, and toxic contaminants that are globally present in the environment, wildlife and humans. Consequently, phase-out actions and use restrictions to reduce the environmental release of long-chain PFCAs, PFSAs and their precursors have been taken since 2000. In particular, long-chain perfluoroalkyl substances (PFASs) are being replaced with shorter-chain homologues or other fluorinated or non-fluorinated alternatives. A key question is: are these alternatives, particularly the structurally similar fluorinated alternatives, safe to humans and the environment? Over 20 fluorinated alternatives including a new type of perfluoroether carboxylic acids (PFECAs) have been recently identified. However, the scarcity of experimental data prevents comprehensive hazard assessments for these substances. In this study, we use state-of-the-art *in silico* tools to assess some properties of these newly identified fluorinated alternatives. [i] COSMOtherm and SPARC are used to estimate physicochemical properties including the octanol-water (K_{OW}), air-water (K_{AW}) partition coefficients, and acid dissociation constants (pK_A). The US EPA EPISuite software package is used to predict half-lives in air, water and soil. [ii] In combination with estimated chemical properties, a global-scale multimedia mass-balance model – the OECD Overall Persistence (P_{OV})and Long-Range Transport Potential (LRTP) Screening (OECD) Tool – is used to assess the likely environmental fate of these alternatives. Even though the fluorinated alternatives contain some structural differences, their physicochemical properties are not significantly different to their long-chain predecessors. Furthermore, most of the alternatives, e.g. the PFECAs, are estimated to be similarly persistent and transportable as the long-chain PFASs. The models therefore predict that the fluorinated alternatives will become globally distributed in the environment like their long-chain predecessors. The alternatives may also bioaccumulate in biota and humans, but it is not possible to accurately predict bioaccumulation of PFASs with existing *in silico* tools. Nevertheless, whilst such *in silico* methods are coupled with uncertainties, this preliminary assessment provides enough cause for concern to warrant experimental work to better determine the hazard properties of these fluorinated alternatives.

Biophysical Interactions at the Bio-nano Interface: Relevance for Aquatic Nanotoxicology (I)

376
A novel two-compartment barrier model for investigating nanoparticle transport in fish intestinal epithelial cells
M. Geppert, L. Sigg, K. Schirmer, Eawag / Environmental Toxicology
The rapid growth in development, production and use of engineered nanoparticles (ENPs) leads to a strong increase in both exposure of humans and the ecosystem to these new materials. However, the current knowledge of effects potentially caused by these new materials is still limited. We developed a new two-compartment intestinal barrier model using a fish cell-line and investigated its ability for studying nanoparticle transport through fish intestinal epithelium. Rainbow trout (*Oncorhynchus mykiss*) cells (RTgutGC) were successfully grown on transwell inserts with membranes of different pore sizes (0.4, 1 and 3 μm) leading to a two-compartment barrier model that allows to investigate the transport of ENPs through a model of fish intestinal epithelium. The cells form a polarized monolayer and express the tight junction protein ZO-1 as shown by immunohistochemistry. Measuring the transepithelial electrical resistance (TEER) reveals that the cells build up an epithelium with TEER values comparable to the *in vivo* situation. Incubation of the cells with fluorescent polystyrene nanoparticles (PS-NPs; average hydrodynamic diameter: 73 ± 18 nm) for 24 h lead to a very intense fluorescent signal in the apical medium indicating that most of the particles still remain in the apical compartment after the incubation period. However, there was also a detectable fluorescent signal in the cells, demonstrating accumulation of at least some of the PS-NPs in the cells. In contrast, the basolateral medium shows no significant fluorescence which indicates that a transport of PS-NPs through the cell layer does not occur. The situation is different when empty (cell free) inserts were used: Here, fluorescence in the basolateral compartment was detectable at least for the inserts with larger (1 and 3 μm) pore sizes. These results show that a transport of the PS-NPs by simple diffusion to the basolateral compartment is possible and thus validates the system as suitable for investigating nanoparticle transport. In addition, these results further demonstrate that the RTgutGC cells function as a barrier preventing the uptake of ENPs to the basolateral chamber that could be extrapolated to the blood stream *in vivo*. *Acknowledgement* – This research has been supported by EU FP7 grant NanoValid no 263147.

Citrate gold nanoparticle exposure in the marine clam Ruditapes philippinarum: Uptake, elimination and effect
M. Volland, Instituto de Ciencias Marinas de Andalucía CSIC; M. Hampel, Instituto de Ciencias Marinas de Andalucía CSIC / Consejo Superior de Investigaciones Cientificas; C. Trombini, Institute for Marine Science of Andalucia CSIC; C. Garcia-Negrete, A. Fernandez, Instituto Ciencias de los Materiales de Sevilla CSIC; T. Gomes, University of Algarve / CIMA; M. Bebianno, University

of Algarve; J. Blasco, Inst Ciencias Marinas de Andalucia / ECOLOGY AND COASTAL MANAGEMENT
Engineered gold nanoparticles (AuNPs) are introduced into a growing number of commercial products. The resulting increase in likelihood of release into various environmental compartments needs to be met by an increased understanding of their effects on the species within. Up to date limited information is available on the ecotoxicological risk for non-target organisms in marine environments, with the majority of research focusing on magnified expectable environmental concentrations. In our laboratory-based study the bivalve *Ruditapes philippinarum* was chosen as a model to evaluate uptake, elimination and sub-cellular effects of citrate-stabilized AuNPs (21.5 ± 2.9 nm) at an environmental relevant concentration (0.75 μg L^{-1}) over 14 days. Tissue (digestive gland and gills) was sampled on days 0,1, 7 and 14 to record changes in the expression of chosen endpoints over time. Gold concentration in tissue and faeces, enzymatic biomarkers of i.) oxidative stress (CAT, GST, SOD, GPx, GPx-Se), ii.) damage (lipid peroxidation, DNA strand breaks) and iii.) exposure (Metallothionein, AChE), as well as gene expression by means of quantitative reverse transcription PCR (qRT-PCR) for selected sets of genes were measured. We observed an uptake of AuNPs in both organs and an effect on the activity of the tested biomarkers, with the digestive gland being the primary target organ. While qRT-PCR expression levels raise some concerns regarding the effects of chronic AuNP exposure, at the tested concentration the particles did not cause significant oxidative damage. Further we could demonstrate a significant elimination of Au from the digestive track within a 7 day purification period, with excretion being an important pathway.

First evidences of PAMAM dendrimers internalization in microalgae and cyanobacteria: linkages with toxicity and oxidative stress
F. Fernandez-Piñas, Universidad Autónoma de Madrid / Biology; I. Rodea-Palomares, Universidad de Alcala / Biology; S. Gonzalo, Universidad de Alcala; R. Rosal, Universidad de Alcala / Ingenieria Quimica; F. Leganes, Universidad Autónoma de Madrid / Biology
Algae and cyanobacteria are ecologically relevant organisms which are at the base of aquatic food webs and have essential roles in nutrient cycling therefore being especially well suited to study possible ecological impacts of nanomaterials. We have applied a multi-end point approach to get insights into the toxic mechanisms of action of poly(amidoamine) (PAMAM) dendrimers on both *Chlamydomonas reindartii* (microalga) and *Anabaena* sp. PCC 7120 (cyanobacterium). Dendrimers are considered "perfect" polymers due to their symmetry, and have exponentially increasing applications in a variety of medical and technological fields. We chose generations G2, G3 and G4 native $–NH_2$ and NH-C-$(CH_2OH)_3$ (-OH) surface functionalized PAMAMs. In our approach, physicochemical properties of nanomaterials on relevant biological media were studied and linked with the biological information from the organisms. Special focus was posed on internalization and intracellular alterations induced by PAMAM dendrimers and their relationship with oxidative stress. We found that native $–NH_2$ PAMAM were toxic to both organisms in a generation-dependent manner; (-OH) surface functionalized PAMAM presented reduced toxicity with respect to their $–NH_2$ counterparts except the G4-OH congener which showed similar toxicity to that of G4-NH_2. The observed toxicity correlated with an increase in intracellular oxidative stress in both organisms, as identified by flow cytometry and confocal microscopy. However, the photosynthetic machinery seemed to remain unaffected which is in disagreement to results reported elsewhere [1,2]. Experiments performed with Alexa-Fluor488:PAMAM dendrimers revealed fast (10 min) internalization of dendrimers (in a generation dependent manner) with low retention time in cell wall/outer membranes, and a cytoplasmatic homogeneous distribution. However, chlorophyll---dendrimer/ROS colocalization was almost absent; emphasizing that the photosintetic machinery seemed to be unafected, and possibly it is not the source of oxidative stress. Toxicity and accumulation of silver in Euglena gracilis upon exposure to silver nanoparticles and silver nitrate
X. Li, Environmental Toxicology; K. Schirmer, L. Sigg, Eawag / Environmental Toxicology; S. Pillai, Eawag Swiss Federal Institute of Aquatics; R. Behra, Eawag / Department of Environmental Toxicology
Engineered silver nanoparticles (AgNP) are potentially harmful to aquatic life. Little is known about AgNP interactions with algae. In the present study, the short-term effects and accumulation of cit-AgNP (citrate-coated) are examined in the alga *Euglena gracilis*, which has a pellicle on the surface instead of a cell wall, and is able to carry out endocytosis. The AgNP in exposure medium were characterized by dynamic light scattering. The level of AgNP dissolution was determined by ultracentrifugation and centrifugal-ultrafiltration. ICP-MS was used for metal analysis. Algae were exposed to various concentrations of cit-AgNP (0.1 – 40 μM) and to $AgNO_3$ (5 – 400 nM) as a source of Ag^+. After 1 and 2 hour, the photosynthetic activity was measured fluorometrically. To access the contribution of Ag^+ in the toxicity of cit-AgNP, cysteine was used as silver ligand. Biovolume were examined with 5 μM cit-AgNP and 50 nM $AgNO_3$ using cell counter, and morphology changes were also assessed by confocal microscopy. For accumulation experiments, *E. gracilis* were exposed to $AgNO_3$ (25 – 500 nM) and cit-AgNP (1 – 10 μM) for 1 hour and collected for ICP-MS measurments. The cit-AgNP remained stable during exposure in the medium, with a size range of 34 ~75 nm and a zeta-potential of -20 ~ -33 mV. The level of dissolved Ag^+ was 0.5% ~ 3.5%. Cit-AgNP and $AgNO_3$ lead to inhibition of photosynthesis with EC_{50} of 1858 nM for cit-AgNP and 85 nM for $AgNO_3$ based on total silver mass. Incresed biovolume and changes in morphology were oberserved upon exposure to both cit-AgNP and $AgNO_3$. Inhibitory and morphological effects of cit-AgNP were all prevented by cysteine. The accumulation of silver (Ag_{acc}) with $AgNO_3$ was linear when expressed as mol per cell, but non-linear when expressed as mol per Liter cell resulting from increased biovolume. In the case of cit-AgNP, the Ag_{acc} showed a non-linear increase. Based on dissolved Ag^+, Ag_{acc} was ~15 times higher with cit-AgNP compared to $AgNO_3$, which could corespond to 38~156 NP per cell, or to a dissolution of particles up to 44%. In sumary, the effects of cit-AgNP on *E. gracilis* photosnythesis, biovolume and morphology are mediated by dissolved Ag^+. The level of silver accumulation in *E. gracilis* upon AgNP exposure is high compared to $AgNO_3$, indicating sorption on to algal surfaces or cellular internalization.

Uptake of gold nanoparticles into Gammarus pulex from synthetic and natural waters
S. Park, University of York / Environment; J. Woodhall, Food and Environment Research Agency; A. Boxall, University of York / Environment Department
Engineered nanoparticles (ENPs) are used in a range of product types, including personal care products, electronics and display technologies and other various applications. The increasing use of ENPs will result in increasing amounts of ENPs being released into the aquatic environment. Concerns have therefore been raised over the potential impacts of ENPs on aquatic organisms. Many studies of ENPs for ecotoxicological effects are based on acute or chronic tests following traditional test guidelines. However, most ecotoxicological risk investigations have ignored the fact that ENPs will aggregate to different degrees in different media types and the use of standard studies could either over or under estimate the real risk of ENPs. Our previous work demonstrated that the model gold nanoparticles (Au NPs) show different degrees of aggregation in both various ecotoxicological test media and in natural waters. In this study, we build upon our previous work and explore the implications of differences in aggregation in artificial media and natural waters for the uptake of ENPs by the fresh water shrimp, *Gammarus pulex*. The study used a set of model Au NPs with different properties and four different synthetic test waters and a variety of natural waters. In each medium, Au NPs showed different ranges of particle aggregation depending on the composition of the applied test media and natural water. To explore whether size explained the observed differences in uptake, we related mean particle sizes for each NP at the end of the uptake phase to measured uptake. The results indicate that size differences do not explain the observed differences in uptake and that other factors such as, the surface charge of nanoparticles and charge of the cell or gut membrane in a particular treatment may be influencing the uptake and internalization of the particles in test organisms. Therefore, for the risk assessment of nanoparticles, not only is important to select appropriate test media that reflect the uptake of NPs that will occur in natural systems. A better understanding of the interactions between the NP surface properties and environmental factors and uptake is required to understand how to extrapolate from effects observed under laboratory conditions to effects on the natural environment.

381
Toxicity of silver nanoparticles to a fish gill cell line: role of medium composition
Y. Yue, Eawag Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology; R. Behra, Eawag / Department of Environmental Toxicology; L. Sigg, Eawag / Environmental Toxicology; S. Pillai, Eawag Swiss Federal Institute of Aquatics; P. Fernandez Freire, Universidad Autónoma de Madrid; K. Schirmer, Eawag / Environmental Toxicology
With the increasing application of silver nanoparticles (AgNP) in daily life, more attention is paid to the effects of AgNP on aquatic environments. In aqueous solutions, AgNP behaviour is affected by a variety of factors which lead to altered AgNP size and toxicity. This work aims to explore the effect of media composition on AgNP behaviour and toxicity to the RTgill-W1 cell line, which was derived from rainbow trout (*Oncorhynchus mykiss*) gill. Citrate coated AgNP (cit-AgNP, 20 nm, -30 mV) were used in this work. Cit-AgNP were added to three different exposure media: L15/ex, L15/ex w/o Cl and d-L15/ex. L15/ex is a modification of the original Leibovitz (L15) culture medium, which contains only salts, sodium

pyruvate and galactose. In this medium, cit-AgNP showed moderate agglomeration with sizes of 200-500 nm and zeta potential of -15 mV. L15/ex w/o Cl is a chloride free medium in which chloride is replaced with nitrate to avoid the formation of AgCl. Cit-AgNP heavily agglomerated in this medium (1000-1750 nm, -10 mV). Finally, to maintain cit-AgNP stable, a new medium, d-L15/ex, was developed by diluting L15/ex w/o Cl medium with water and adding NaCl. Cit-AgNP size ranged 40-100 nm in this medium and zeta potential was around -20 mV. The impact of cit-AgNP and $AgNO_3$ on cell viability was investigated. The extent of cit-AgNP toxicity differed between media with the toxicity rank order (highest to lowest) being L15/ex w/o Cl > L15/ex > d-L15/ex. When dissolved silver in cit-AgNP media was measured with ICP-MS (dissolved ratio: 0.4%-1.89%) and dose-response curves recalculated based on dissolved silver, the rank order changed to L15/ex w/o Cl > d-L15/ex > L15/ex. The low toxicity in L15/ex could be due to the high concentration of chloride, allowing AgCl formation. Furthermore, comparing cit-AgNP toxicity as function of dissolved silver and $AgNO_3$, $AgNO_3$ was less toxic in all media (10-40 fold). Besides, silver ligands could not prevent the cit-AgNP toxic effect to cells. Both indicated a particle-specific contribution to toxicity. In summary, our results showed that the toxicity of cit-AgNP is due to not only the dissolved silver, but also the particle-specific effect. Linked to the cit-AgNP behavior, deposition of cit-AgNP on cells might explain the higher toxicity of agglomerated cit-AgNP compared to that of suspended cit-AgNP.

Bioaccumulation processes and mechanisms: Implications for experimental assessments and modelling (I)

A tiered strategy for evaluating Bioaccumulation data in PBT assessments

A. Lillicrap, NIVA / Ecotoxicology and Risk Assessment; J.A. Arnot, ARC Arnot Research Consulting / Department of Physical Environmental Science; K. Borga, Department of Biosciences University of Oslo / Departmenf of Biosciences

Tiered approaches to aquatic bioaccumulation (B) testing and also guidance on evaluating bioconcentration factor (BCF) data for organic chemicals generated using internationally recognised test guidelines (such as the Organisation for Economic Cooperation and Development [OECD] 305 [1]), have previously been proposed (e.g. Parkerton et al. [2] etc). However, there is a lack of guidance available for regulators and risk assessors for considering other bioaccumulation/bioconcentration (B) data, particularly when categorizing chemicals to be B or very B (vB) (i.e. BCF >2000 or >5000) in PBT assessments (i.e. persistent, bioaccumulative and toxic). Alternative approaches may be sufficient to determine whether a substance is clearly B or vB or if a substance is clearly not B (e.g. BCF < 500). However, some risk assessments or substance evaluations may not consider that sufficient information is available to perform the B assessment without having data from a full bioconcentration test. This means that substance evaluations and risk assessments may be relatively subjective depending on the understanding of the individual that is performing such evaluations. Furthermore, this may result in unnecessary testing requirements being requested by Regulatory Authorities. In addition, international regulations such as the Registration, Evaluation, Authorisation and restriction of Chemicals (REACH) regulation (EC No. 1907/2006) advocates the use of alternative (validated) approaches prior to the use of animal testing for data gap requirements. One difficult area of B assessments using alternative approaches is where there is some ambiguity as to whether the substance would cross the BCF 2000 threshold and be assigned as a bioaccumulative substance. These chemicals may be considered to be in the “grey area” of chemical bioaccumulation assessment and those within this category would require further testing in order to strengthen the B assessment. This paper summarises existing approaches which are available for assessing Bioaccumulation in fish and proposes a tiered testing approach to provide guidance to regulators and risk assessors on how to assess these data.

Octamethyltrisiloxane (L3): Assessment of biomagnification and toxicity through aquatic/dietary lab studies, fugacity ratios, and field data

K.B. Woodburn, D.E. Powell, R.M. Seston, Dow Corning Corporation / Health Environmental Sciences; J.A. Durham, Dow Corning Corp / Health and Environmental Sciences; J. Sushynski, Dow Corning Corporation; C.A. Staples, Assessment Technologies Inc

Lipophilic chemicals, such as the linear volatile methylsiloxanes (LVMS), are considered likely candidates for potential bioaccumulation in aquatic food webs, and sorb well to particles/surfaces, making sediments a key sink when performing environmental risk assessment evaluations. This project examined the laboratory and field data concerning the bioaccumulation and ecotoxicity of octamethyltrisiloxane (L3), an LVMS material. Experimental BCF and BMF results for L3 with various fish species are discussed in detail and then collectively used to model a TMF value for a Great Lakes aquatic foodweb. A fish BCF value of >5000 L/kg-ww exists for L3, a compound for which food uptake should dominate over water accumulation (log K_{ow} >6). To further evaluation of L3 bioaccumulation potential, a BMF study was conducted in accordance with OECD regulatory guidelines, consisting of a 35-day uptake and 30-day depuration phase and ^{14}C-L3 spiked into fish food (~500 μg/g) fed to juvenile rainbow trout (*Oncorhynchus mykiss*). In the dietary BMF study, an assimilation efficiency for food-to-gut transfer of 32% was determined, along with a steady-state kinetic BMF_K value of 0.26 and a lipid-adjusted kinetic BMF value ($BMF_{K(L)}$) of 0.86. All bioaccumulation data for L3 are then evaluated collectively as dimensionless fugacity ratio values in a weight-of-evidence approach, testing whether such ratios are collectively greater than (i.e., bioaccumulation) or less than (i.e., biodilution) 1.0. To evaluate environmental risk, chronic benthic toxicity no-observed effect concentrations (NOECs) for L3 are compared to field sediment concentrations using a probabilistic risk assessment (PRA) approach, which allows the risk assessor to include stochastic properties of both exposure and response. The PRA method examined field sediment L3 concentrations at a variety of global locations and compared the 95th centile concentration to the 5th centile chronic toxicity NOEC value from benthic organism studies. The analysis revealed no overlap of exposure and toxicity at these levels and a factor greater than 10,000-fold between the respective exposure and NOEC centile levels. Collectively, these analyses indicate an absence of bioaccumulation and risk to aquatic species posed from this linear methylsiloxane.

384

How well can we model bioconcentration factor (BCF) from dietary accumulation or biomagnification factor (DAF / dietary BMF)?

D.T. Kuo, City University of Hong Kong / Civil and Architectural Engineering

Bioaccumulation potential is a fundamental indicator of ecotoxicological behavior and ecological risk of chemicals. It is commonly measured by the aqueous exposure-based bioconcentration factors (BCF). However, BCF does not reflect a chemical’s bioaccumulative potential via dietary uptake; furthermore, its measurement can be operationally challenging for chemicals with low aqueous solubility. Consequently, it is desirable to measure the bioaccumulation potential of chemicals through dietary exposure, which would produce dietary accumulation factors (DAF) or dietary biomagnification factor (dietary BMF). Although dietary bioaccumulation protocol has been incorporated in recent standard chemical testing guidelines, regulatory statutes are predominantly established based on BCFs. In order to bridge the gap between dietary bioaccumulation studies and the regulatory need for BCF values, this study examined the basis and the extent to which we can estimate BCF from dietary bioaccumulation experiments. Fish dietary BMF data (n≈600) corresponding to a total of 184 weakly polar to apolar organic chemicals were reviewed and extracted from primary literature. BCF was predicted from the dietary bioaccumulation data using measured or derived total depuration rate constant (k_T) and predicted respiratory uptake rate constant (k_1) based on various k_1 models. Analysis suggested that k_T determined from dietary and aqueous exposure experiments were statistically identical. This implied that k_T can be determined from dietary exposure and may be applied in the bioconcentration scenario. Using dietary accumulation data and an accurate respiratory uptake rate constant (k_1) model, BCF can be estimated to within ±1 log unit (root mean square of errors = 0.64) of the mean experimental values. Furthermore, the estimated BCF is independent of the dietary dosage applied for up to 4 orders of magnitude in the exposure concentration, and this eliminated the need for case-by-case normalization. Although the examined BMF-BCF estimation protocol is generally successful, further improvement in our ability to predict k_1, greater confidence in experimental BCF values, and more dietary studies on organic chemicals with lower hydrophobicity are critical if a tighter convergence between dietary BMF and BCF is desirable.

385

The environmental relevance of active transport inhibition

D. Kurth, Helmholtz Centre for Environmental Research UFZ; T. Luckenbach; T. Schulze, W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis

The uptake of organic chemicals into the cell as the frist step of toxicokinetics is believed to be governed by physico-chemical partitioning. Recently, there is increasing evidence that this purely physico-chemical process is superimposed by active transport, resulting in an energy-dependent efflux of chemicals, which reduces the bioavailability and bioaccumulation of chemicals in cells. This transport mechanism may be inhibited by chemosensitisers. These are mainly xenobiotic substances which are commonly present in the environment, such as pharmaceuticals, pesticides, fragrances and surfactants. Available data on active transport inhibition has been collected and analysed with regard to the environmental relevance of this mechanism. On the one hand, membrane and cell-based in-vitro assays predict effect concentrations of active transport inhibitors in the range of several mg/L. However, they are often conducted using unrealistically high exposure concentrations and single or binary mixtures, only. Moreover, artificial active transport protein overexpression may lead to the underestimation of toxicity in such test systems. On the other hand, in-vivo tests have produced lower effect concentrations. Those still exceed environmental

aqueous concentrations by several orders of magnitude. Despite this, exposure of organisms to environmental mixtures could be proven to enhance the bioaccumulation of active transport substrates, thus suggesting the presence of chemosensitisers in environmental samples causing observable effects in organisms. In conclusion, from the data present it is difficult to come to a decision about the environmental relevance of chemosensitisation. While the comparison of effect concentrations with environmental data suggest that no effects should occur in the environment, there is evidence for the opposite stemming from the exposure of aqueous organisms to complex environmental mixtures. As this evidence is few, more focus needs to be put on such complex and more realistic exposure scenarios.

386

The power of analogy: predicting the properties and bioaccumulation behaviour of per- and polyfluorinated alkyl substances (PFASs) using their fatty acid counterparts.

C.A. Ng, ETH Zurich / Institute for Chemical and Bioengeneering; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

Poly- and perfluorinated alkyl substances (PFASs) are analytically challenging, with physicochemical properties that are difficult to measure. Their bioaccumulation behavior differs from that of neutral hydrophobic organic compounds in important ways. They accumulate preferentially in the blood and liver, rather than in lipids, and there is growing evidence that their strong associations with proteins may be key controllers of their elimination half-lives and bioaccumulation potential. In this talk we will consider how the analogy between PFASs and fatty acids can be used to help predict their physicochemical properties and interactions with proteins, and how this information can be integrated into new models for PFAS bioaccumulation. We have surveyed the PFAS and fatty acid literature in order to identify parallels in their properties and behavior that will allow us to use existing fatty acid research to help fill persistent data gaps surrounding PFAS properties. We explore these properties and protein interactions using a mechanistic bioconcentration model we recently developed for perfluorinated alkyl acids in fish. By incorporating the interactions of PFASs with three key protein types—serum albumin, membrane transport proteins, and fatty acid binding proteins—into a physiologically-based pharmacokinetic model, we explore the way these interactions control the tissue distribution and elimination kinetics of different PFAS structures. Previous attempts to correlate PFAS bioconcentration factors with BSA-water distribution coefficients have met with only limited success. A model structure than can integrate multiple protein interactions is required. This indicates that attempts to develop new QSARs for these chemicals will need to somehow incorporate these multiple interactions.

387

Screening for Low Aquatic Bioaccumulation: Prediction Confidence and Quantitative Weight of Evidence with the BCF Waiving Scheme

M. Nendza, Analytisches Laboratorium; R. Kühne, Helmholtz Centre for Environmental Research UFZ / Department of Ecological Chemistry; T. Aldenberg, RIVM; G. Schuurmann, Helmholtz Centre for Environmental Research UFZ / Department of Ecological Chemistry

Aquatic bioconcentration factors (BCF) are critical in PBT and risk assessment of chemicals under REACH. High costs and consumption of more than 100 experimental animals per standard BCF study (OECD 305) call for filters based on quantitative structure-activity relationships (QSARs). The BCF waiving scheme allows to identify substances with low aquatic bioaccumulation (nonB, BCF < 2000) based on physico-chemical properties related to media-specific exposures and bioavailability (hydrophobicity, air/water partitioning, biodegradability, hydrolysis, ionisation). The nonB compounds cannot classify as PBT and their bioconcentration testing may be waived because of low concern with regard to the B criterion. The initial BCF waiving scheme [1] has been improved with an extended dataset of reliable BCF data for 998 compounds and complies with the OECD principles for valid QSARs. It performs with 100% sensitivity (no false negatives) and 60% efficacy (waiving potential). Specific bioaccumulative chemicals are excluded from the applicability domain. Reliability is based on (i) the number of physico-chemical property criteria triggered by query compounds, (ii) the distance of property estimates from thresholds and (iii) the structural similarity with known nonB and B substances. Prediction confidence of the BCF waiving scheme relies on applicability domain coverage defined by structural features (chemical classes, atom centred fragments (ACF)) and on the reliability rating. Quantitative Weight-of-Evidence (WoE) for low aquatic bioaccumulation is inferred from a Bayesian combination of BCF waiving scheme predictions, weighted by their reliability, and consistency with other available information including estimates from independent QSARs. Bayesian statistics provide quantitative measures of the WoE and inform users about the reliability of the classifications as either nonB (BCF definitively < 2000) or "unknown" (BCF may be >2000). *Acknowledgement* - This work was supported by the EU 6th Framework Integrated Project OSIRIS (contract no. GOCE-ET-2007-037017). [1] Nendza M, Herbst T. 2011. Screening for low aquatic bioaccumulation (2): Physico-chemical constraints. SAR QSAR Environ. Res. 22, 351-364.

Mechanistic effect modeling - beyond concentration response and constant environments (I)

Toxicokinetics and toxicodynamics of imidacloprid in six aquatic macroinvertebrates: model calibration and evaluation of predictions

A. Focks, Wageningen UR / Ecotoxicology Environmental Risk Assessment Team; I. Roessink, Alterra; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra

The systemic insecticide imidacloprid (IMI) is a nicotinoid insecticide that has been used for insect pest control since many years. Non-target aquatic organisms could potentially be exposed to imidacloprid via input from spray drift, leaching, or runoff after spraying. We used raw data on the survival over time of *Asellus aquaticus, Caenis horaria, Cloeon dipterum, Chaoborus obscuripes, Gammarus pulex* and *Plea minutissima* from acute and chronic laboratory tests on the toxicity of IMI (Roessink et al., 2013) to estimate the parameters of two TKTD models, namely the reduced versions of the stochastic death (SD) and the individual tolerance (IT) model (Jager et al., 2011). The more sensitive species (*C.horaria, C.dipterum* and *P. minutissima*) stand out with higher killing rates (kk, SD model) and lower internal median threshold values (α, IT model), respectively. The interpretation of the parameter values suggests that the reported higher toxicity of IMI towards these species is related to an increased internal sensitivity and not to an increased uptake or accumulation. Furtheron, model predictions of the survival of the six species under chronic exposure were done using the parameter sets of the fitted models for the acute experiments, and vice versa. The goodness-of-fit of the predictions was evaluated by calculating the ratios between the log-likelihood values of the predictions and the fits, respectively. For *A.aquaticus, C.obscuripes, C.horaria* and *C.dipterum* the log-likelihood values for model predictions were not deviating by more than a factor of 1.5 from the model fit, hence indicating a quite good quality of model predictions. Model predictions for *G.pulex* deviated strongly from the evaluation data sets. Reasons for the latter observation are not clear yet. This study demonstrates that it is possible to use data from standard toxicity testing of aquatic invertebrates for the parameterisation of TKTD models. The resulting parameter values were useful for an improved understanding of the reasons for the high toxicity of imidacloprid to some aquatic macroinvertebrates. The quality of the parameterised TKTD models with respect to predicitons of survial under new exposure situations was evaluated to be surprinsingly good for most species. It appears that it is possible to use TKTD model parameterisations based on standard toxicity testing of a range of species for extrapolations of the survival under more complex exposure scenarios.

389

A SYSTEMS BIOLOGY APPROACH REVEALS A NOVEL CALCIUM-DEPENDENT MECHANISM FOR BASAL TOXICITY IN DAPHNIA MAGNA

P. Antczak, University of Liverpool / Institute of Integrative Biology; T. White, University of Birmingham / Schoon of Biosciences; A. Giri, Assam University; F. Michelangeli, M.R. Viant, University of Birmingham; C. Vulpe, University of California Berkeley / Nutritional Sciences and Toxicology; F. Falciani,

The release of an increasingly larger number of anthropogenic chemicals into the environment and the interaction between pollution, land use and climate change, represents a formidable challenge in ecological risk assessment. An important component in this process is a consideration of the potential toxicity of chemicals to ecologically relevant organisms. Rapid, predictive, mechanism based and cost effective approaches for ecological risk assessment of chemicals are urgently needed to preserve the integrity of the natural environment. Recently, adverse outcome pathways (AOPs) have been suggested as a framework for risk assessment to link the molecular mechanisms of chemical action through to the adverse effects (toxicity) on an organism. Quantitative structure activity relationships (QSARs) provide an established alternative to traditional toxicity tests for the identification of toxic chemical. However, these computational approaches generally do not provide a mechanistic link between physical chemical features and the predicted adverse outcome. To overcome these limitations, our group has recently proposed to integrate QSAR analysis approaches with the molecular response of an organism and relevant biological endpoints into a comprehensive strategy to provide structure guided adverse outcome pathway prediction. Here, we address the question of identifying toxicity mechanisms of a panel of diverse chemicals in the crustacean *Daphnia magna*, a species of great environmental relevance. The approach we use relies on computational models that link compound Physical Chemical Features (PCFs) with molecular response pathways defined by sub-lethal transcriptional signatures predictive of organism toxicity. Model predictions and experimental validation support the hypothesis that intracellular calcium release triggered by lipophilic chemicals may be one of the initiating events that underlie basal toxicity of these compounds. We have described the first example of an experimentally validated integration of traditional QSAR analysis, functional genomics and ecotoxicology in a quantitative and predictive computational framework. This approach led to formulating the first working model explaining the molecular basis

of the basal toxicity of lipophilic chemicals, a finding that is bound to have broad implications across all areas of toxicology.

An energy-based model to evaluate toxicity of an endocrine disruptor: a case study with tributyltin and the pond snail
A. Barsi, INRA and VU University Amsterdam / Dept of Theoretical Biology; T. Jager, Vrije Universiteit / Dept of Theoretical Biology; L.L. Lagadic, INRA / UMR INRAAgrocampus Ouest Ecology and Ecosystem Health; V. Ducrot, INRA / Ecotoxicology and Quality of Aquatic Ecosystems
Endocrine disruptors are compounds that adversely alter functions of the endocrine system with consequences for population stability and recruitment. Therefore, the European Union allows marketing and use of chemicals only if they do not exert endocrine disrupting properties. Aquatic molluscs are recognised as organisms sensitive to such chemicals and the development of standardised mollusc toxicity tests is under way. However, these tests do not aim at an integrated assessment of the effects of chemicals on all endpoints over time. To demonstrate that such an integrated assessment can aid the risk assessment of endocrine disruptors, we present a case study with tributyltin (TBT), a chemical known for its endocrine disrupting properties in some molluscs. We combined experimental and toxicokinetic-toxicodynamic (TKTD) modelling approaches to evaluate toxicity of TBT in the freshwater gastropod species *Lymnaea stagnalis*. Effects of TBT on life-cycle traits were interpreted within the framework of dynamic energy budget (DEB) theory. To obtain data suitable for model calibration, we exposed adult and juvenile snails (which became adults during the test) to TBT in two independent toxicity tests over a part of the life cycle. Snails were fed with fresh lettuce. Additionally, snail eggs were exposed to TBT concentrations to assess effects of the compound on the embryonic development. A TKTD model called DEBkiss was used to analyse effects of TBT on survival, growth, and reproduction of snails simultaneously. TBT affected survival of juveniles only, and growth and reproduction of juveniles and adults. The complete set of data from the two partial life-cycle toxicity tests was well described by DEBkiss. The overall pattern of effects on growth and reproduction strongly suggests that assimilation of energy from food is decreased by TBT. Relevant output for ecological risk assessment (ERA) are no-effect concentrations (NECs) for survival and sub-lethal effects of 49.5 and 1386 ng Sn/L, respectively. Furthermore, TBT induced a decrease of hatching success to less than 10%, but only at the highest concentrations. The lack of effects on hatching time and hatchling size indicates that TBT affects an aspect of the feeding process that is specific for exogenous feeding on lettuce. We demonstrate that coupling a relatively simple test design with TKTD modelling approaches offers a great potential for the improvement of current ERA for endocrine disruptors in invertebrates.

Combined effects of an endocrine disrupting chemical, elevated climatic temperature and inbreeding on sexual development and population viability in fish
A. Brown, S. Owen, AstraZeneca / Safety Health Environment; D.J. Hosken, University of Exeter; C.R. Tyler, Biosciences College of Life and Environmental Sciences
Sex determination in many fish is temperature dependent; therefore the sex-related effects of endocrine disrupting chemicals (EDCs) could be exacerbated by future changes in climate. Small inbred fish populations, which are susceptible to inbreeding and stochastic variation in population size and sex ratio are likely to be particularly at risk from environmental impacts on sex determination. In a laboratory-based empirical study we investigated the masculinising effects of the EDC clotrimazole, in combination with elevated temperature. These combined effects were studied with inbred and outbred zebrafish (*Danio rerio*). Experimental results were used to parameterise a population viability analysis model to assess the population consequences of masculinisation. Inbred (F_{IT}=n+0.25) and outbred (F_{IT}=n) wild-type zebrafish families (n=20) were exposed in the laboratory from 40-100 days post fertilisation (dpf) to clotrimazole (0, 1.7, 8µg l^{-1}) at 28°C and an elevated water temperature (33°C). Sex ratios were skewed towards males in inbred and outbred fish following exposure to 8µg clotrimazole l^{-1} at 28°C (82% and 60% males, respectively) and skews were greater at 33°C (97% and 83% males, respectively). There was also significant male-skew in inbreds (82%), but not outbreds following low-level clotrimazole exposure (1.7mg l^{-1}), in combination with elevated temperature. Population viability analysis showed that probability of extinction (PE) was largely insensitive to these sex ratio skews. Population growth rate (r), however, declined sharply in response to male-skews with a lower decline threshold in inbreds (>80%) compared with outbred fish (>90%), highlighting a risk for inbreds based on our experimental results. Including compounding inbreeding depression on juvenile survivorship further reduced r, with minimum viable population size increasing from 500-10000 adults. In summary all three factors, clotrimazole exposure, temperature elevation and inbreeding, skewed sex ratios significantly towards males and their effects were additive, having the potential to impact fish populations. High fecundity in zebrafish (r-strategist) offers a buffer against environmental skewing of sex ratios, but short generation times, leading to rapid inbreeding and inbreeding depression in survivorship can erode this buffering capacity in small, isolated populations.

392
Extent and time-dependency of synergistic effects in D. magna after pulsed exposure to azole and pyrethroid pesticides
K. Dalhoff, University of Copenhagen / Department of Plant and Environmental Sciences; M. Gottardi, A.C. Kretschmann, University of Copenhagen; N. Cedergreen, University of Copenhagen / Department of Plant and Environmental Sciences
Two of the most commonly used classes of pesticides in agriculture are azole fungicides and pyrethroid insecticides, which constitute a large proportion of the total fungicide and insecticide usage. Several studies including both laboratory and field studies have reported synergistic interactions between azole fungicides and pyrethroid insecticides towards both insects and aquatic invertebrates. Azole fungicides are believed to enhance the toxicity of pyrethroids by inhibiting the cytochrome P450 monooxygenases responsible for xenobiotic detoxification and possibly also by increasing the uptake rate of the pyrethroids. The purpose of this study was to investigate the extent and time-dependency of azole induced synergism on acute toxic effects of alpha-cypermethrin in the freshwater invertebrate *Daphnia magna*. Since cytochrome P450 inhibition by the azoles is known to be fast and reversible, we hypothesise that the persistence of the synergistic potential after exposure to an azole pulse is primarily determined by the elimination kinetics of the azoles. Hypothesis were tested by exposing *D.magna* to a 18 hours pulse of one of the azoles propiconazole or prochloraz followed by a six hours pulse of alpha-cypermethrin. The dependency of the synergistic potential on the time between pulses was analysed by varying the time between the two pesticide pulses and simultaneously monitoring alpha-cypermethrin induced effects on mobility. GC-ECD was used for complementary measurements of internal azole concentrations - linking the time course of internal concentrations to the synergising potentials. For the treatments where the daphnids were exposed to the alpha-cypermethrin pulse immediately after the azole pulse, propiconazole and prochloraz caused a 7 and 13-fold increase in effect, respectively. Observed synergism decreased with increasing time between the pulses. The estimated first-order elimination rate constant of the synergistic potential of propiconazole was 0.31 h^{-1} (95 % CI: 0.08-0.54), indicating that for more than 13h between pulses no difference in immobility between daphnids treated or non-treated with azoles can be observed anymore. The elimination rate constant for the internal concentrations of propiconazole was 0.23 h^{-1} (95 % CI: 0.21-0.26) (Fig 2b). We therefore conclude that toxicokinetics of the azoles seem to be determining for the persistence of the synergistic potential towards alpha-cypermethrin in *D. magna*.

393
Predicting population recovery from chemical exposure: the influence of the environmental scenario
F. Gabsi, RWTH Aachen University / Institute for Environmental Research; T.G. Preuss, Bayer CropScience / Institute for Environmental Research
Recovery of populations is an important attribute in ecological risk assessment of chemicals. Recovery in the field does not depend on the chemical's properties and the exposure profile only, but it is strongly linked to important environmental variables as well. Yet, these are only marginally considered in risk assessment due to the limitation of the experimental methods in grappling with such complexity. Here, we use individual-based modelling to investigate how the environmental scenario affects the recovery of *Daphnia magna* populations from chemical exposure. Simulation experiments were performed for chemicals with lethality levels ranging from 40% to 90 % at different food and temperature conditions. The same toxicity levels were then tested in combination with species interactions including predation or competition. We showed that recovery of populations strongly depended on the environmental scenario. This dependency was reflected in the highly heterogeneous population responses to the same chemical when the environmental context is changed. We conclude that it is necessary to define the ecological scenario when assessing the recovery of populations in ecological risk assessment of chemicals. Validated population models will greatly assist with such an investigation.

Policy assessment in an integrated systems perspective: indicators and targets to ensure operating within safe planetary boundaries (I)

The UNEP/SETAC Life Cycle Initiative: Mainstreaming Life Cycle Approaches for Sustainable Consumption and Production
L. Mila i Canals, UNEP; S. Valdivia, UNEP DTIE Paris / SCP; B.W. Vigon, SETAC
In order to put life cycle thinking into effective practice, UNEP and SETAC launched the Life Cycle Initiative (Initiative) in 2002. The first phase (2002-2007) focused on establishing the Initiative as a global focal point of life cycle (LC) related knowledge and activities, and building a community of practitioners and stakeholders. During phase 2 (2007-2012), the Initiative became more participative with increasing involvement from global stakeholders. Common understanding and agreement were achieved on questions like Life Cycle Assessment (LCA) databases. Results of surveys and consultations in 2011 showed that whilst LC capacities have increased, especially in Asia and Latin America, efforts are still needed to support progress in many countries which have limited LC based experience and knowledge, and weak regulations. Such issues are being addressed in phase 3 (2012-2017). Finally, more and better communication is required to engage with current and potential decision makers towards better informed decisions on more sustainable products (UNEP/SETAC, 2012). Building on the achievements and outputs from phases 1 and 2, the phase 3 vision agreed is a world where LC approaches are mainstreamed. Activities focus on creating the enabling conditions to (a) enhance the global consensus and relevance of existing and emerging LC methodologies and data management; (b) expand capabilities worldwide and make LC approaches operational for organizations; and (c) communicate current LC knowledge to influence and partner with stakeholders. The adoption of the Ten-Year Framework of Programmes (10YFP) on sustainable consumption and production (SCP) and its five initial programmes in 2012 in Rio+20 (UNEP, 2012), provides a good opportunity for the Initiative to support countries strengthening the delivery of LC approaches. The abstract provides a brief overview of past activities of the Initiative and first insights in the plans for phase 3 and introduces the possibilities for interlinkages with the programmes adopted under the 10YFP in support of the development of SCP plans worldwide. UNEP (2012). A 10-year framework of programmes on sustainable consumption and production patterns. A/CONF.216/5 UNEP/SETAC (2012). Greening the economy through life cycle thinking. Paris, 2012

Multidimensional assessment of natural resources in LCA for resource policy support
L. Mancini, European Commission Joint Research Centre / Sustainability Assessment Unit Institute of Environment and Sustainability; S. Sala, Joint Research Centre European Commission / Sustainability Assessment Unit Institute of Environment and Sustainability
Availability of natural resources and access to them are two fundamental conditions for the well-being of human societies. The sustainable use of natural resources and the access to them has become a high policy priority, both from an environmental and sustainability point of view but also from an economic and business oriented perspective. Several impact assessment methods exist for assessing resources in LCA; there isn't consensus in the scientific community on how to assess this aspect across sustainability assessment methodologies. Based on literautre review, a scheme for a multidimensional approach to resource has been depicted in order to support resource policies. The identified research needs for improving the impact assessment of resources regard: enlarging the number and typologies of resources modeled; developing a common framework that allow resource comparison and options for substitution; considering the effect of scarcity in natural environment and the ecological role of resources; assessing the effects of recycling and anthropogenic stocks in the overall evaluation of availability and taking into account socio-economic and strategic issues such as security of supply and criticality. A list of aspects that should be taken into account in a comprehensive impact assessment of resources has been compiled. These aspects can be clustered into five groups: 1. aspects related to resource properties (e.g. thermodynamic loss due to the resource extraction; resource renewability; involvement in biogeochemical cycles; role as natural habitat (e.g. freshwater/forest) and in natural habitats); 2. Aspects related to resource availability (e.g. biophysical availability; resource scarcity, resource criticality, which includes also the geo-political constrains); 3. technological constrains/opportunities (e.g., recyclability and substitutability) and 4. environmental impacts (e.g. damages on habitats, landscape, etc.).

396
Geopolitical Supply Risk Assessment: The case of France
E. Gemechu, Universitat Rovira i Virgili / Institute of Molecular Sciences ISM; G. Sonnemann, University of Bordeaux; C. Helbig, University of Augsburg / Production Supply Chain Management; A. Thorenz, University of Augsburg / Resource Strategy; A. Tuma, University of Augsburg
The supply riks of resources is one of the priorities in the political agenda of the European Commission. The list of critical raw materials (CRM) for the European Union (EU) was identified under the framework of the EU Raw Materials Initiative, with the aim of helping decision makers to take relevant action to avoid potential supply disruption and to secure a sustainable supply of resources. Mineral resource impacts are typically quantified in Life Cycle Assesment (LCA) through assessing depletion. However, the use of mineral resource use beyond its rate of replacement as an impact assessment metric has several problems and it has been widely debated within the LCA community. Resource use evaluation for materials such as metals should go beyond depletion. Life cycle impact assessments (LCIA) need to address the supply riks issue, which does include not only the geological element but also socio-economic and other geopolitical factors that affect accessibility. This requires a new perspective of LCIA that would rather give emphasis to a broader dimension of availability. In this work we mainly aim at looking how the issue of resource criticality assessment could be brought under the general framework of life cycle sustainability assessment (LCSA). A method to assess geopolitical related supply risk is proposed and also applied for the case of selected strategic resources for France. The result suggests that REE, Sb, Nb, and Be are the top four resources which are subjected to high supply risk. The largest portions of the risk in the case of REE for example, are mainly contributed by China. China is by far the leading global supplier of REEs which results in having higher market concentration, one of the determinant supply risk factors in the proposed method. Besides having the largest global market share, China is also one of the most important trading partners of France for REE supply, which accounts for around 90 of the total import shares. In the case of Nb the supply risk value is determined by the large import reliance on South Africa, Germany and the UK . The geopolitical supply risks of In, RE, PGM, Co, U and Se are relatively low. This could be in most cases due to their wide global market distribution: i.e. in the case of Uranium the HHI value is 0.19 compared with the highly concentrated mining for REE which has an HHI value of 0.91.

397
Full integration of LCA with other assessment tools – new application areas and harmonized modelling approaches
J.H. Schmidt, LCA consultants
Commonly, life cycle assessment (LCA), input-output analysis (IOA) and mass flow analysis (MFA) are seen as separate assessment tools each with specific application areas. Recent and ongoing EU 6th and 7th framework projects are creating and integrating several different national accounts enabling for a full integration of the above mentioned assessment tools. The following projects together have led to the creation of the, to date, most detailed and complete set of integrated model for LCA, IO analysis and MFA: Exiopol, FORWAST, CREEA and DESIRE. The integrated model, which is called the exiobase, is a global multi-regional hybrid IO database which is based on fully balanced monetary, mass and energy accounts (supply use tables). The current database includes the following extensions: economic value added, and physical accounting for resources, emissions, land use, and water consumption. Further, work is ongoing for integrating with more detailed LCA databases such as ecoinvent, adding social issues to the extensions, and to separate land use change activities from existing industries enabling for explicit modelling of indirect land use changes (iLUC). The database has several application areas for use as an assessment tool for policy development at different levels of scopes like product, corporate, project, program and policy impact assessment, at different levels of organization from individual company to government/intergovernmental, and at different geographical scales from local to global. Some of the advantages of integrating the different assessment tools and data are that much overlap and inconsistency are avoided. Further, the use of a common classification and terminology also adds to increasing consistency. Having one integrated framework enables for using any new data together with existing data in a complete database rather than having several separate incomplete and inconsistent models, databases and assessment tools. With the database environmental footprints of nations can be calculated using exactly the same models and data as corporate environmental footprints of enterprises (such as environmental profit & loss accounts) as well as product specific LCAs. With an integrated assessment tool the advantages of several separate tools and datasets are merged, and coherence between international and national policy development with lower levels such as projects, programmes, products and enterprise is facilitated.

Integrating LCA, Scenario Modelling and Multi-criteria Decision Analysis for Sustainable Policy-Making in the Energy Sector
K. Volkart, N. Weidmann, C. Bauer, Paul Scherrer Institut / Laboratory for Energy Systems Analysis
In the light of climate change, concerns about security of energy supply and limited non-renewable resources, new policies for the energy sector are urgently required. Policy-making in this field is affected by various environmental (e.g. greenhouse gas emissions), economic (e.g. investment cost) and social (e.g. impacts on human health) aspects, i.e. by all three pillars of sustainability. In order to evaluate different policies in the energy sector (e.g. nuclear phase-out) concerning their impact on a sustainable development, scenarios are developed. To quantify scenarios, economic partial equilibrium (PE) models are used to find the cost-optimal energy technology mixes that satisfy exogenously defined energy service demands under the relevant political boundary conditions.
Complementarily, methods assisting policy-makers to make sound decisions in consideration of multiple sustainability criteria are applied. Multi-criteria decision analysis (MCDA) is a decision-making tool that aims at the comparison of different options taking into account a variety of sustainability criteria on the one hand and subjective stakeholder preferences on the other hand. MCDA integrates all three pillars of sustainability and applies the life-cycle approach in the environmental, economic, and social areas. In the present work, the two approaches, PE models and

MCDA, are combined with the purpose of assisting policy-makers in evaluating the role of Carbon Capture and Storage (CCS) in future Swiss energy policy. This work uses the Swiss MARKAL PE model for the quantification of three exemplary scenarios. The three cost-optimal energy technology mixes are calculated for a scenario without climate goals, one with climate goals but no CCS available, and one with climate goals and CCS available. Based on these three cost-optimal energy technology mixes in 2035, on the 15 calculated economic, social and LCA-based environmental indicators and on the subjective weighting profile of the decision-maker, the sustainability ranking of three scenarios is established using MCDA. Depending on the weighting, the three scenarios are ranked differently, revealing the advantages and disadvantages of the three policies under assessment. The two methods are complementary, combining the system-wide perspective of PE models and the broad suite of criteria considered in MCDA. This work can be taken further towards an integrated method including multi-criteria assessment in the optimisation process.

Evaluating the sustainability of recycling packaging materials combining LCA and Fuzzy Set Theory

F. Dinkel, Carbotech AG; R. Schelker, Redilo

In a study for the Swiss retailer association the possibility to extend the actual recycling to various materials has been examined. The Swiss retailer association wanted to know which recycling and logistics system (e.g. separate or combined collection) would be the best from an overall point of view. For some criteria's and materials quantitative results from LCA and LCC were available for other materials only estimations. For a sustainable system other criteria's are also important like satisfaction and acceptance of consumers or future markets. For these only qualitative knowledge and estimations exist. To combine and evaluate the different type of information Fuzzy Set Theory (FST) was used because this mathematical framework permits to combine the available quantitative results from LCA and LCC with the qualitative or linguistic expert judgements. Floating transitions typically for environment can be handled and the uncertainty of estimations are taken into account. To model and evaluated this complex system in a transparent and comprehensible way a FST model has been developed together with experts from different fields like logistics, recycling technologies, ecology and economy. The result of this study was twofold. First of all it gave a good decision base for the retailers as well as for the municipalities and national administration to there policy of sustainable, future collection and recycling systems. Second it could be shown that this methodological approach is not only useful but very powerful for decision support of complex systems. The important advantages of this method are: • representation of qualitative expert knowledge with linguistic terms • bringing together quantitative and qualitative data and knowledge from different fields like ecology, economy and societal as well as technical aspects • nonlinear relations can be handled • floating transitions which are typical for environment can be handled • Fuzzy logic can deal with more than one 'right' judgement typical for human reasoning • doing all this in a transparent way. So we gained the experience that for complex decisions FST will be one of the efficient ways for decision making according to the statement of Lofti Zadeh: "In almost every case you can built the same product without FST, but fuzzy is faster and cheaper."

Environmental OMICs: high-throughput strategies to decipher mechanism of response to stressors (II)

Proteomic response of L. rubellus, the red earthworm, to metal stress under different soil temperatures

M. Höckner, University of Innsbruck / Biology; M.J. Zuzow, L. Tomanek, California Polytechnic State University / Biological Sciences

Proteomic approaches bear the possibility to study the response to changing environmental conditions on the organismic level. This may lead to a deeper understanding of stress-induced cellular processes compared to classical approaches. In the present study, *L. rubellus*, the red earthworm, was exposed to Cadmium under different soil temperatures with the perspective to unravel putative synergistic effects between environmental pollution and the impact of global warming. The availability of a sequenced genome, a peptide-, EST- and RNA-Seq database for this species renders *L. rubellus* a highly suitable model organism to explore the impact of environmental stressors also on the proteome level. Protein extracts from controls and Cd exposed earthworms (15°C and 20°C) were separated according to their isoelecteric point. Gels were stained with colloidal coomassie blue and digitized for statistical analysis. Significantly changed protein spots were excised from the gels and analyzed on a mass spectrometer obtaining peptide mass fingerprints (PMF) which were combined with tandem mass spectra to search the *L. rubellus* peptide and EST databases to identify the protein spots using Mascot software. Statistical analysis revealed 69 significantly changed protein spots in the treatment groups out of 549 detected spots on the fusion image. 45 protein spots revealed significant ID hits, whereas for 25% of protein spots no significant hits were obtained from the database search. However, all significant hits reveal 3 groups of proteins with similar expression patterns in the heat map. Significant protein hits were assigned to functional categories such as Cytoskeletal, Energy metabolism, Calcium Signaling, Vesicle-, Ion- and Oxygen Transport, Redox System, Lysosomal and Thrombolytic proteins. Cd exposure at 20°C clearly showed a different expression pattern compared to the control group and is, moreover, also differing from the Cd-exposure at 15°C. In fact, 64% of significant changes differ within the two temperature groups, whereas only 36% show a similar behavior in the treatments compared to the controls. The proteomic response to Cadmium stress seems to draw a distinction under different habitat temperatures. Weather this effect has a severe negative impact on the earthworm, or might rather reflect the induction of detoxification mechanisms, is still to be elucidated.

401

Stressor-induced proteome alterations in zebrafish: widespread artefacts or a universal stress response?

K.J. Groh, Eawag / UTOX Environmental Toxicology; M.J. Suter, Eawag Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology

Proteomics are being increasingly applied in ecotoxicology on the premise that the identification of changes in the expression of specific proteins and/or protein groups occurring in response to a certain chemical would allow elucidation of the underlying molecular pathways leading to an adverse effect. This in turn could promote the development of focused testing strategies for specific groups of toxicants. Unfortunately, the global proteome characterization techniques applied most often, both gel-based and gel-free, do not allow a complete coverage of all proteins expressed at a given moment, measuring instead only a fraction of those being most abundant in the sample. Nonetheless, such analyses do detect expression changes for some proteins, based on which certain conclusions are drawn regarding the cellular processes affected. The somewhat disturbing feature of such studies is the fact that a few protein groups seem to respond regardless of the nature of stressor applied. To investigate the issue more closely, we analyzed the studies that looked into the changes induced by various physical, chemical and biological stressors in the proteome of zebrafish, a model organism popular in ecotoxicology. Our meta-analysis highlights several protein groups, including heat shock proteins, enzymes involved in energy metabolism and cytoskeletal proteins, to be most frequently identified as responding to a stressor in zebrafish, regardless of tissue or stressor analyzed. With this we demonstrate that the "hit parade" situation previously described for mammalian studies seems to be a common phenomenon readily spreading to other species and research fields. The question that arises next is whether these proteins are truly responding and thus may potentially represent a "footprint" of a general stress response, or if this situation is a consequence of current technical limitations to global proteomics analysis. We present data evidence, ideas and hypotheses in support of both options and would like to promote an open dialog on the topic. We suggest that the results of any differential proteomics experiment performed with zebrafish (or any other species) should be interpreted keeping in mind the list of the most frequent responders identified. Careful consideration of the reliability and significance of observed changes is necessary in order to prevent the proliferation of false positive linkages between the stressor and the cellular functions it perturbs.

402

Deciphering the major egg yolk proteins from the amphipod Gammarus fossarum by proteogenomics: key lessons regarding prediction of the functions of ecotoxicology-relevant proteins.

J. Trapp, Irstea / Laboratoire décotoxicologie; J. Armengaud, CEA / Laboratoire de Biochimie des Systemes Perturbés; G. Imbert, CEA / Laboratoire de détection et de caractérisation des agents du risque environnemental; J. Gaillard, CEA / Laboratoire de Biochimie des Systemes Perturbés; a. chaumot, O. Geffard, Irstea / UR MALY Laboratoire Ecotoxicologie

Recently, we proposed an approach for quickly identifying proteins of the freshwater crustacean *Gammarus fossarum*, an ecologically and ecotoxicology relevant by the alliance of genomic and proteomic (*i.e.* proteogenomic). We have generated a large transcriptome dataset using Illumina-Solexa pyrosequencing and in parallel acquired massive shotgun proteomics data. By now, we were able to identify a total of 1,873 proteins that have been certified by tandem mass spectrometry. These proteins were functionally annotated on the basis of sequence similarities. But for a new model organism with important phylogenetic distance compared to available sequenced models, automatic pipelines as shortcut for functional annotation can leads to inaccurate predictions due to quite different evolutionary scenari. Here, we aimed to provide accurate functional annotation to proteins members of the large lipid transfer protein (LLTP) family, characterized by an intense functional diversification. We specifically identify vitellogenin (VTG), proteins involved in the formation of egg-yolk in our model species. Using label-free proteomic quantitation, analysis on embryos and ovaries sampled at different stages of their development resulted to the identification of 378 and 573 proteins respectively. Next, we focused our attention on the proteome dynamics for identification of putative VTG candidates proteins with accumulation profiles over the oogenesis cycle were chosen. On the over way around, as egg yolk protein are consumed during embryogenesis, providing resources for organogenesis, proteins with pattern of consummation profiles over the embryos development were chosen. Finally, the cross comparison between the proteins isolated from the relevant temporal variations and the ones previously classified as female specific, led to a list of 8 major egg yolk proteins for *G. fossarum*, all part of the LLTP family. For the two most abundant ones, functional predictions annoted then as clottable proteins, *via* decapods homology queries. Our study pointed out the necessity that for any new model organism, data from omics studies must be confirmed in terms of organism-specific function before being considered in terms of ecotoxicological perspectives. For the sentinel species *G. fossarum*, our multi-omics results identified the gene products specifically involved into its reproductive function. This should result in interesting biomarker of endocrine disruptor exposure.

403

Physiological and omic analysis reveal cryptic effects of low environmentally-relevant levels of chemical stressors on terrestrial plant species

A. Serra, UMR / UMR CNRS ECOBIO; I. Couee, D. Renault, C. Sulmon, Université de Rennes / UMR CNRS ECOBIO; G. Gouesbet, UMR CNRS ECOBIO

Terrestrial plant communities can be confronted with xenobiotic combinations of bioactive molecules, degradation products, and adjuvants that constitute chemical challenges potentially affecting plant growth and fitness. Such complex challenges involving residual contamination and mixtures of pollutants are difficult to assess. The model plant *Arabidopsis thaliana* was subjected to chemical stress involving the herbicide glyphosate, the fungicide tebuconazole, the glyphosate degradation product aminomethylphosphonic acid (AMPA), and the atrazine degradation product hydroxyatrazine, which had been detected and quantified in soils of field margins in an agriculturally intensive region. Field margin contamination levels were shown to have significant effects on plant growth and metabolism despite low levels of individual components and the presence of less toxic pesticide-derived metabolites. Metabolomic and molecular analysis of these physiological effects demonstrated that pesticide degradation products AMPA and hydroxyatrazine elicited significant plant responses, thus indicating underlying mechanisms of perception and transduction. Such mechanisms were also in line with observed interactions, whether positive or negative, between the effects of AMPA and hydroxyatrazine and the effects of bioactive xenobiotics (glyphosate and tebuconazole). Furthermore, the metabolic and molecular perturbations induced by low levels of xenobiotics and associated degradation products were shown to affect processes (carbon metabolism, amino acid metabolism, hormone balance, stress-response mechanisms) that are likely to determine environmental stress sensitivity. These effects of low levels of edaphic contaminants were also investigated in *Lolium perenne*, a plant species that is commonly found in field margins and used in vegetated filter strips at the edge of agricultural fields. Combination of physiological and omic analysis revealed that residual environmentally-relevant levels of chemical stressors induced significant modifications of carbon-, nitrogen- and stress-related pathways at the transcriptomic and metabolomic levels. Detailed knowledge of these fine and subtle perturbations and regulations in terrestrial plant species, under conditions of single or multiple pollution, is necessary for the complete understanding and predictive modelling of environmental risks associated with residual contamination.

404

Health impact assessment of emerging contaminants tested at low environmentally relevant doses individually and in mixture using genomic and metabolomics approach

H.R. Habibi, University of Calgary / Biological Sciences; A. Zare, Department of Biological Sciences; J. Jordan, University of Calgary / Biological Sciences; A. Weljie, University of Pennsylvania / Department of Pharmacology

There is increasing evidence that contaminants of emerging concern (CEC) pose health risk to animals and humans. However, insufficient information is available about the mechanisms by which these compounds cause adverse physiological and pathological effects. Previous studies demonstrated the presence of a number of pollutants in the Oldman River, Canada. This study was carried out to investigate the effects of a number of more abundant contaminants at low environmentally relevant concentrations, individually and in mixture, using genomic and metabolomics approach. To test the hypothesis that CECs cause disruption of health in fish, we performed controlled laboratory experiments in which goldfish and fathead minnows were exposed to the same concentrations of chemicals detected in the river system, individually and as mixtures. Multiple end points, including expression of various genes involved in gonadal development and differentiation were measured. Using ^{1}H-NMR metabolomics as a tool, we also measured the concentrations of multiple metabolites in the liver, gonad and brain tissue, and evaluated net metabolic dysregulation due to exposure. The results suggest significant dysregulation of amino acid, lipid, energy, carbohydrate, nucleotide and cofactor/vitamin metabolism. In the liver and testis, the effects of contaminant mixture were found to be significantly different from those of individual compounds tested. We also exposed fathead minnows to the same contaminants, individually and in mixture, and performed microarray analysis. The "Omics" data collectively provide information on cellular response to contaminants and identified novel biological endpoints. The findings will facilitate development of better tools to evaluate risk through mechanism-based cell and tissue response, and assess susceptibility of fish exposed to environmental contaminants. In particular, metabolomics and genomics study of low dose response to individual and mixture of chemicals allowed us to make a more accurate assessment of adverse health impact in fish. Together with our previous field data, the present results provide a framework for better understanding of ecological consequences of exposure to CECs in fish and other vertebrates. *Acknowledgement* - The authors thank NSERC of Canada to provide funding.

High-throughput nanospray metabolomics to identify mixtures of chemical stressors and their effects in fish exposed to wastewater effluents

A. David, University of Sussex / School of Life Sciences; A. Abdul-Sada, University of Sussex; A. Lange, C.R. Tyler, Biosciences College of Life and Environmental Sciences; E. Hill,

Many biologically active contaminants are present in final effluents of wastewater treatment work (WwTWs) and can bioaccumulate as complex mixtures in fish. The use of LC-MS-based nontargeted chemical profiling and metabolomics analyses is a very promising tool to assess both chemical exposure and its associated metabolite effects in the same sample. Current metabolite profiling methods do not detect trace levels of endocrine signalling compounds present in extracts of tissues or plasma due to interference from highly abundant components. We developed novel nanoflow ultraperfomance liquid chromatography-nanoelectrospray ionization-time-of-flight mass spectrometry, and improved solid phase sample extraction techniques in order to profile low abundant components in the metabolome. The aim of this study was to investigate the chemical mixtures accumulating in fish, and the associated changes in the tissue metabolomes to determine the potential deleterious physiological effects arising from effluent exposure. Sexually mature roach were exposed for 15 days to either a treated effluent from a WwTWs or to clean water. Extracts of plasma and tissues (gonads, kidney, liver and gill) from effluent-exposed and control fish were compared using nontargeted chemical and metabolite profiling methods. Identified contaminants accumulating in tissues of effluent-exposed fish included endocrine disruptors and mixtures of many pharmaceuticals such as nonsteroidal anti-inflammatory drugs, selective serotonin re-uptake inhibitors, benzodiazepines, antipsychotics, anticonvulsants, beta blockers, fibrates, and anticoagulants. Metabolite profiling revealed disturbances in eicosanoid, steroid, serotonin, bile acid, carnitine and sphingosine pathways. Effluent exposure resulted in widespread reduction of prostaglandins in many tissues and these mediators are important in ion transport, immune function and reproduction. In addition, reduction in androgen and increases in serotonin metabolites were observed, indicating potential effects on reproductive and neurological endpoints. Metabolite disruption was apparent although the plasma concentrations of the likely causative contaminants were 3-1000 fold below human therapeutic levels indicating possible mixture effects. The use of this nontargeted ‘Omics’ approach could be extremely informative for ecotoxicological investigations on the health effects and associated contaminant mixtures in fish exposed to wastewater effluents.

Soil Biodiversity and Ecotoxicology (II)

What do we need to improve ecological relevance in soil risk assessment? State of the art and perspective for Collembola

J. Filser, University of Bremen; V. Roeben, RWTH Aachen University Institute for Environmental Research / Institute for Environmental Research BioV; G. Ernst, Bayer CropScience / Ecotoxicology; U. Hommen, Fraunhofer IME; M.S. McKee, University of Bremen / Ecology; M. Ross Nickoll, A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; F. Scherr, Bayer CropScience AG / Environmental Modelling; B. Scholz Starke, RWTH Aachen University Institute for Environmental Research; T.G. Preuss, Bayer CropScience / Institute for Environmental Research

The current tier 1 risk assessment of plant protection products (PPP) for soil organisms according to the EU Regulation (EC) 1107/2009 involves a test on earthworm reproduction and one on nitrifying microorganisms. An additional Collembola reproduction test is required under specific conditions. Higher tier studies should take into account a more realistic substrate and/or exposure regime, or communities, e.g. in (semi-) field studies. We introduce potential intermediate and higher tiers involving Collembola, in particular a modelling approach which takes into account the vertical distribution of PPP and Collembola. We discuss potentials and limitations of different approaches which had been presented and discussed on a workshop at RWTH Aachen University on October 22-23, 2013. Emphasis is given on the identification of data requirements and gaps that would be necessary to better meet existing protection goals for soils.

407

Prediction of effects of sea level rise on soil ecosystems
C.S. Pereira, Life Sciences; I. Lopes, University of Aveiro / CESAM Biology Department; J.P. Sousa, University of Coimbra; S. Chelinho, IMAR CMA / IMARCMA Dept of Life Sciences
The increase of global mean temperature is raising serious concerns all over the world due to its potential negative effects on the planet such as droughts and melting of glaciers and ice caps. These events are originating the rising of the seawater level and, thus, facilitating its intrusion into the terrestrial systems. The estimations for 2100 predict that such rise will be between 47 and 190 cm. Expected impacts on soil compartment include floodings, water intrusions and subsequent use of saltwater for irrigation, with unknown effects on soil ecosystems and their inhabitants. Integrated in a broader research project, the present study aimed at evaluating the effects of salinisation on soil ecosystems due to sea level rise. The reproduction and mortality of three standard soil invertebrates (the springtail *Folsomia candida*, the enchytraeid *Enchytraeus crypticus* and the predatory mite *Hypoaspis aculeifer*) in standard artificial OECD soil irrigated with serial dilutions of seawater or concentrations of salt (NaCl), was evaluated according to standardised guidelines. Results showed no effects of all the seawater dilutions used in adult mortality. However, for reproduction, an increased sensitivity was observed in the following order: *H. aculeifer*

408
Deriving a terrestrial PNEC for silver: use of research findings in risk assessment
G. Merrington, Environment Agency; P. Simpson, WCA Environment Ltd; M. McLaughlin, CSIROUniversity of Adelaide; K. Langdon, NSW Office of Environment and Heritage; K.P. Rothenbacher, EPMF
The presence of silver (Ag) in the terrestrial environment and the potential risks that may be associated with this metal are currently receiving increased interest. A research programme was undertaken by the Commonwealth Scientific and Industrial Research Organisation (CSIRO) into the toxicity and bioavailability of silver in soils funded by the European Precious Metals Federation. The programme was undertaken to assess the influence of leaching, aging and soil properties on the behaviour, bioavailability and ecotoxicity of silver, primarily to allow this knowledge to be incorporated in regulatory risk assessment e.g. under the EU REACH regulation. This presentation will describe the interpretation of the findings of the CSIRO programme in order to deliver a terrestrial risk assessment for the uses of silver under REACH. The fundamentals of this process have been performed for other metals, such as copper and nickel. However, this is the first time that site-specific bioavailability-based assessment has been undertaken for silver.

409
Characterization of ecotoxicity and phytotoxicity of a cyanobacterial extract containing microcystins under realistic environmental concentrations and in a soil-plant system
S. Corbel, Pessac; C. Mougin, INRA PESSAC; F. Martin-Laurent, INRA; N. Bouaicha, UNIVERSITE PARIS
The occurrence of harmful cyanobacterial blooms in surface waters is often accompanied by a production of variety of cyanotoxins that represent a hazard for human and animal health. Microcystins (MCs) are the most common cyanotoxins and may be expected wherever blooms of cyanobacteria occur in surface water with more than 80 variants have been characterized. Microcystin-LR (MC-LR) is generally recognized as being the most studied variant due to its high toxicity and frequent, and concentrations in surface waters often exceed the World Health Organization (WHO) advisory level of 1 μg L^{-1}. More recently, phytotoxic effects of MCs after irrigation were evidenced. But, to our knowledge, there is no study reporting experiments performed in realistic exposition: environmental concentrations and using soil-plant system approach. Here, we used these conditions to characterize both the ecotoxicity on soil microorganisms and the phytotoxicity on the tomato plant *Solanum lycopersicun* var. MicroTom of a toxic crude extract of *Microcystis aeruginosa* (PCC 7820) at environmental concentrations usually reported in the surface waters (0, 20, 50, and 100 μg equivalent MC-LR L^{-1}). Soil enzymatic activities (arylsulfatase, β-D-glucosidase, phosphatase and urease), nitrification potential and growth of seedling were studied. The effect of MCs on bacterial nitrification communities was evaluated by RT-PCR using primers for genes linked to Ammonia-Oxidizing Achaea (AOA) and Ammonia-Oxidizing Bacteria (AOB). In the presence of MCs at the high concentration (100 μg equiv. MC-LR L^{-1}), the germination of seeds was not inhibited and the global soil microbial activities are not altered. However, the activity and abundance of nitrifying bacteria are significantly affected at the lower concentration (5 μg equiv. MC-LR L^{-1}). In addition, the growth of tomato seedlings increased significantly at this concentration.

410
Earthworm reproduction studies: Is the growth of body weight during the range finding test a good indicator for successful reproduction?
T.W. Schmidt, Harlan Laboratories Ltd / Ecotoxicology Registration; G. Eisner, Harlan Laboratories Ltd; S. Hoeger, Innovative Environmental Services IES Ltd / Environmental Toxicology
Earthworms are the standard test organisms for testing possible side-effects on soil organisms caused by plant protection products (EC REGULATION No 1107/2009) or chemicals (ECHA Guidance on Information Requirements and Chemical Safety Assessment, Chapter R.7c: Endpoint specific guidance (2012)). For the environmental risk assessment, the endpoints LC_{50} (acute toxicity: test concentration which results in 50% mortality) and NOEC (sublethal toxicity: No-Observed-Effect-Concentration) are required. Normally, these endpoints are delivered by the OECD TG 207 for the acute toxicity during 14 days of exposure and OECD TG 222 for sublethal toxicity, i.e. reproduction rates of earthworms exposed for 28 days. Generally, the relevance of these endpoints is based on the careful selection of test concentrations which is especially critical for the NOEC. Therefore, the EC_x-approach is recommended for the substitution of NOEC by EC_{10}/EC_{20}. For the selection of the test concentrations in the definitive test with 5-6 concentrations, usually a range-finding test is performed. In the case of acute toxicity (OECD TG 207), the design of the range-finding test is similar to the definitive test with the endpoint mortality, but with a reduced number of concentrations and replicates. In the case of the sublethal test (OECD TG 222), the respective range-finding is an acute test with an exposure of 14 days and the determinination of body weight loss as sublethal endpoint. From our point of view, the critical question should be asked which relation can be expected between body weight loss and reproduction in earthworms. Earthworm body weight and reproduction might be positively or negatively correlated due to allocation of energy investments dependent on the actual biotic and abiotic conditions for an individual worm. Therefore, we present a meta-analysis of earthworm acute toxicity and earthworm reproduction studies in order to answer the question to what extend the body weight growth is a good indicator for successful reproduction and propose amendments for the next revision of the OECD TG 222.

411
Guideline values of lead in soils: a new soil-ecotoxicity approach
A. Romero, UGR / edafologia y quimica agricola; F. MARTIN PEINADO, University of Granada / Soil Science Department Faculty of Sciences; M. SIERRA ARAGON, University of Granada / Soil Science Department; F. MARTINEZ GARZON, University of Granada / Department of Soil Science
Soil contamination with lead is known worldwide and can cause adverse effects on human health and the environment. Mobility and availability of Pb in terrestrial environment is strongly controlled by the soil properties. An usual key tool for the analysis of bioavailability and toxicity of metal(loid)s is the use of bioassays, which contribute to assess the ecological risk and help as reference to declare contaminated soils. The aim of this work is to study the influence of different soil properties and constituents on the solubility of lead in laboratory-contaminated soils, to propose guideline values of this element based on toxicity bioassays. We used seven soils with contrasting properties (H1-H7), with different polluted levels of Pb selected from Andalusia proposed values (0-500-1000-2000-4000-8000 mg kg^{-1}) and performed three bioassays: Root Elongation Toxicity Test (*L. sativa*), Microtox® Test (*V. fischeri*) and Soil Respiration Test. According to our results, there was a significant correlation between bioassays; while the main variables influencing toxicity in all soil types were pHW, PbW and PbT. In the non carbonated soils, the toxicity was also significantly related to OC, P and CEC. Furthermore, concentrations of soluble lead show significant differences between samples in all polluted levels, being carbonate-rich soils (H1, H2 and H3) the samples with lower Pb solubility. Thresholds obtained (NOEC, EC10 and EC50) indicate that soils with the lowest phytotoxic effect were those rich in carbonate content (H2 and H3); with reductions below 50% for the maximum contamination level (8000 mg kg^{-1}). Followed by the soils rich in organic carbon (H1 and H5), being the no carbonated and low organic content soils (H4, H6, H7), the ones with highest toxicity response. Out of the three bioassays carried out was *L. sativa* test which presented the highest sensitivity to toxicity. Andalusian Government proposes guidelines values based exclusively on the pH, however, our results show that these values could be overestimated when referring to carbonated and organic-rich soils and underestimated in other soil types. Lead toxicity is strongly influenced by soil properties; therefore soil guideline values of Pb should be set at different levels depending on soil properties, to avoid over- and under-estimations and to optimise the efficiency and profitability in the application of generic environmental quality standards.

Community and ecosystem ecotoxicology (II)

Effects of abiotic factors on structure and abundances of freshwater macrofauna in ditches along bulb fields
O. Ieromina, Institute of Environmental Sciences Leiden University / Conservation Biology; W.J. Peijnenburg, RIVM / Center for Safety of Substances and Products; K.J. Musters, Leiden University / Institute of Environmental Sciences; G.R. de Snoo, Leiden University; M.G. Vijver, CML Leiden University

A large area in the Netherlands is used for flower cultivation. Maintaining balance between high yields and low risk to the environment is a main purpose of the environmental policy in the Netherlands. The amount of pesticides used in bulb crops has decreased in the last 20 years, however despite this fact the amount of chemicals applied in bulb fields remains relatively high. Ditches therefore are continuously affected by chemical contamination that results in adverse effects on non-target aquatic biota. Current research aimed to assess the effects of pesticides in combination with abiotic factors on the structure and abundances of aquatic macrofauna communities in ditches next to bulb fields. Field work was based in flower growing region of the Netherlands. The area is intensively used for flower bulb growing, mainly hyacinths, lilies, daffodils and tulips. There are several patches of pastures and grasslands. Macrofauna samples in the field ditches and water chemistry data were collected in the period April-November (2011-2012). Field data was assessed by means of multivariate analysis. Abundances of sensitive insect taxa Odonata and Diptera were larger at the nature reserve sites. Whereas high numbers of the insect Hemiptera, mollusks Basommatophora, Heterostropha and the annelid Haplotaxida were associated with the agricultural area. Abiotic factors, along with pesticides, contributed significantly to variations in the macrofauna community structure. In the natural aquatic environment organisms are affected by multiple stressors. Abiotic factors should be considered when evaluating the effects of pesticides on aquatic biota. \n

A glimpse in the black box – Ecotoxicological impacts on the Yangtze Three Gorges Reservoir, China
T. Floehr, Institute for Environmental Research RWTH Aachen; B. Scholz-Starke, RWTH Aachen University Institute for Environmental Research / Institute for Environmental Research BioV; H. Xiao, Rwthaachen University / Department of Ecosystem Analysis; J.T. Koch, RWTH Aachen / Institute for Environmental Research; L. Wu, Key Laboratory of Yangtze River Water Environment; J. Hou, East China Sea Fisheries Research Institute; A. Wolf, IWW Water Centre / Water Resources Management; X. Yuan, Chongqing University / College of Resources and Environmental Sciences; M. Roß-Nickoll, RWTH Aachen University / Institute for Environmental Research; A. Schäffer, RWTH Aachen University / Inst. for Environmental Research (Biology V); H. Hollert, RWTH Aachen University / Institute for Environmental Research
The creation of the Three Gorges Reservoir caused the flooding of former urban, industrial and agricultural areas. Consequently, substantial amounts of organic and inorganic pollutants were released into the reservoir. Beyond contaminants and nutrients enter the reservoir by runoff from adjacent agricultural areas as well as from sewage of industry, aquacultures and households. In addition the dam reduced the flow velocity of the river for about one magnitude, changing this section from river-like to lake-like. This has a serious influence on the dilution of the pollutants that enter the water body, and also an impact on the sedimention rate of supended particles. Sediment functions as a sink for a large variety of organic contaminants from which they can again be remobilized. Periodical changes in water level cause flooding events and thereby a relocation of contaminated water, particulate matter and sediment onto agriculturally used areas along the reservoirs shore. Although a large number of studies have been performed along the Yangtze River, the TGR section remains a black box, little iluminated only by a couple of studies mainly focusing on the chemical analysis of pollutants in the compartments water and sediment. Thus, it is reasonable to ask (a) what is the current pollution status of this newly created ecosystem, which is a source of food and water for millions of people, (b) is the local fauna, e.g, fish species affected and (c) which would be the responsible priority pollutants. In order to assess (i) possible links between molecular/biochemical responses and ecologically relevant effects, and (ii) if ecotoxicological effects might be related to adverse effects in fish from the field, sediment samples and fish were collected at different locations in the Three Gorges Reservoir as well as its catchment area and analyzed using a weight-of-evidence (WOE) approach with several lines of evidence. So far sediment and fish samples have been taken at major cities as well as feeder rivers and their estuaries along the Yangtze Three Gorges Reservoir in order to characterize the state of contamination and the potential risk for human and wildlife. The monitoring strategy should help to observe the water body's quality and to serve as a basis to initiate if necessary counteractive measures. **Keywords:** Yangtze, sediment, fish, monitoring

Hexabromocyclododecane affects plankton communities and benthic-pelagic coupling in an experimental ecosystem
C. Bradshaw, Stockholm University / Department of Ecology Environment and Plant Sciences; J. Naslund, Stockholm University; J. Hansen, Stockholm University / Baltic Sea Centre; B. Suzuki, Universidade Federal do Estado do Rio de Janeiro / Departamento de Ecologia e Recursos Marinhos; B. Sundstrom, Vanadisvägen; K. Gustafsson, Stockholm University
Hexabromocyclododecane (HBCDD) is an additive brominated flame retardant used mainly in expanded and extruded polystyrene foam for insulation and construction, textiles and electronic appliances. HBCDD was recently added to Annex A of the Stockholm Convention on Persistent Organic Pollutants due to its persistent, bioaccumulative and toxic properties. As for most chemical substances, evidence for HBCDD's ecotoxicity comes mainly from standardised single species tests. However, little is known about its effects on coastal species, and even less on ecosystem effects. We investigated the effects of a range of HBCDD concentrations on experimental ecosystems over an 8 month period. The ecosystems were assembled in 1000 L mesocosms from naturally-occurring components of shallow coastal Baltic Sea areas. HBCDD was added spiked into a phytoplankton suspension at the start of the experiment and a range of structural and functional endpoints were measured. Of relevance to this presentation are: phytoplankton and zooplankton community structure; nutrient concentrations in the overlying water; biomass of *Macoma balthica*, an infaunal filter- and deposit feeder; HBCDD concentration in water, sediment and *M. balthica*. Changes in plankton community structure were analysed using correspondence analysis. Generalized Additive Mixed Models (GAMMs) were used to analyse the time-dependent relationships between chlorophyll *a*, nutrients and HBCDD dose. Structural equation modelling (SEM) was used to test the hypothesis that HBCDD can affect ecosystem structure and function, and two SEMs were constructed; pelagic system interactions and benthic-pelagic coupling. Increasing HBCDD dose had a negative relationship on the biomass of large *Macoma balthica,* apparently due to higher mortality of large *M. balthica* at high HBCDD exposure. This in turn appears to have led to lower bioturbation rates and related recirculation of nitrogen to the water column (i.e. a decreased benthic-pelagic coupling) at these higher doses. Changes in pelagic communities were then observed, first in the phytoplankton and a few weeks later in the zooplankton communities. These results demonstrate the complexity of the ecosystem response to HBCDD, incorporating many indirect effects in the system over time. Such responses can only be quantified and understood by using realistic experimental set-ups, and by including knowledge of system-specific ecological interactions when assessing ecotoxicity.

415
Pesticide mixture toxicity and effects on benthic invertebrates and algae in agricultural streams – field and laboratory studies
W. Goedkoop, Swedish University of Agri Sciences / Department of Aquatic Sciences and Assessment; J. Rydh Stenstrom, Swedish University of Agricultural Sciences / Aquatic Sciences and Assessment; J. Gardetrom, Swedish University of Agricultural Sciences; J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides
Within the framework of a national monitoring program, we collected water samples from 4 streams in small agricultural catchments to study pesticide mixture toxicity. Mixture toxicity was assessed by calculating ∑Toxic units and the Swedish pesticide toxicity Index (PTI) for algae, Daphnia and fish. In the lab growth inhibition tests were run with green algae and Daphnia to test for effects at 0.1, 1, 10, and 100 times the observed ∑TU in the field. Tests were run with reconstituted water samples containing observed peak pesticide concentrations (∑TU).In the field, samples of benthic invertebrates and diatoms were collected in the 4 streams on a monthly basis (spring to fall) to study community effects. More than 10 pesticides were detected in ≥63% of the 902 samples collected during 2002–2010, with 90-percentiles ranging 21–29 pesticides. The average number of pesticides in a single water sample ranged from 8.8±3.7 to 17.8±7.4, while the maximum was 41 pesticides. Our data show marked peaks in estimated toxicity (PTI and ∑TU), mainly occurring between May and July. Despite the high number of pesticides detected, mixture toxicity (∑TU) was frequently dominated by only one or a few compounds. Algal growth was inhibited at concentrations corresponding to between 1 and10-times the ∑TU observed in the streams. Also for daphnids effects were found at 10–100- times the observed ∑TU in the streams. These results show that negative effects occur at concentrations. PLS showed that the diversity of benthic diatoms was negatively correlated to our estimates of toxicity (i.e. $\sum TU_{algae}$ and PTI), suggesting lower diversity at higher levels of toxicity. Effects on the macroinvertebrate community were mainly explained by in-stream physical and chemical conditions. Our results show that mixture toxicity is a common feature in agricultural streams. Our results also suggest that diatom diversity is negatively related to pesticide toxicity and that the well established metrics developed for eutrophication and/or organic loading do not detect these effects.

416
Pollution Induced Community Sensitization (PICS): exploring the relevance of the conceptual coun-terpart of Pollution Induced Community Tolerance (PICT)
T. Backhaus, S. Faraz, A. Arrhenius, University of Gothenburg / Department of Biological and Environmental Sciences; M.M. Eriksson, Chalmers Technical University / Department of Shipping and Marie Technology
Ecotoxicological experiments and assessments usually build on the assumption of a continuous exposure to one single toxicant. Validated concepts for assessing the ecological consequences of pulsed exposures, e.g. from spray or run-off events are still largely missing. Central for generating a hypothesis on the expected overall joint ecological effects after sequential exposure to toxicants is the phenomenon of Pollution-Induced Community Tolerance (PICT). PICT postulates that pollution

events from compounds with a similar ecological mode of action lead to an increased community tolerance. Here we present its conceptual counterpart, Pollution-Induced Community Sensitization (PICS). PICS builds on the assumption that an organism's susceptibility towards dissimilarly acting chemicals is negatively correlated: an organism that is highly susceptible towards a particular substance is assumed to be less sensitive to a compound with a completely different ecological mode of action, and vice versa. Experimental results from a study of sequential pulses of antibiotics thought to be targeting predominantly gram-negative (Colistin), respectively gram-positive bacteria (Novobiocin) in microbial biofilms indeed indicate an elevated toxicity after pulsed exposure, in comparison to a continuous exposure. These results will be presented and discussed, also making use of modeling studies that employ species-sensitivity distributions.

417

Competition determines toxicant -effect, -recovery and -culmination of successive toxicant pulses

M. Liess, UFZ Center for Environmental Research / Department of SystemEcotoxicology; K. Foit, Helmholtz Centre for Environmental Research; S. Knillmann, HelmholtzCentre for Environmental Research UFZ; A. Becker, UFZ Center for Environmental Research; E. Hassold, Federal Environment Agency UBA; I. Dolciotti, UFZ Leipzig / System Ecotoxicology; M. Kattwinkel, Eawag Swiss Federal Institute of Aquatic Science and Technology / System Analysis Integrated Assessment and Modelling; S. Duquesne, UBA Federal Environment agency

Pesticides applied in agriculture can affect the structure and function of non-target populations at lower doses and for longer timespans than predicted by the current risk assessment frameworks. Obviously the sensitivity of communities in real-world ecosystems are strongly determined by the environmental context. In detail we identified that the (i) strength of the toxicological effect is governed by the magnitude of intraspecific competition; the (ii) duration of recovery is governed by the magnitude of interspecific competition; when (iii) successive exposure is present an enhancement of trans-population effects culminate in a strong final effect. The underlying processes are experimentally identified and reconstructed using a simulation model. We conclude that repeated toxicant pulse of populations that are challenged with interspecific competition may result in a multigenerational culmination of low-dose effects.

Environmental biodegradation rates and pathways: Dependence on environmental conditions

How a new builder in automatic dishwashing detergent became ready biodegradable in the U.S.: Widespread microbial adaptation

K. McDonough, PG / Environmental Stewardship; N.R. Itrich, The Procter Gamble Company / Environmental Stewardship Organization; K. van Ginkel, AkzoNobel Technology and Engineering; E. Schaefer, Wildlife International, Ltd.; K. Casteel, Procter and Gamble Company; J.Z. Menzies, The Procter Gamble Co; M. Mathews, Wildlife International; E. Bisinger, Akzo Nobel; J. Lepage, AkzoNobel Functional Chemicals; T. Federle, Procter and Gamble Company

L-GLDA (Glutamatediacetate) is a builder that was introduced as a phosphate replacement in a United States (U.S.) automatic dishwashing detergent (ADW) in early 2010. Prior to ADW use, L-GLDA failed multiple biodegradation screening tests (OECD 301B) in the U.S. and was not considered ready biodegradable in this geography. However, results from a more realistic continuous activated sludge treatment test (OECD 303A) predicted that a microbial population pre-exposed to L-GLDA would extensively degrade it after a lag period. Other evidence indicating L-GLDA's potential to biodegrade included positive ready biodegradability test results obtained in The Netherlands and the isolation of a bacterium that could utilize L-GLDA as a sole nitrogen, carbon and energy source [1]. The market introduction of this new ADW in the U.S. and the subsequent widespread distribution of L-GLDA in wastewater offered a unique opportunity to monitor for potential microbial adaptation in the field. After launch of the ADW, a series of OECD 301B tests were conducted using inoculum collected from multiple WWTPs in two U.S. regions. Within several months, WWTP inoculums that had previously produced negative results, measuring 9-21% CO_2 production, demonstrated that L-GLDA was "ready biodegradable" (65-100% CO_2). Inoculum from additional WWTPs also showed positive ready test results and a decrease in the measured lag period (< 10% CO_2) was observed as distribution of the ADW grew, indicating an increase in the field population of competent degraders. To our knowledge, this is the first systematic study showing how a new chemical, that consistently failed ready biodegradation tests prior to market penetration became ready biodegradable across a wide geographical region following its introduction in a commercial product. The ready test is required under most regulatory schemes for the registration of a new chemical and to demonstrate a lack of persistence. However the use of pre-exposed inoculum is strictly prohibited in some regions. This work demonstrates that when pre-exposure occurs under realistic conditions, laboratory tests can accurately predict ultimate real world behavior indicating the importance of considering potential adaptation in regulatory assessments.

Using biodegradation for the removal of sulfonamides

B. Ricken, University of Applied Sciences Northwestern Switzerland / Institute for Ecopreneurship; M. Lenz, University of Applied Sciences and Arts Northwestern Switzerland FHNW; D. Cichocka, University of Applied Sciences and Arts Northwestern Switzerland FHNW / Institute for Ecopreneurship; H.E. Kohler, Eawag Swiss Federal Institute of Aquatic Science and Technology; B.A. Kolvenbach, University of Applied Sciences and Arts Northwestern Switzerland FHNW / Institute for Ecopreneurship; P.F. Corvini, University of Applied Sciences and Arts Northwestern Switzerland (FHNW)

It has been shown, that the presence of antibiotics in the environment, contribute to the formation and spread of resistance genes among bacterial strains (Baran et al. 2011). Especially waste water treatment plants (WWTP) are proposed to be a hotspot for the emergence of resistant bacterial strains (Gao et al. 2012) and one of the major sources for the input of micropollutants into the environment (Abegglen and Siegrist 2012). Sulfonamide antibiotics are the second most used antibiotics worldwide in human and in veterinary medicine with a release of ~20,000 tons $year^{-1}$ (Baran et al. 2011). Nonetheless the biodegradation pathway of sulfonamide antibiotics is not understood. In addition, several studies reported insufficient sulfonamide removalrates by conventional sewage treatment(Gros et al. 2010). Even tertiary treatments like chlorination and ultraviolet radiation for disinfection, seem to have limited effect on the removal of sulfonamides (Batt et al. 2007). *Microbacterium* sp. BR1 was the the first isolated strain with the proven capability to partially mineralize Sulfamethoxazole (SMX) (Bouju et al. 2012). Degradation studies were carried out with this strain and revealed that the initial attack of SMX is carried out by the biological rare *ipso*-hydroxylation and that 3-amino-5-methylisoxazole is released as a stable metabolite, whereas the aniline moiety was mineralized by *M*. BR1. It could be shown, that *M*. BR1 is not only able to degrade SMX, but also five other tested sulfonamide antibiotics (Sulfadiazine, Sulfadimehoxine, Sulfamethizole and Sulfamethazine) and the herbicide Asulam. It is likely, that much more sulfonamides with a similar structure can be degraded by *M*. BR1, which makes it a suitable candidate for the biological treatment of sulfonamides. We were able to concentrate the protein responsible for the initial sulfonamide attack and identified as a $FMNH_2$ dependend monooxygenase. The results presented in this work lead to a better understanding of the biodegradation of sulfonamides. It is initiated by the biologically rare *ipso*-substitution and releases a predictable metabolite, which might be used as a biomarker together with a screening for the monooxygenase genes. Based on those results operational parameters of WWTP might be adapted to optimize sulfonamide degradation during the biological treatment, or at least clarify if the sulfonamide removal in WWTPs occurs due to biodegradation or other processess.

Fate and metabolism of Tetrabromobisphenol A in soil under different environmental conditions

J. Liu, Duke Univeristy; F. Li, F. Sun, S. Wang, J. Gu, Nanjing University; P. Nastold, University of Applied Sciences Northwestern Switzerland; B. Jiang, Nanjing University; B.A. Kolvenbach, University of Applied Sciences and Arts Northwestern Switzerland FHNW / Institute for Ecopreneurship; H. Guo, Nanjing University; P.F. Corvini, University of Applied Sciences and Arts Northwestern Switzerland (FHNW); R. Ji, Nanjing University / School of thee Environment

Tetrabromobisphenol A (TBBPA) is one of the most commonly used flame retardants and has become an environmental contaminant worldwide. However the fate and metabolites of TBBPA in the environment are still unclear. Using ring-^{14}C-labelled tetrabromobisphenol A (TBBPA), the transformation of TBBPA in soil under oxic and anoxic conditions and in water saturated soil with plant (rice and reed) growth was studied. While debromination was the predominant pathway for TBBPA degradation in anoxic soil, aerobic degradation of TBBPA in soil resulted in large amounts of mineralization (CO_2), single benzene ring metabolites, and *O*-methylation metabolites. Four primary metabolic pathways are proposed for aerobic degradation of TBBPA in soil, i.e., oxidative skeletal rearrangements, *O*-methylation, type II ipso-substitution, and reductive debromination. The presence of wetland plants (rice and reed) stimulated degradation of TBBPA and accumulation of mono- and di-*O*-methyl-TBBPA in soil. Substantial bound residues were formed during both aerobic and anaerobic degradation of TBBPA in soil. When soil redox potential altered from anoxic into oxic state, almost half of the anoxically formed bound residues were released as TBBPA and lower brominated BPAs, which were then persistent during oxic incubation. Our results provide detailed information about metabolites of TBBPA in soil and the first evidence for release of bound residues during alteration of the redox environment.

pH-dependent Biotransformation of Ionizable Organic Micropollutants in Activated Sludge

R. Gulde, Eawag Swiss Federal Institute of Aquatic Science / Environmental Chemistry; D. Helbling, Eawag Swiss Federal Institute of Aquatic Science; K. Fenner, ETH ZürichEawag

A variety of organic micropollutants originating from households and industry enter wastewater treatment plants (WWTPs) where they are partially removed through conventional activated sludge treatment. The operating conditions as well as the removal efficiencies for micropollutants vary between different WWTPs. Since, on average, every second micropollutant contains an ionizable functional group and the pH of WWTPs can range between 6 and 8, the chemical species actually present in the WWTP may range from fully uncharged to fully charged. Therefore, it is not suprising that the removal efficiency of ionizable compounds has been observed to be pH-dependent. Besides pH-dependent sorption, pH-dependent biotransformation might be a plausible explanation for this findings. The goal of this project was to elucidate the mechanisms responsible for the pH-dependence of biotransformation of ionizable organic micropollutants in activated sludge. Biotransformation experiments were carried out in laboratory batch reactors seeded with activated sludge at pH 6, 7 and 8. A mixture of 20 compounds, consisting of 16 basic, two acidic and two neutral compounds, was spiked into the reactors each at a starting concentration of 100 μg/L. Samples were taken at 13 time points over a period of four days and analyzed with liquid chromatography coupled to high-resolution tandem massspectrometry. Additional control experiments that accounted for losses through sorption and abiotic processes were run in parallel. Concentration time series were fitted and corrected for sorption and abiotic processes, yielding rate constants that represent microbial biotransformation only. pH-dependence of the biotransformation rate constant was observed for most tested compounds. Basic compounds generally showed increasing rate constants with increasing pH, whereas the acidic test compounds showed the opposite trend. The underlying reasoning for this observation is the following: The fraction of neutral species is depending on the pH of the medium and the pKa of the compound. The uptake of uncharged molecules into the cell is assumed to be much faster than that of charged species, whereas biotransformation in the cell is expected to be similar at different external pHs due to cell homeostasis. This suggests that biotransformation is faster at pH levels where the uncharged species of a specific compound dominates. This hypothesis will be quantitatively tested based on the results from our study.

Potential for biodegradation of crude oil in the arctic marine environment

K. Scheibye, University of Copenhagen / Department of Plant and Environmental Sciences; A.R. Johnsen, Geological Survey of Denmark and Greenland / Dept of Geochemistry; J.H. Christensen, University of Copenhagen

Suggested presence of oil and gas resources in the seabed off Greenland has along with climate change induced reductions in sea ice created interest in exploration of the area. Exploratory drillings are performed at up to 1000 m depth which has led to concern for deep sea oil spills. In deep sea oil spills biodegradation is a key factor for oil removal however the capacity for oil biodegradation in the arctic marine environment is not elucidated. To investigate this, a microcosm study was performed using water samples from 150 m depth in the Disko Bay, Greenland. Indigenous marine microorganisms were exposed to crude oil in concentrations of 0 mg, 2.5 mg, 5 mg, and 10 mg × l^{-1}. Microcosms were incubated for 71 days and samples were withdrawn at six sampling times in total. Bulk water phase was extracted separately from remaining water and oil phase. Through oil fingerprinting analysis by gas chromatography mass spectrometry (GC-MS) weathering effects on the oil phase were evaluated. Extensive biodegradation was evident for saturated hydrocarbons and alkyltoluenes at all oil concentrations. Shorter chain saturated hydrocarbons were preferentially degraded compared to longer chains and the highest oil concentration provided the lowest degradation rate. Limited biodegradation of PAHs and their alkylated homologs was seen for 2-3-ringed PAHs and some alkylated homologs in the 2.5 and 5 mg × l^{-1} microcosms, while more extensive biodegradation was found for the same compounds in the 10 mg microcosms. These results were, however, affected by large replicate variation. Changes in oil fingerprint over time were similar in all concentration microcosms and extensive biodegradation was seen in 10 mg microcosms suggesting that oxygen was not a limiting factor in the experimental set up. The separation of water and oil phases in the present study further demonstrated that PAHs and their alkylated homologs were highly affected by dissolution, with an inversely proportional relation between dissolution and number of aromatic rings as well as degree of methylation. Results obtained from the present study indicated that should a deep sea oil spill occur in the Disko Bay saturated hydrocarbon fraction and alkyltoluene fraction of crude oil will be rapidly biodegraded by indigenous marine microorganisms. PAHs and their alkylated homologs may be biodegraded to a lesser extent. Keywords: Crude oil, biodegradation, arctic, oil spill

Modelling the fate of petroleum hydrocarbons in bioengineered piles in the Antarctic

M. Whelan, University of leicester / Geography; F. Coulon, Cranfield University / Environmental Science and Technology; S. Ian, G. Hince, R. McWatters, Australian Antarctic Division; J. Rayner, CSIRO

Antarctic and sub-Antarctic soils are commonly contaminated with petroleum hydrocarbons. Biopiles can be used effectively to treat hydrocarbon contamination but their efficacy at low temperatures has, hitherto been uncertain. Here, we describe a dynamic multi-media model of petroleum hydrocarbon behaviour in biopile soils in which the temperature dependency of partitioning and degradation is included. The activation energy for degradation was derived by fitting the Arrhenius equation to hydrocarbon concentration data from temperature-controlled laboratory experiments using diesel- and crude oil- contaminated soil from Kerguelen Island. The model was then applied to a remediation biopile system containing soil contaminated with Special Antarctic Blend (SAB) diesel fuel at Casey Station, Antarctica. The model was able to describe temporal changes in total petroleum hydrocarbon concentration very well, provided temperature adjustments for degradation and partitioning were included. The quality of model fits for individual hydrocarbon fractions was variable but generally acceptable (disparity between measured and predicted concentrations < factor 2 for all fractions and in all biopiles). For most fractions, biodegradation was predicted to be the dominant loss mechanism, except for the lighter aliphatic fractions for which volatilisation was predicted to be most important. Despite the fact that losses during the winter are expected to be negligible for most fractions, summertime losses were significant, resulting in concentrations between 48 and 60 % of initial concentrations one year after the start of treatment.

Identification and prioritisation of hazardous emerging pollutants (II)

Changes of Accumulation Profiles from PBDEs to Brominated and Chlorinated Alternatives in Marine Mammals from South China Sea

B. ZHU, City University of Hong Kong / Biology and Chemistry; J. LAM, The State Key Laboratory in Marine Pollution; P. LAM, City University of Hong Kong

The present study investigated the composition profiles and levels of polybrominated diphenyl ethers (PBDEs) and five PBDE alternatives in the blubber of two species of marine mammals, Indo-Pacific humpback dolphins (*Sousa chinensis*) and finless porpoises (*Neophocaena phocaenoides*) from the South China Sea. Despite the fact that PBDEs were the most predominant brominated flame retardants in the samples analyzed, decabromodiphenyl ethane (DBDPE), 1,2-bis(2,4,6-tribromophenoxy) ethane (BTBPE), bis- (2-ethylhexyl) -tetrabromophthalate (TBPH), 2-ethylhexyl 2,3,4,5-tetrabromobenzoate (TBB) and Dechlorane Plus (DP) were all detected in both cetacean species. In addition, significant increasing temporal shifting trends of Deca-BDE to DBDPE, Octa-BDE to BTBPE, and Deca-BDE to DP were observed in porpoise samples between 2003 to 2012 and dolphin samples between 2003 and 2011. These patterns may be attributed to the replacement of PBDEs by alternative halogenated flame retardants (HFRs) and the increasing usage of these alternatives following the restriction/voluntary withdrawal of the production and use of PBDE commercial mixtures. Our findings suggest that the study region may be a source of contamination by PBDE alternative flame retardants due to the high detection frequencies and levels of these compounds in marine mammals.

425

Environmental fate and effects of new generation flame retardants

S.L. Waaijers, University of AmsterdamIBED Institute; M. Kraak, University of Amsterdam; J. Parsons, University of Amsterdam / IBED; W. Admiraal, University of Amsterdam; P. de Voogt, University of Amsterdam / IBED

There is a growing need to substitute brominated flame retardants (BFRs) with alternative halogen-free flame retardants (HFFRs). Many of these HFFRs are already being marketed, although their environmental behavior and toxicological properties are known to only a limited extent and their potential impact on the environment cannot yet be properly assessed. Therefore the aim of the present project was to study the environmental fate and effects of a selection of halogen free flame retardants that are currently replacing brominated flame retardants in polymers. To this purpose we: 1. Published a rewiew on the publicly available PBT data of HFFRs, identifying large data gaps and inconsistent observations on the properties of individual compounds. 2. Quantified the aerobic biodegradation of HFFRs and observed that only TPP was mineralised rapidly enough to be classified as readily biodegradable. The rates of primary biodegradation of the OPFRs varied, with TPP, RDP and DOPO being removed to undetectable levels in less than 14 days. In contrast, no significant removal was observed for BDP. 3. Assessed the aquatic ecotoxicity of HFFRs. MPP, MHO, ZHS and ZS showed no effect at their saturated water concentration (Sw) and APP, ALPI and DOPO had a low toxicity, suggesting that these compounds are not hazardous. ATO had a moderate toxicity (EC_{50} = 3.0 mg L^{-1}) and TPP was highly toxic to *D. magna* (EC_{50} = 0.55 mg L^{-1}). ATH and BDP caused limited mortality at Sw (26 and 25% respectively) and have low solubilities (< 10 mg L^{-1}). The chronic toxicity experiments revealed that the toxicity of ALPI increased with increasing exposure time from a 48 h LC_{50} of 18 mg L^{-1} to a 21 day LC_{50} value of 3.2 mg L^{-1}, resulting in an acute-to-chronic ratio of 5.6. This may imply a change in classification from low to moderate toxicity.

DOPO showed only sublethal effects with an EC_{50} value of 48 mg L^{-1} for cumulative reproductive output and an EC50 value of 73 mg L^{-1} for population growth rate. The toxicity of DOPO to *D. magna* was classified as low and likely occurred above environmentally relevant concentrations. The present project obtained a first indication whether or not the selected HFFRs are suitable candidates for BFR replacement in polymers.

Prioritization and monitoring of pollutants from emerging thin-film photovoltaic technologies

Y. Zimmermann, University of Applied Sciences Northwestern Switzerland; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; P.F. Corvini, University of Applied Sciences and Arts Northwestern Switzerland (FHNW); M. Lenz, University of Applied Sciences and Arts Northwestern Switzerland FHNW

Thin-film photovoltaic cells (TF-PV) are a rapidly growing branch among electricity-generating technologies. In particular, price, light-weight structure, semi-transparency and mechanical flexibility offer novel application possibilities. TF-PV can be categorized into well-established inorganic PV (IPV, e.g. copper indium gallium selenide cells, CIGS) and emerging organic PV (OPV). Both represent complex structures composed of manifold organic molecules, metals and metalloids. Despite their potential in renewable energy production, the environmental impact of such TF-PV is still largely unknown. In order to avoid adverse impacts, the most problematic components of TF-PV have to be prioritized, their potential emission monitored, the effects determined and components replaced if necessary. Substances were prioritized as problematic pollutants about which either ecotoxic/bioaccumulation effects are reported (i.e. Cd, Se, Ag) or toxic effects were not yet investigated (i.e. In, fullerenes). Actual emission to environmentally relevant model waters was assessed in laboratory experiments for long-term. In the leachates, metal(loid)s were quantified by Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Single organic components of complex leachate mixtures are detected by size exclusion chromatography coupled to organic carbon and light scattering detection as well as high resolution MS techniques (qTOF). From leaching results, predicted environmental concentrations (PEC) were calculated assuming realistic end-of-life leaching scenarios (roof-top acidic rain run-off; dumping in lakes and marine environments). PEC were put into perspective to WHO drinking water limits (human exposure) as well as toxic concentration for aquatic organisms. From the prioritized CIGS and OPV components, in leaching experiments high amounts of Se and Cd were leaching from CIGS. For instance, calculated PEC for Cd (173.4 μg L^{-1}, in acidic rain) would exceed drinking water limits (3 μg L^{-1}) many times and were even acutely toxic for *Daphnia magna* (LC_{50} = 25.5 μg L^{-1}, 48h). In contrast, OPV metal(loid)s did not pose any risk to the environment even under most conservative scenarios. Regarding organic molecules, no fullerenes have so far been detected in the leachates. The lack is probably due to the extreme hydrophobicity (Log K_{ow} = 10.45, determined by HPLC method) of fullerenes wherefore it is not mobilizable in environmentally relevant aqueous leaching tests.

427

Integration of effect-directed analysis in the chemical risk management in a Chemical Industry Park in China

X. Zhang, Nanjing University / Environmental Science; W. Shi, Nanjing University / School of Environment; P. Xia, Nanjing University / Environment; H. Yu, Nanjing University / State Key Laboratory of Pollution Control and Resource Reuse & School of the Environment

Chemical Industry Park is a large-scale regional industrial zone mainly for chemical manufacturing, which poses a potential source of risk to human and ecological system. To develop and enhance the technologies of chemical risk assessment and control for the chemical industry parks in China, a series of works has been developed in the Nanjing Chemical Industry Park, as an example of chemical industry park along the Yangtze River. 1) Firstly, a systematic chemical reporting & registration were performed in Nanjing Chemical Industry Park; 2) Secondly, chemicals applied in all manufacturing process were surveyed in over 20 manufacturers in Nanjing Industry Park, and a chemical inventory of 300 chemicals was developed. 3) A database with the physical-chemical parameters, toxicities, and usage data was developed for the chemical inventory. 4) Simultaneously, effected-directed analysis was carried out to investigate the potential hazardous chemicals in the industry park. Water, soil and sediments were sampled from the surrounding area and within the chemical industry park. Ongoing efforts are to identify the chemicals that may cause risk to the environment by the combination of instrumental analysis and bioassays. 5) Finally, tools and methods are being developed to manage the chemicals of high risk based on the information of hazardous chemical storage, production, transportation, and disposal. Here the overall strategies and the progress will be presented and discussed.

428

Finding toxic needles in a haystack: identification of estrogenic chemicals in oil industry process waters using effect-directed analysis

A. Scarlett, University of Plymouth / School of Geography Earth and Environmental Sciences; C.E. West, Plymouth University / SoGEES; S. Lengger, University of Plymouth / School of Geography Earth and Environmental Sciences; H. Reinardy, University of Plymouth; T.B. Henry, HeriotWatt University / School of Life Sciences; C. Dummett, University of Plymouth; S.J. Rowland, University of Plymouth / SoGEES

In addition to the multitude of new synthetic chemicals entering the environment, thousands of unidentified polar compounds derived from the breakdown of oil could also present a hazard to ecosystems. These polar compounds, such as carboxylic acids, traditionally referred to as “naphthenic acids” (NA) within the oil industry, can be present as super-complex mixtures within process waters from oil industries and have been implicated with hormonal disruption. An extreme example of this is the oil sands process-affected waters (OSPW) which result from mining operations in Alberta, Canada. Trillions of litres of OSPW are currently stored in ponds close to the Athabasca river and this is predicted to grow many-fold over the coming years. It is therefore critical that we obtain a better understanding of the nature and toxicity of these waste waters before they enter the environment. Estrogenic activity has been observed in fish following exposure to OSPW but which of the many thousands of unidentified compounds are responsible? Using liquid chromatography (argentation solid phase extraction) followed by tandem gas chromatography – mass spectrometry (GCxGC-MS) together with preparative GC and toxicity tests utilising vitellogenin gene-expression in zebrafish larvae, we were able to significantly limit the number of possible NA structures that could be causing the estrogenic activity. This effect-directed analysis approach has greatly improved our understanding of the nature of NA within OSPW. We now know that although both alicyclic and aromatic acids contribute towards the acute toxicity of OSPW, it is the aromatic acids that are primarily responsible for the estrogenic activity. Further preparative GC will permit greater quantities of individual acids so that improved structural identification can be performed using nuclear magnetic resonance. Within just a few years we are now on the brink of finding the first toxic needles in a haystack that was believed to be impossible to resolve. The Canadian oil sands are just one of many such operations around the globe and NA are present in process waters from oil drilling activities and also result from biodegradation of spilled oil such as from the Deepwater Horizon spill. Pollutants may emerge by being synthetically created but some have always been there but we didn’t realise it due to previous limitations of analytical ability.

Identification of emerging pharmaceutical pollutants in a river impacted by an industrial effluent combining passive sampling and effect-directed analysis

C. Gardia Parege, EPOCLPTC / UMR CNRS EPOCLPTC; N. Creusot, INERIS; M. Devier, University of Bordeaux / UMR CNRS EPOCLPTC; S. Ait Aissa, INERIS; H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC

The occurrence of endocrine disrupting compounds was previously detected in a French river impacted by an urban and a pharmaceutical wastewater treatment plants (WWTPs). Indeed, first investigations were conducted in surface water using polar organic compound integrative sampler (POCIS) at upstream and downstream of the WWTPs. Toxicological profiling of POCIS extracts was evaluated using *in vitro* bioassays based on luciferase gene reporter. Strong activities were found in POCIS extracts downstream from pharmaceutical factory. The identification of 60 chemicals (pharmaceuticals, antibiotics and steroids) by targeted chemical analyses (LC-MS/MS) did not totally explain the activities. In order to isolate the active chemicals and to identify them, POCIS crude extract was fractionated using Reverse Phase – High Performance Liquid Chromatography (RP-HPLC). Each fraction was then tested individually on *in vitro* cell lines. Several steroid compounds were detected by target analyses using LC-MS/MS and these chemicals explained the majority of observed activities in the selected fractions. For many highly active fractions, compounds responsible for these activities remained unknown. In this study, a LC-HRMS system (LC-QTOF) was used to identify these active compounds. The HPLC fractions were analyzed in (data-dependent) auto-MS/MS acquisition mode. Detected compounds in fractions of POCIS extract were compared to those found in the corresponding fractions of the blank sample. The characterization of compounds was performed on molecules only present in POCIS fractions. The procedure allowed the identification of several candidate molecules including drugs, steroids and some of their metabolites. The identification of some of them has been confirmed with purchased reference standards. The activity of these identified chemicals is still under process and results will be presented. Colloidal stability dictates the toxicity of nZVI towards the green alga P. subcapitata.

S. Gonzalo, Universidad de Alcala; V. Llaneza, University of Florida / Environmental Engineering Sciences; G. Pulido, Biologia; F. Fernandez-Piñas, Universidad Autónoma de Madrid / Biology; J. Bonzongo, University of Florida / Department of Environmental Engineering Sciences; F. Leganes, Universidad Autónoma de Madrid / Biology; R. Rosal, Universidad de Alcala / Ingenieria Quimica; I. Rodea-Palomares, Universidad de Alcala / Biology

Aggregation is one among those parameters focusing the attention in Nanotoxicology due to its methodological implications [1, 2]. Aggregation is a physical symptom of a more general physicochemical condition of colloidal particles, that is, colloidal stability. A destabilized colloidal system may tend to reduce its net surface energy by self-aggregation, generating aggregated engineered nanomaterial (ENM) suspensions, but also by hetero-aggregation, including location at bio-interfaces. In this regards, colloidal stability may have an important role as driver of ENM bioactivity. In this study, a spontaneous ENM speciation phenomenon was found when generating a dose gradient of zero-valent iron nanoparticles (nZVI) in algal OCDE culture medium. It consisted of a exceptionally stable ENM suspension with particles in their primary size (4 - 12 nm) which occurred within a tight dose range (0.1-0.5 mg/L). Outside this range, aggregates (150-400 nm) were formed. Interestingly, nZVI exhibited toxicity to the test model organism, except in the 0.1-0.5 mg/L dose range. Stability analyses, TEM images and FTIR analyses revealed that nZVI toxicity was mediated by nZVI-alga interaction, and that the increased colloidal stability of nZVI suspensions in the 0.1-0.5 mg/L dose range was preventing nZVI-algae interaction. Furthermore, destabilization of this particular suspension resulted in toxicity. These observations demonstrate that colloidal stability has a major role in nZVI toxicity, and presumably in ENM toxicity in general. Our results open a new research window on linkages between the stability conditions of ENM suspensions and environmental health and safety (EHS) assessment of ENMs by emphasizing the role of colloidal stability as driver of bioactivity. 1. Platinum nanoparticle toxicity in freshwater algae and crustaceans: A physical or chemical effect?

S.N. Sorensen, DTU Environment / Environmental Engineering; A. Baun, Technical University of Denmark / Department of Environmental Engineering; C. Engelbrekt, Technical University of Denmark / Department of Chemistry; C. Giron Delgado,

Despite intensive research into aquatic toxicity of various nanoparticles, only few studies involve platinum nanoparticles (PtNPs). From an environmental exposure perspective, PtNPs are highly relevant due to extensive use in automobile catalytic converters and the findings of particulate matter containing platinum (Pt) alongside roadways. The aims of this study were to: 1) Determine the toxicity of PtNPs towards freshwater algae and crustaceans, 2) Investigate if observed responses results from physical effects like light obstruction in algal tests and mechanical fixation of organisms in daphnia tests, rather than toxicity induced by PtNPs and 3) Propose alternative test setups to allow for this distinction. The toxicity of $PtCl_4$ and 2 nm starch stabilized PtNPs towards algae and daphnia was assessed. A standard OECD 202 48h acute immobilisation tests with *D. magna* was conducted. In addition, 48h mobility and lethality was assessed in a double-beaker setup with a net separating the daphnia from direct contact with aggregated and sedimented PtNPs. Tests with freshwater green algae *P. subcapitata* included a standard growth inhibition test (ISO 8692:2004) with 48h incubation using fluorometric quantification of algal pigments. Furthermore, a short-term (2h) ^{14}C-assimilation was applied, where algal uptake of ^{14}C-labelled bicarbonate was determined by scintillation counting. Characterization of PtNPs included ICP-OES, DLS and TEM. The tested PtNPs were found less toxic than $PtCl_4$, but still harmful to aquatic life, with 48h EC_{50} values from standard algal and daphnia tests of 14 and 17 mg Pt/L, respectively. The observed 48h algal growth rate inhibition from PtNPs is likely due to a toxic response and not physical shading during pigment analysis, since PtNP toxicity was confirmed in the 2h algal ^{14}C-assimilation test, where scintillation counting is used that is not sensitive to the presence of NPs. However, any shading effects during exposure should be further investigated. In the daphnia test, substantial adhesion of PtNPs to the organisms’ exterior was observed, causing physical rather than toxicity induced immobilization. Consequently, immobilization and lethality endpoints differed greatly, with EC_{50} and LC_{50} values of 17 and 26 mg Pt/L respectively. From the double-beaker setup, comparable EC_{50} and LC_{50} values were 31 and 34 mg Pt/L were obtained, indicating that lethality is a more robust and accurate endpoint than immobility for NPs in *D. magna*.

432

The effect of DOM on the algal toxicity of carbon nanotubes

L. Zhang, Z. Long, Zhejiang University; D. Lin, Department of Environmental Science

With their rapid growth in production and application, carbon nanotubes (CNTs) possess a growing potential for being discharged into the aquatic environment and thereby threaten aquatic organisms via the toxic mechanism which remains unclear. Dissolved organic matter (DOM) is ubiquitous in the environment and may influence the toxicity of the discharged CNTs, which however has not been well investigated. In this study, the individual and combined toxic effects of a type of MWCNTs and three model DOMs (sodium dodecylbenzenesulfonate-SDBS, octyl phenoxy polyethoxyethanol-TX100 and humic acid-HA) to a green alga (*Chlorella Pyrenoidosa*) were investigated by measuring algal biomass, settling curves, malondialdehyde (MDA), reactive oxygen species (ROS), and fluorescence, scanning and transmission electron microscopies (FM, SEM and TEM, respectively). Five principal toxic mechanisms, including oxidative stress, agglomeration and physical interaction, shading effects, metal catalyst residues, and adsorption of nutrient elements, were discussed. Results show that the MWCNTs could significantly inhibit the algal growth under light and dark conditions and the inhibitory effect was dose-dependent. The algal toxicity of the MWCNTs was mainly attributed to the combined effects of oxidative stress, shading effect and physical interaction. The contributions of metal catalyst residues in the MWCNTs and the MWCNT adsorption of nutrient elements to the algal growth inhibition were negligible. Different DOM exhibited different effect on the algal toxicity of the MWCNTs. HA alleviated the algal toxicity of the MWCNTs mainly through reducing oxidative stress and preventing the physical injury of algal cells; whereas the presence of SDBS and TX100 increased the production of intracellular ROS by the MWCNTs, thus enhancing the toxicity.

433

Toxicity of different sized and shaped nanoparticles in zebrafish embryos

J. Hua; M.G. Vijver, CML Leiden University; W.J. Peijnenburg, RIVM / Center for Safety of Substances and Products

Abstract: Nanoparticles (NPs) are widely used in biomedical, optical and electronic fields. Various studies found Cu, ZnO NPs could increase zebrafish embryos mortality, inhibite hatching, cause changes in viability or morphology, as well as the dissolved ions from NPs. Many studies have provided evidence that particles shape have relationship with the degree of toxicity, although the underlying mechanism remains unclear. Dissolution and shedding of ions also play an important role in NPs induced toxicity. However, there should exist a particle-mediated mechanism. Therefore, we determined whether the particle form of NPs with different shape (ruling out toxicity caused by their shedding ions) have an lethal effect in zebrafish embryos. Three types of Cu NPs with different size, and two types of ZnO NPs with different shape were exposed to zebrafish embryos in egg water. In order to determine whether the particle form of NPs ($NP_{(particle)}$) effect differed from the toxicity of $NP_{(ion)}$, embryos were treated with NPs as well as their nitrate salt solutions. The LC50 values of Cu $NP_{(particle)}$ demonstrated that their toxicity is size-dependent. It can be concluded that smaller Cu NPs were more toxic than larger sized ones, which might be related to the larger surface-to-volume ratio of the smaller particles. Concentrations of shedding Cu^{2+} from Cu NPs were low, and the Cu^{2+} caused less toxicity to zebrafish embryos. Our results showed that Cu $NP_{(particle)}$ dominated the explanation of toxicity. The higher contribution to toxicity by Cu $NP_{(particle)}$ could be caused by the existence of a particle-mediated mechanism. The dissolution characteristics of ZnO nanoparticles play an important role in its toxicity in zebrafish embryos. Ruling out the toxicity caused by Zn^{2+}, The LC50 values of ZnO $NP_{(particle)}$ showed that nano stick was more toxic than nanospheres. The reason could be stick-shaped NPs have a larger contact area with the cell membrane than spherical NPs as the longitudinal axis of the sticks interacts with the cell membrane. Moreover, nanospheres aggregated to large particles, a more effective macrophage clearance for larger particles compared to smaller ones, leading to reduced toxicity of NP aggregates larger than 100 nm. The aggregation of nanoparticles in water is an important factor in assessing their toxicity. **Keywords**: copper and zinc oxide nanoparticles, shedding ions, aggregate state, nanotoxicity

434

Smaller cladoceran species are more vulnerable to CuNPs

L. Song, Institute of Environmental Science / Dpt of Conservation Biology; M.G. Vijver, CML Leiden University; G.R. de Snoo, Leiden University; W.J. Peijnenburg, RIVM / Center for Safety of Substances and Products

Adverse effects of NPs are largely associated with NP and environmental characteristics. However, little is known about the toxicity of NPs among different NPs and among different species. The prediction of toxicity of NPs to untested NPs and untested species is largely impossible.We propose that interactions between NPs and organisms are target-oriented and which may strongly associated with morphology of organisms [1]. Hence, we exposed five cladoceran species (*Daphnia magna, Daphina pulex, Daphnia galeata, Ceriodaphnia dubia* and *Chydorus sphaericus*) to four sizes of copper nanoparticles (CuNPs, nominal size : 25, 50, 78 and 100nm) to investigate if morphological attributes of cladoceran species can be

used to interpret the toxicity of CuNPs across species. We found that all CuNPs suspensions showed high toxicity to all tested species. Moreover, even though the size, shape and ion release rate of CuNPs were different, the toxicity of CuNPs suspensions and of $Cu(NO_3)_2$ are positively correlated with the body length, surface area and body volume of neonates of different species, indicating the morphological attributes of species could be the parameter which can be used to predict and extrapolate the toxicity of nanoparticle suspension to untested species. Our study shows it is important to include the attributes of species together with the characterization of NPs and offers a new approach to predict the toxicity of nanoparticles for untested species [2]. Bioaccumulation processes and mechanisms: Implications for experimental assessments and modelling (II)

435
Using COSMOmic as a Mechanistic Model to predict Phospholipid-Water Partition Coefficients of Anions

K. Bittermann, Analytical Environmental Chemistry; S. Spycher, Agroscope ChanginsWaedenswil Research Station ACW / Analytical Environmental Chemistry; K. Goss, Department of Analytical Environmental Chemistry

Membrane lipids are of central importance for bioaccumulation as well as toxicity. The majority of cell membranes consist of phospholipids that form a lipid bilayer – knowledge of the partition behavior of chemicals between water and phospholipid bilayers is thus of special interest. While the partitioning of neutral chemicals can be reliably predicted with empirical $\log K_{ow}$ relationships, the sorption of anions is more complex and not well understood so far. A mechanistic modelling approach is necessary to account for the anisotropy of the membrane. Therefore reliable published data on liposome-water partition coefficients of organic anions have been gathered from literature and were extended with own measurements, using the equilibrium dialysis method. The overall 53 experimental partition data of compounds with a diverse chemical composition shows that there is no constant difference between the sorption of neutral and corresponding anionic forms. An extension of COSMO-RS (Conductor-like Screening Model for Real Solvents) called COSMOmic (COSMO-RS for micelles) has been used to model all experimental data – it is based on quantum chemical calculations and fluid phase thermodynamics. COSMOmic accounts for the anisotropy of the membrane by representing the membrane as a layered structure of consecutive homogeneous liquids. Proven to serve as a mechanistic model for neutral compounds it only needs the atomic distribution of the membrane (via MD simulations) and the structures of every molecule that is involved in the partition system as input files. COSMOmic gives a satisfying statistical correlation when predicting the experimental logarithmic partition coefficients (R2=0.70; RMSD=0.69) with a few outliers. In contrast to the calculations for neutral compounds the COSMOmic-predictions for anions still need to be calibrated with experimental data. It is not fully clear why this additional fitting step is necessary. This fitted prediction for anions is applied to a number of versatile emerging pollutants and the results are compared to a Bioconcentration factor of 2000 and a Biomagnification factor of 1 – with deliberately chosen simple and conservative assumptions. Here it can be shown that at a physiological pH of 7 partially as well as completely ionized organic compounds may have a considerable bioaccumulation potential.

436
Partitioning of POPs into different lipid classes

A. Ruus, NIVA / NIVA; I.J. Allan, Norsk Institutt for Vannforskning; K. Baek, Norwegian Institute for Water Research; K. Borga, Department of Bioscences University of Oslo / Departmenf of Biosciences

Lipids generally represent the major component contributing to the absorptive capacity for hydrophobic persistent pollutants in aquatic ecosystems. Thus, concentrations are often reported normalized to a lipid weight basis in biological samples. The aim of the present study was to determine if contaminants partition in a different degree into two different storage lipid classes, namely wax ester (WE) and triacylglycerol (TAG). This was done by investigating the partitioning of organochlorine compounds (hexachlorobenzene and selected polychlorinated biphenyls) and selected polybrominated diphenyl ethers between lipids (WE or TAG) and a silicone phase. The results suggested that hydrophobic compounds have a higher affinity for WE than for TAG. These results support the hypothesis that contaminants accumulate in a greater extent in Arctic food webs (where WE is an important class of storage lipids at low trophic levels), compared to temperate, and that this can be partly explained by higher water-lipid partitioning at the lower trophic levels. Furthermore, the results suggest that normalizing concentrations of hydrophobic contaminants to lipids in general (e.g. in deductions of trophic magnification factors, TMFs) may be too simplistic, and that information regarding the dominant types of storage lipids in the organisms in question may improve estimates.

437
Abiotic and biotic drivers of Arctic food web contaminant bioaccumulation in a changing climate

K. Borga, Department of Bioscences University of Oslo / Departmenf of Biosciences; J. Starrfelt, NIVA; J.H. Christensen, Aarhus University; A. Ruus, NIVA / NIVA; K. Hanssen, Aarhus University DMU; A. Evenset; G. Gabrielsen, The Norwegian Polar Institute

Seasonality in Arctic marine food web contaminant concentrations is known from separate empirical and modeling studies, but the link between the two is missing. The aim of the present study was to identify drivers of seasonal contaminant accumulation pattern in the Arctic marine food web, and to use this knowledge to make predictions of food web accumulation in a changing climate. The effect of the annual cycle of exposure, temperature, lipid content and food web structure on g-HCH, PCB-52 and PCB-153 bioaccumulation in an Arctic marine food web, Svalbard, was modeled using the AQUAWEB model. Results were compared to measured data in the same food web from 2007. The Danish Eulerian Hemisphere Model estimated temperature and contaminant concentrations in air and water in 2007 using real meteorological input data, and projected results for the decade 2090-2099 using climate meteorological data. When varying only contaminant exposure seasonally, delayed peak concentrations moving into the year and up the food web was found, corresponding to empirical data. Modelled bioaccumulation metrics (trophic magnification factor TMF) however, did not correspond with the observed pattern. Best fit scenario between modelled and measured bioaccumulation metrics included highest ecological relevance, allowing also lipids and trophic relations to vary. In the best fit scenario, food web biomagnification varied seasonally, with lowest TMFs in spring, and highest in summer and autumn, as also found in the empirical 2007 study. The results indicate that lipid is not the only important ecological driver of seasonal contaminant accumulation (as previously hypothesised for the Barents Sea), but also food web relations and diet composition (as previously hypothesised for the Arctic). In the future Arctic climate a century ahead, simulated bioaccumulation metrics were marginally higher than at present. Thus, results show that seasonal variation in bioaccumulation is greater than alteration as a response to predicted climate change. As the best fit seasonal scenario included the annual cycle in lipid content and trophic relations, these physiological and ecological factors are crucial for making sound predictions of contaminant food web bioaccumulation for the future. Changes in abiotic drivers alone are not sufficient to explain food web bioaccumulation on a temporal scale.

438
Trophic dilution of cyclic volatile methylsiloxanes (cVMS) across the pelagic food web of a temperate, deep water lake.

D.E. Powell, Dow Corning Corporation / Health Environmental Sciences; J.A. Durham, Dow Corning Corp / Health and Environmental Sciences; R.M. Seston, K.B. Woodburn, Dow Corning Corporation / Health Environmental Sciences

The bioaccumulation behaviours and trophic transfer of cyclic volatile methylsiloxanes (cVMS) and polychlorinated biphenyls (PCB) will be evaluated for the pelagic food web of Lake Champlain, which is a deep water lake located in the USA on the border between the States of Vermont and New York, and extending north into Quebec, Canada. The cVMS included octamethylcyclotetrasiloxane (D4; CAS 556-67-2), decamethylcyclopentasiloxane (D5; CAS 541-02-6) and dodecamethylcyclohexasiloxane (D6; CAS 540-97-6). The PCB included 2,3,4,5,2’,4’,5’-heptachlorobiphenyl (PCB-180) and 2,4,5,2’,4’,5’-hexachlorobiphenyl (PCB-153), which are "legacy" chemicals known to bioaccumulate in aquatic organisms and biomagnify in aquatic food webs. The PCB congeners were used as a benchmark chemical (PCB-180) to calibrate the food web and as a reference chemical (PCB-153) to validate the results. Surface sediments were collected from 60 locations by systematic sampling over a defined study area of 800 km^2 across the main lake basin. Samples of the food web were collected by methods that were deployed to sample the dominate populations of pelagic species. A rigorous quality control program that included reference samples, control samples, and blanks was followed in the field to verify that samples were not contaminated by sample storage and processing procedures. BSAF and TMF will be generated for the sampled food web using $\delta^{15}N$ as a continuous variable for assigning trophic level position. The $\delta^{15}N$ trophic enrichment factor ($\Delta^{15}N$) used to estimate trophic level position will be derived for the food web using PCB-180 as a benchmark having an assumed TMF of 4.0. Standard TMF will be calculated using univariate methods based on linear, least-squares regression analysis. Multivariate probabilistic methods will also be used to calculate TMFs that incorporate natural variability and minimize biases associated with the experimental design, $\Delta^{15}N$, omnivorous feeding, and migration.

The interrelationship between BSAF and TMF will be used to minimize bias and uncertainty associated with TMF and to correct for variable exposure across concentration gradients. Results for Lake Champlain will be compared to results from other studies and quantitative weight of evidence (WoE) methods will be applied to evaluate the impact of experimental design, environment, food web structure, species composition, and exposure on TMF.

439
Limits of transferability of biodynamic parameters to the field for metal bioaccumulation modelling in macro-invertebrates

S. Massarin, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; T. Galle, CRP Henri Tudor / CRTE; r. carafa, TUODOR / CRTE; S. Classen, gaiac Institute for Environmental Research RWTH Aachen; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology

The evaluation of the impact of metal contamination on aquatic ecosystems remains important with a biological indices oriented WFD. Determining the exposure to metals by measuring the bioaccumulation in organisms allows assessing more accurately the risk in water bodies. Nevertheless metal bioaccumulation is a complex process dependening on many physiological and physicochemical parameters. The main objective of this work is to investigate the variability of metal bioaccumulation in macro-invertebrates in the field using the biodynamic model (DYMBAM) and a critical appraisal of the published parameters and assumptions. Metal concentrations in Ephemeroptera, Trichoptera, water and Suspended Particulate Matter (SPM) were analysed at 9 sites in Luxembourgish rivers. Both food and animals were also analysed for carbon and nitrogen isotopes. The DYMBAM model was used to make predictions of the internal concentrations in the field species. The C/N isotopic results imply that the same species has a different diet depending on the sites and the environmental conditions. Different diet suggests variable metal contamination and assimilation efficiencies and hence different exposure through food. The DYMBAM predictions using biodynamic parameters from the litterature underestimated the bioaccumulation in the field species. Although the dissolved uptake was the dominant uptake pathway for *Serratella ignita* due to its fast uptake rate from water and low elimination rate, dietary uptake contributed to 80% to the metal bioaccumulation in *Hydropsyche*. These results suggest that dietborne metal uptake is an important pathway for metal accumulation for individual traits like filterers. In addition, the feeding rate and growth of the animals under field conditions is unknown. It would be fruitful to explore relationships between food availability, feeding and growth with energy budget models to reduce these uncertainties. We conclude that metal bioaccumulation in moderately contaminated rivers falls within parameter ranges showing high uncertainties for biodynamic predictions. In light of the importance of dietary exposures in metal accumulation of aquatic macro-invertebrates, metal toxicity depending on dietary uptake routes needs to be investigated more in depth.

Terrestrial field studies are needed to derive bioaccumulation potential of chemicals

N.W. van den Brink, Wageningen University / Dept of Toxicology; J. Arblaster, ENVIRON International Corp; S.R. Bowman, The Ohio State University / Evolution Ecology and Organismal Biology; J.M. Conder, ENVIRON International Corporation; W. Drost; J.E. Elliott, Environment Canada / Science Technology Branch; M.S. Johnson, US Army Institute for Public Health / Toxicology Portfolio; D.C. Muir, Environment Canada / Water Science and Technology Directorate; T. Natal da Luz, University of Coimbra / Department of Life Sciences IMAR CMA; B.A. Rattner, USGSPatuxent Wildlife Research Ctr / USGS; B.E. Sample, Ecological Risk Inc; R.F. Shore, CEH Lancaster

The potential of compounds to bioaccumulate in organisms and biomagnify in food webs is key to the regulation of chemicals in several jurisdictions. However, the vast majority of research on bioaccumulation of compounds in food webs (further referred to as “B-assessment”) has been conducted in marine or freshwater ecosystems. This bias overlooks several essential issues with regards to terrestrial ecosystems. In order to asses and optimise the use of data from terrestrial field studies for regulatory B-assessment, a workshop was organised (January 2013) to: i) identify existing knowledge and data on terrestrial B-assessment, ii) provide recommendations to optimise and improve existing approaches by including information from terrestrial studies, and, iii) suggest means of integration of laboratory, model and field derived data. For this, a review was performed on existing data on B-assessment in terrestrial field studies. Additionally, a comparison was made between metrics describing B-potential in aquatic and terrestrial ecosystems. Based on the review, it was concluded that B-bioaccumulation information from aquatic studies are not typically predictive for B-assessment . Participants agreed that this would ignore specific issues of bioaccumulation processes in terrestrial food webs e.g. spatio-temporal variation, bioavailability, physiological-life history differences, etc. Furthermore, bioaccumulation in aquatic food webs is generally driven by the k_{ow} of a chemical; however, in terrestrial food webs persistence of a chemical in various biotransformation outcomes may be more important. It was evident that large data gaps exist and that further research is needed. This research should focus on: i) the use of stable isotopic signals in terrestrial ecosystems, ii) the development of non-destructive/invasive methods, iii) inclusion of bioavailability and metabolism in B-assessment, iv) greater understanding in wildlife physiologically-based pharmacokinetic dynamics, and v) development of modelling approaches to integrate relevant environmental variation in B-assessment. Studies of terrestrial food webs in the field may be challenging, due to ethical but also practical limitations. However, based on the current review it is clear that terrestrial field studies should play an important role in B-assessment.

Mechanistic effect modeling - beyond concentration response and constant environments (II)

441
Mechanistic effect model of a field earthworm and its application to interpret chemical risk assessment field trials

A.S. Johnston, University of Reading / Biological Sciences; P. Thorbek, Syngenta / Environmetal Safety; M. Hodson, University of York; T. Alvarez, EcoRisk Solutions Ltd / Dept of Ecological Sciences; R. Sibly, University of Reading

Although current risk assessments aim to be protective, interactions between chemical, biological and physical stress in nature are generally unaccounted for. Primary decisions on chemical risks to populations are investigated under standardised laboratory conditions. However, field populations are rarely exposed to chemicals at a single dose under constant environmental conditions. At the higher tier field trials can also be highly variable and/or site specific, making interpretation of ecotoxicity results difficult. To addresss these issues we develop and evaluate a mechanistic effect model of the dominant arable earthworm *Aporrectodea caliginosa*. By combining energy budget and agent based modelling (ABM) we describe how populations are altered by both environmental and chemical stress. The energy budget model dictates how individuals assimilate energy from ingested food and expend available energy on maintenance, growth and reproduction. A priori parameter estimates represent individual physiology under specified environmental conditions. Environmental variables in the ABM landscape then act to limit energy expenditure to life cycle processes. Chemicals also alter energy allocation to the physiological processes via imposed dose-response relationships identified from laboratory data. We simulate two chemical risk assessment field trials under both control conditions and following the application of the toxic standard carbendazim. We use toxic standard data here to test whether the model is adequately sensitive to chemical applications. The ABM landscape is set up to represent a vertical cross-section of a soil profile, with environmental factors (food availability, food quality, soil temperature, soil texture and soil water content) varying with depth. We present good model fits to population density and biomass data in both field trials and scenarios simulated. Variability between population dynamics in the field trials is caused by different soil organic matter contents and soil water conditions. Changes in these conditions drive individual movement along the soil profile, essential in capturing the exposure of populations to chemical stress. Combining energy budget and ABMs provide insights into the mechanistic effects of chemicals on field populations living in spatially explicit landscapes.

442
Impact of toxicant stress on the stability characteristics of 2-species competition models

h. baveco; A. Focks, Wageningen UR / Ecotoxicology Environmental Risk Assessment Team; F. De Laender, Université de Namur ASBL / Lab of EnvToxApplEcol; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra

Classical models of species competition have as outcome competitive exclusion, coexistence or bi-stability (dependence on initial conditions). The same behaviour should be expected in individual-based models (IBMs) including competition. In the Chimera project we coupled IBMs for *Asellus aquaticus* and *Gammarus pulex*, added competition terms to each, and tested whether the dynamics of the resulting model could be approximated with a simpler Lotka-Voltarra competition model (LVM). The particular form of the LVM, as derived from the IBM, was not the *r—K* one with coefficients *r* (per capita growth rate) and *K* (carrying capacity). Instead, the *r-alpha* form resulted with *r* and *alpha* (intra-specific competition coefficient). The LVM was used to analyse the impact of toxicant mortality in single or repeated pulses on the stability characteristics of the system. We found that the IBM showed the same qualitative behaviour as the LVM, in the 4 regions of parameter-space associated with coexistence, exclusion of *Asellus* or *Gammarus*, and bi-stability. Oscillations in the IBM dynamics resulted from non-equilibrium initial conditions (age-structure). In contrast to previous analyses with the *r-K* form, with the *r-alpha* form of the LVM (and thus for the IBM) we found that reduced *r* from chronic exposure (or repeated pulses) could change the stability characteristics. Chronic exposure (or repeated pulses) could convert the competitive exclusion state into competitive coexistence or the bi-stable state into competitive exclusion. A single pulse exposure could affect stability only in the

bi-stable state, if abundance of the winning species was reduced enough to move the system into another basin of attraction. The presence of a competitor slowed down recovery. Details of this 'transient' behaviour depended on context: the state of the sensitive and the competing population, and the stability characteristics of the system as a whole. With two interacting species, toxicant stress acting on one species affects the dynamics of both. Therefore, recovery should take into account return to 'normality' of the whole system, and measures should be based on combined state of both populations. *Acknowledgement* – The Chimera project is financed by the Long Range Initiative of CEFIC (www.cefic-lri.org) (project code: LRI-ECO19)

Dynamic modelling and mechanistic effect models to analyse ecological interactions and toxic effects within a microcosm

d. Iamonica, Université Claude Bernard Lyon; C. BERNARD, ENTPELEHNAIPE / UMR CNRS LEHNA; S. Charles, University Lyon / Laboratory of Biometry and Evolutionnary Biology; C. Lopes, Université Lyon UMR CNRS

In 1998, Clément and coll. worked out a new protocol for a laboratory microcosm bioassay, which has been widely used to assess the toxicity of contaminants. Within the microcosm, toxic effects on classical life history traits are assessed on five species: microalgae (*Pseudokirchneriella subcapitata*), duckweeds (*Lemna minor*), daphnids (*Daphnia magna*), amphipods (*Hyalella azteca*) and chironomids (*Chironomus riparius*). Such an innovative approach allows one to take into account interactions between species and with the abiotic compartment. Within the microcosm, organisms are exposed to contaminants through multiple ways, making difficult to relate observed effects to exposure concentration, which varies in time and space. Moreover, conversely to single-species bioassays where individual responses are directly linked to contaminant concentration, the responses in the microcosm may result from indirect and/or direct effects of the contaminant. Facing such a complexity, modelling appears as a relevant tool to improve results interpretation. Taking into account functional interactions within mechanistic effects models provides a more in-depth understanding of biological responses and a proper way of testing various assumptions on the underlying mechanisms. In this study, experiments were conducted under controlled conditions without and with contaminant (cadmium). The experiments without cadmium were designed to empirically describe the interactions between species. The functioning of the whole microcosm was described through several partial models (for duckweeds/algae, algae/daphnids, etc.) based on ordinary differential equations. Then, effects observed within contaminated microcosms were described through stress functions impacting both species dynamics and interactions between species. Model parameters were estimated using Bayesian inference. Combining each of the partial models without cadmium, we got a complete model with a good description of the global microcosm functioning, with biologically meaningful values for all parameters. The integration of stress functions to describe the effects of cadmium on partial microcosms gave encouraging results to extend the modelling to the whole microcosm with cadmium. Values of interesting parameters without and with cadmium can be compared to quantify the effects within the microcosm, making the microcosm a useful standardized tool for predictive risk assessment.

Food web modelling of a river ecosystem for risk assessment of down-the-drain chemicals: a case study with AQUATOX

A. Franco, Unilever / Safety and Environmental Assurance Centre; A. Barausse, A. Pivato, A. Lombardo, University of Padova

Ecological models are a useful platform to assess the impact of chemicals on the structure and function of a whole ecosystem. The fate and effects models AQUATOX is probably the best known example of an integrated fate and effects model combining water quality, food web, chemical fate and ecotoxicological constructs. A case study was developed to simulate the effects of two ingredients of home and personal care products, the anionic surfactant linear alkylbenzenesulphonate and the antimicrobial triclosan, on a lowland riverine ecosystem. The objectives of this study were to construct a realistic food web model of a lowland river ecosystem and to demonstrate how individual-level ecotoxicological data can be scaled up to predict impacts on community and ecosystem dynamics. The model was build for a section of the river Thames (UK), for which detailed ecological surveys were available, allowing for a quantification of energy flows through the whole ecosystem. This offered a unique opportunity for calibration, often impossible for similar models. Key modelling challenges are presented and discussed for each step of the study, including: the definition of a food web structure, the stabilisation of the dynamic food web model and its calibration, the use of the ecotoxicology sub-model and the articulation of a suitable assessment endpoint. The control scenario was calibrated for a simulation period of one year, and tested for stability over six years. Two perturbed scenarios were simulated: one corresponding to environmental realistic concentrations of the chemicals and one with hypothetical inflow concentrations equal to the lowest EC50 value. The difference between the control and the perturbed simulation at environmentally realistic concentrations for the river Thames was statistically insignificant. At hypothetical higher concentrations, direct and indirect effects of chemicals on the ecosystem dynamics emerged from the simulations. Uncertainties in key assumptions remains high as the validation of perturbed simulations remain extremely challenging. The study is a step towards the development of realistic ecological scenarios for use in prospective risk assessment of down-the-drain chemical. The ability to simultaneously simulate the effects of chemicals (including mixtures) and of other water quality stressors associated with domestic wastewater (organic matter, nutrients) enables the evaluation of chemical impacts in realistic, multi-stressed scenarios.

445

Using biological traits in ecological modeling: How to model the temporal dynamics of benthic invertebrate communities?

C.P. Mondy, Eawag Swiss Federal Institute of Aquatic Science and Technology / SIAM; N. Schuwirth, System Analysis Integrated Assessment and Modelling

Ecological quality of streams has become, with the Water Framework Directive, a central concern in European environmental policy. Ecological quality assessment is only the first step for streams to reach good ecological status. Considering the limited subsidies available, one also have to (i) identify the stressors that could have led to ecological impairment, (ii) predict how the system could respond to new stressors and (iii) predict which management options could potentially lead to the best improvement of ecological quality and recovery of ecosystems function. Mechanistic ecological models that integrate different environmental stressors can provide useful information on the future evolution of systems under changing environmental conditions. The present study details a food-web model (Streambugs) aimed at predicting the seasonal development of the benthic community composition in streams based on temporally variable environmental conditions (e.g. water quality, temperature and floods). However, such models require information for a large set of parameters that is usually scarce. Thus, the identifiability of such parameters from observed data could be a major issue. To limit such problems, one could use a Bayesian approach and include available information on biology and ecology of organisms, the so-called traits, to derive prior information about parameters. We propose to integrate traits in the Streambugs model in two steps. First, as it was previously done, traits related to habitat requirements or to stressor tolerance of taxa are compared to local environmental conditions to derive factors that modify growth and death rates of taxa. As a second step, we propose to analyze if posterior distributions of taxon-specific parameters derived from Bayesian inference correlate with traits that were not yet included in the model. This could help to refine the model to increase its predictive power and universality. With a first manual calibration we got promising results when applying the model to the Sihl river (Switzerland), where we have biweekly abundance data over one year. We will apply Bayesian inference and analyze results as described above to improve the model. Using the calibrated model, we will apply scenario analysis to analyze effects of a pesticide contamination and/or of changing saprobic conditions on the modelled community.

446

Modelling community dynamics under toxicant stress

M. Kattwinkel, P. Reichert, Eawag Swiss Federal Institute of Aquatic Science and Technology / System Analysis Integrated Assessment and Modelling

In pesticide risk assessment simple and complex experimental setups with aquatic macroinvertebrates are used for risk characterization. However, the combined effects of contamination and biological interactions are often not well enough understood for sound extrapolation to untested conditions. In particular the recovery of populations and communities under realistic conditions is difficult to assess. Here, ecological modelling can support the risk assessment by improving the understanding of the involved processes and feedbacks and by allowing the examination of numerous different experimental settings. Therefore, we developed a dynamic, stochastic, individual-based model (IBM) of a macroinvertebrate community. It is based on the metabolic theory of ecology, that describes the relationship between individual biomass and vital rates. The model incorporates food web interactions including predation and competition (Fig. 1). It describes food uptake, respiration, individual growth, reproduction (including emergence pattern), and mortality. In addition, the model represents individual variability, intrinsic stochasticity and different life-stages of the individuals. For parameter estimation, available trait data bases for macroinvertebrates are used. Here, we present the model and apply it to data of a stream mesocosm experiment to investigating the consequences of toxicant effects on life cycle functions for community dynamics. In particular, we explore the role of community interactions including food competition and predation, going beyond the capacity of single population models.

Policy assessment in an integrated systems perspective: indicators and targets to ensure operating within safe planetary boundaries (II)

Environmental assessment of waste management policies: a Waste Input-Output Analysis

A. Beylot; J. Villeneuve, S. Vaxelaire, BRGM; C. Roussel, J. Payet, Cycleco

When environmentally assessing waste management policies in a context of economic variations, the interdependence between the flows of goods and waste in the economy needs to be taken into account. Developments in Waste Input Output Analysis (WIOA) are therefore crucial to consistently address such environmental issues. This study aims at i) compiling Waste Input Output Tables (WIOT) for France, combining data in monetary units and data in physical units in a so-called "mixed-unit" or "hybrid" framework and ii) applying WIOA to investigate the environmental benefits of waste management policies on air emissions embodied in the final demand, in the specific case of France and in a context of economic growth. Input Output tables are compiled for France for the year 2004. Coefficients relative to service activities are directly extracted from Eurostat in monetary units, whereas coefficients of products uses, emissions and resource consumption are compiled in physical units mainly from national statistics. Coefficients of waste generation are finally deduced based on mass balance identities. The compiled French WIOT are integrated in a specifically designed web application enabling to perform multiple scenario analyses. Three distinct scenarios are considered, depicting and combining the projected upward trend of final demand from 2008 to 2020, the increase in recycling rates and the larger implementation of Best Available Techniques (BAT) for incineration. The combined implementation of recycling and BAT is observed not to overcome the increase in gaseous emissions induced by the evolution of the final demand. However, their implementation enables to limit the increase in emissions resulting from the evolution of the final demand, by 19% considering fossil CO_2 emissions up to 34% considering SO_2 emissions. Waste management therefore appears an important lever in the perspective of decoupling gaseous emissions embodied in the French final demand from the latter's evolution. Yet waste management policies only have limited effects relatively to the total gaseous emissions embodied in the final demand and may only be seen as one piece of a larger panel of policies.

448

Discussion on methods to include prevention activities in waste management LCA

S. Nessi, Politecnico di Milano; L.L. Rigamonti, Politecnico di Milano / DIIAR; M. Grosso, Politecnico di Milano

Over the last decade, life cycle assessment (LCA) has increasingly been used as a decision support tool in waste management planning at different scale.
Nevertheless, waste prevention has rarely been included in the analysed systems, despite it is indicated as the most favourable option of the so-called waste hierarchy. This may be ascribed to a number of reasons. The first is that traditional waste management LCA has been originally developed with some methodological characteristics that, while simplifying the analysis, prevent its use for the comparison of scenarios where different overall amounts of waste are generated. In this research, the amendments proposed so far in the attempt to overcome this limitation were reviewed first. Two alternative methodological LCA approaches were then identified for the analysis of waste management systems which, beyond conventional treatment methods, include also the effects of waste prevention activities. The two approaches were conceived for the comparison of waste management scenarios including one or more waste prevention activities with baseline scenarios in which no prevention activities are undertaken. For both of them, the functional unit was defined and the system boundaries were described with reference to different typologies of waste prevention activities identified in an extensive review. The procedure for the calculation of the LCA impacts of scenarios was defined as well. The two approaches provide the same result in terms of difference between the LCA impacts of a waste prevention scenario and of a baseline one. However, because of the partially different upstream system boundaries considered for such scenarios by the two approaches, different values of the impacts of single scenarios are obtained. Moreover, their application is more suitable in study with different purposes. The two approaches can be used for many purposes such as, among the most general, quantifying the upstream and downstream environmental consequences of implementing particular waste prevention activities in a given waste treatment system, complementing waste reduction indicators with LCA-based indicators, providing the basis for decoupling evaluations and supporting with quantitative evidence the strategic and policy relevance of waste prevention at national and European level.

449

Taking account of expert stakeholder knowledge: constructing a framework to meet WFD requirements using LCSA and PES for metal removal at abandoned non-coal mine sites.

H.A. Baxter, University of Hull / Centre for Environment and Marine Sciences joint with Department of Engineering; W. Mayes, University of Hull / Centre for Environment and Marine Sciences

The European Water Framework Directive (WFD) requires that water bodies meet good ecological and chemical status. In the UK a significant contributor to surface water pollution, notably Zn, Cd, Cu and Pb, are abandoned non-coalmine sites to which no legal liability for their cleanup is attached. This situation creates a number of different problems which need to be tackled so that individual abandoned noncoal mines can be remediated. These problems include a) identifying sources of funding b) identifying suitable remediation technologies c) justifying the need for remediation to stakeholders and the wider public. A framework has been developed to address these problems and its development has been informed by interviews conducted with expert stakeholders who have connections with or an interest in water bodies or metal pollution. This presentation will present the results of the interviews with expert stakeholders illustrating how different sectors from industry, government agencies and special interest/conservation/stewardship organisations, view this particular issue. Interviewees were asked about their knowledge of and views on payments for ecological services(PES), as a mechanism for funding noncoal mine site remediation, and their opinions on the usefulness of life cycle assessment (LCA) for quantifying the benefits and impacts of the technologies being considered. Their thoughts about what is additionally needed to motivate their organisation to act to cleaner this source of pollution were sought and their knowledge and experience of the current situation was also requested. The similarities and differences of the different sectors perceptions of problems, attitudes and roadblocks will be highlighted in addition to their reflections on potential drivers that would induce their organisation to act to solve this specific problem.

450

Emerging LC Communities around the world: taking the right steps towards sustainable development

A. Quiros, ECO GLOBAL ALCALA; R. Schenck,

There have been many attemps to make sustainable development operational. Activities around LCA and EPD labeling are coming together as market drivers. The European Commission announced the single market for green products pilot program underway to stsndardize EPDs on consumer goods. Inclusion of LCA and EPDs into the USGBC LEED V4 document is creating a significant demand for LCA services. Several governments are including LCA-based Sustainable Product Purchasing Programs as a step to move the market towards more sustainable practices. This is a welcome development for it opens greater opportunities for environmental and economic development to encompas and transcend this product-by-product approach. ¨Programs like "Life Cycle Communities" created by IERE in 2010 offer much broader action towards sustainability. The goal is to help municipalities use their environmental performance to drive economic growth, redefine policies and sustainable pracitices as well as to use the information developed to obtain EPD labels. An example of the success of this program is the city of Tacoma. Other activities world-wide are following similar approches. Encouraging examples may be found in some leading countries in Latin America. Mexico, Brazil and Colombia are all in the process of implementing Sustainable Consumption and Production (SCP) national policies, including LCAs of priority products in additon to awareness raising, education and progress reporting, amongst other aspects of the SCP programs . In Chile the experience is an EMS certification program for nation wide municipalities, an initiative which to date accounts for at least 10 outstanding communities and which offers the opportunity to gradually move towards LC communities as part of the continual EMS imporvement. ALCALA is currently working in a law project to promote LC communities across Costa Rica as a means to support sustainable development and to contribute to the national goal to be C Nuetral by 2021 in a comprehensive and relaible way. LC Communities have guiding principles: Use LCA and LC Thinking in its policy and operations Have utilities publish their LC Inventories Work with companies to use these inventories for LCA based ecolabels Support educational institutions to build LCA capacity Support SCP practices at all levels Make a public commitment to the above mentioned points (legislation or excecutive order) Continually report to society on performance and improvement

451

Challenges of adding a life cycle perspective to municipal-level decision support for transition to a climate-neutral society

C. Sundberg, Swedish University of Agricultural Sciences

To address the planetary boundaries for greenhouse gas (GHG) emissions, the EU has adopted the long term target of reducing GHG emissions by 80-95% by 2050. A roadmap has been developed to guide climate policy and wider decision-making towards this target. This work is now spreading to national and local levels. One important part of the road-mapping process is modelling of current and future greenhouse gas emissions in the system under study. The GHG emissions models at municipal level in Sweden has evolved from two parts of the national statistics, (a) the energy statistics at municipal level and (b) the breakdown of national climate statistics to the municipal level. If the aim is to reduce the climate impact of the city, it is not enough to switch from fossil fuels to renewable energy in the local energy mix. There is a need to reduce the climate impact from production of the products consumed by the inhabitants in the city, where life cycle assessment-based data is preferred. The aim of this text is to describe and reflect upon some opportunities and challenges of introducing a life cycle approach to municipal-level to development of future scenarios for long-term, major reductions in greenhouse gas

emissions. The main source of information is an ongoing case study in Uppsala, Sweden. It has been possible to include the LCA perspective for direct energy consumption in the city, but for food and consumer products, there is no agreement on how to include LCA data. Some general concerns from the local stakeholders regarding the use of LCA data in the local GHG accounting and road map are that (a) Figures are uncertain (b) Data are not adjusted to the local context (c) Data are not updated annually. A geographical system boundary, reflecting the boundary of the municipality, risks supporting sub-optimal solutions that transfer of emissions outside the boundary, even though they are caused by activities within the municipality . Production of PV cells is an example from an emerging technology of current local interest. It is not evident that it is possible to merge the geographical and life-cycle perspectives into one model. There may be a need for complimentary modelling activities, which will give a wider picture of the opportunities and challenges of becoming a climate-neutral city. It will however require more resources for modelling and may complicate communication with decision-makers.

452
Development of environmental impacts of Swiss consumption and production from 1996 to 2011
S. Buesser, R. Frischknecht, TreezeLtd; C. Nathani, Ruetter Partner; R. Itten, F. Wyss, Treeze Ltd; P. Hellmueller, Ruetter Partner
Human beings consume more and more non-renewable resources, and several renewable resources are being depleted beyond their capacity of regeneration. In a globalised world consumption in one country may cause important environmental im-pacts abroad. This is especially true for small open economies with high shares of im-ported goods such as Switzerland. The extraction, harvesting and processing operations required to produce materials and goods imported into Switzerland contribute to climate change, harm biodiversity and landscapes, pollute soil, water and air in the countries of origin. The study presented here investigates the development of total environmental impacts caused by consumption and production in Switzerland from 1996 to 2011 (Swiss demand based environmental impacts). The study intends to monitor domestic environmental impacts and the importance of foreign trade compared to domestic impacts over time. The development of environmental impacts is compared with the development of population and economic performance. Furthermore, the development of the Swiss impacts due to production and consumption is compared to “planetary boundaries” defined for Switzerland. A few single score impact assessment methods and several impact category indicators covering topics such as climate change, land use, water use and air quality are used to assess the results. The investigation shows that domestic impacts decreased substantially over the last 15 years, mainly due to improvements with regard to air quality. However this reduction is compensated by increasing consumption, i.e. due to increasing foreign trade. Environmental impacts per unit of domestic final demand decrease substantially over the time period analysed. The general trend in Switzerland is towards outsourcing impacts to foreign countries. In developed countries, a responsible environmental policy in view of a green economy should not only focus on domestic environmental impacts but also pay attention to the environ-mental impacts abroad caused by an increasing consumption of goods.

Research on communication and communication of research – pinpointing the best practice to improve our outreach

Bridging the Gap: A Case for the use of Social Media in Environmental Science
G. Biermans, University of Hasselt; S.R. Bowman, The Ohio State University / Evolution Ecology and Organismal Biology; E.K. Brockmeier, University of Florida / Physiological Sciences; A. HICKS, University of Illinois; D.M. Jevtic, Institute of Environmental Sciences Jagiellonian Univeristy / Ecotoxicology and Stress Ecology; J. Rodriguez, University of Guelph
In the last few years, social media have gradually become an important part of our daily lives, either through direct contact or through other ‘conventional’ media such as television or radio. While some might see it as a threat or as a source of procrastination, social media have unquestionably changed the way in which information and knowledge disseminate through our society. Science is still struggling to find a way to adopt and integrate social media into its framework. At the same time, more and more researchers are finding their way into mainstream social media such as Facebook or Twitter. We argue that, instead of perceiving this as a problem, scientists should use social media as an opportunity to share and showcase information. This is an opportunity not only to facilitate more informal dialogue about research between scientific peers, but to provide a chance for the general audience to directly interact with researchers. Environmental science in particular could benefit enormously from such an approach, as it deals with topics such as clean air and water, which directly impact our daily lives. By urging scientists to present their research to a wider audience using social media, a more engaging dialogue can arise among all parties. In this context, we organised a professional training course on social media at the Society of Environmental Toxicology and Chemistry North America Annual Meeting in Nashville in November 2013. The purpose of the course was to present environmental scientists with the benefits as well as potential pitfalls of using social media such as Twitter and Facebook in their research. Furthermore, the course provided insights on how to use popular tools such as ResearchGate, LinkedIn, and Mendeley in order to achieve better networking and productivity. In addition to a short overview of our course, we present the feedback received from the course participants on ways in which scientists in our field are using social media, and how they plan to use it in the future. Finally, we present joint social media initiatives among the SETAC Student Advisory Councils from various Geographical Units, and our plans to engage SETAC students in the use of social media for science communication.

454
Blogging: a tool for informal communication of scientific research and technology
J. Bozich, UWMSFS / SFS; L. Bishop; A. Tillman; L. DeStefano; C. Haynes; F. Geiger; G. Orr; C. Murphy; J. Pedersen; R. Klaper ; R. Hamers,
Blogging is a relatively new approach to bridging the gap that exists between scientific research and the public’s understanding of science, that can also serve as a way to enhance scientists’ ability to engage in informal science communication. With the recent advances in science and technology, the need to make newly found knowledge more accessible to the public is ever growing. Today’s digital world offers tools of the Internet that can be effective in communicating and informing the public of new breakthroughs in scientific research and technology. One tool in particular, web logs or “blogs”, have been around since the late 1990s, however, until recently, their emergence as a professional tool for communicating new ideas has been underutilized and underestimated. With millions of people having access to the World Wide Web and an ever increasing disconnect that science and technology has with the general public, blogs offer a cost-effective and user friendly means of reaching a broad demographic of people to increase awareness and educate people of important scientific research and emerging technologies. This presentation will include a discussion of how informal language style effectively communicates scientific research to lay audiences, offering options for starting a blog or blogging, ways to promote blogs and the benefits of blogging for individuals and for collaborative research teams.

455
Uncertainties in environmental nanoparticle research: what is communicated in scientific literature and mass media
I. Heidmann, Interdisciplinary Research Group for Environmental; J. Milde, University of Koblenz-Landau
There is a high level of scientific uncertainty in nanoparticle research’ is often stated in the scientific community. The research about the fate and behavior of engineered nanoparticles in the environment is despite its wide applications and years of research still in the early stages. Knowledge about related scientific uncertainties might be of interest to other scientists, experts and laymen. However, a characterization of these uncertainties or knowledge about their scientific communication in scientific literature and mass media are rare. Therefore, the current state of scientific knowledge about scientific uncertainty through the example of environmental nanoparticle research was characterized and the communication of these uncertainties within the scientific literature is compared with its media coverage in the field of nanotechnologies. The scientific uncertainty within the field of environmental fate of nanoparticles is dominated by method uncertainties, a general lack of data and by the uncertain transferability of results to the environmental system. In the scientific literature, scientific uncertainties, their sources, and consequences are mentioned with different foci and to a different extent. As expected, the authors in research papers focus on the certainty of specific results within their specific research question, whereas in review papers, the uncertainties due to a general lack of data are emphasized and the sources and consequences are discussed in a broader environmental context. In the mass media, nanotechnology is often framed as rather certain and positive aspects and benefits are emphasized. Although reporting about a new technology, only in one-third of the reports scientific uncertainties are mentioned. Scientific uncertainties are most often mentioned together with risk and they arise primarily from unknown harmful effects to human health. Environmental issues itself are seldom mentioned. Scientific uncertainties, sources, and consequences have been most widely discussed in the review papers. Research papers and mass media tend to emphasize more the certainty of their scientific results or the benefits of the nanotechnology applications. Neither the broad spectrum nor any specifications of uncertainties have been communicated. This indicates that there has been no effective dialogue over scientific uncertainty with the public so far.

Effective environmental risk communication - success stories or urban legends?
A. Hunka, University of Twente / Faculty of Behavioural Sciences; A. Palmqvist,

Roskilde University / Department of Environmental Social and Spatial Change; P. Thorbek, Syngenta / Environmetal Safety; V.E. Forbes, University of Nebraska Lincoln / School of Biological Sciences
We take part in different risk discourses every day both willingly and in passing. By 2012 the Internet has become the most popular source of risk information[1]. Thanks to social media, we also share and create risk information. But what makes risk communication successful? How do we define success – by the size of the audience, the number of people we manage to convince, the effect of the intervention, or the number of tweets? Despite over 30 years of studies, there is still little agreement among risk researchers about the questions above. For a start, research on risk communication can take three different avenues: the content of communication (risk information), the process (how this information is shared), and the implications of communication (why the information is shared) [2]. Many studies tell the readers what risk communication is and why it is needed, while actual analyses of successful interventions are scarce. Our goal was to establish a set of criteria for risk communication success and find common features of successful risk communication campaigns. We focused on environmental risk interventions, but included different communication formats (e.g. spatial risk maps), as long as there was a clear environmental/ecological risk or threat being communicated. Another important criterion was to include only studies in which a risk communication effect was measured and assessed (e.g., in randomized controlled trials). We excluded qualitative studies, which are difficult to compare. We searched known scientific databases (all to March 2014) in English applying the selection criteria. We also reviewed the reference lists and searched for citations of included studies. Despite the voluminous literature in the area (over 1000 titles), we initially focused on 10 studies meeting our criteria. We identified different aims of risk communication, such as: education, raising awareness, and building trust between communicating parties. So far, the results are not consistent – we were not able to identify one communication format that works better than others in educating people and raising awareness, although simple messages seem to be sufficient for the latter. Risk managers working with probabilities might find it interesting that verbal and graphical presentations of probabilities result in better understanding than numerical ones. In comparison to health and personal risk communication, the area of environmental risk communication still remains understudied. 1. National Science Board: *Science and Engineering Indicators 2012*. Science Communication in the Field of Innovative Human Safety Assessment: The SEURAT-1 Dissemination Strategy
T. Gocht, University of Tuebingen / Institute for Experimental and Clinical Pharmacology and Toxicology
SEURAT-1 is the major European research initiative in the field of human safety assessment, focussing on the development of animal-free toxicity testing methods. Consequently, a dissemination strategy targetting on different groups (stakeholders, industry, regulators, the public, and policy and opinion makers) were developed, defining specific means for reaching out to these groups. Questions addressed: - How to deal with the conflict of interest between science communication and lobbyism? Is there any? - What are pitfalls for scientists when communicating their results to the public?

458
Pharmaceutical residues in the water cycle: Challenges of communicating an ‘uncertain risk’ to the public
M. Dreyer, Gemeinnützige Gesellschaft für Kommunikations und Kooperationsforschung mbH
Pharmaceutical residues in the water cycle are *emerging* anthropogenic contaminants mainly in the sense that there is growing recognition of their potential significance as a risk management challenge. In some countries of the Western World the notion is spreading that a precautionary approach is required in light of studies showing that certain substances can have negative effects in the water flora and fauna and that some substances are even present in drinking water, and given an aging population and an increasing use of several prescription and over-the-counter drugs. Further, the notion is spreading that such an approach needs to include communication to the general public on issues of correct disposal and prudent use of drugs. We have dealt in a literature study with this question: What are content-related requirements of risk communication on pharmaceuticals in the water cycle that aims at sensitization, information and behavior adaptation (drug disposal and use)? So far, there are only few empirical insights into public perception of possible risks of pharmaceutical residues to environmental and human health. Therefore our analysis is based largely on theoretical and empirical insights from the broader literature on risk perception and communication. As a result of the literature study the presentation will point out that the risk source „pharmaceuticals in the water cycle“ has attributes that induce people to perceive a risk as negligible as well as attributes which promote the perception that a risk is high. It is mainly the former attributes that make it likely that part of the addresses have only low motivation to deal more intensively with the offered information. Therefore, *cues* (such as information source credibility) require particular attention in designing the risk communication. Framing the issue broader in terms of „Dealing responsibly with pharmaceuticals“ could serve as an attention cue. The latter attributes, promoting the perception that a risk is high, are main elements of the risk pattern that has been termed „risk as an early indication of insidious danger”. This could be taken account of, for example, by relating emotional cues connected with hazard representations to the aquatic fauna and flora rather than to drinking water. The overall conclusion is that risk communication on pharmaceuticals in the water cycle requires balancing between awakening and reassuring. „It’s worth taking precautionary measures” needs to be the main message.

Environmental OMICs: high-throughput strategies to decipher mechanism of response to stressors (III)

459
Ethynylestradiol (EE2) effect on global gene expression in primary rainbow trout (Oncorhynchus mykiss) hepatocytes
M. Hultman, Norwegian Institute for Water Research; Y. Song, Norwegian Institute for Water Research NIVA / Ecotoxicology and Risk Management; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment
Implementation of the 3R`s (refinement, reduction and replacement) in ecotoxicology is crucial as to meet the chemical legislations demands of the chemicals that are in need of testing. Through evaluating *in vitro* models potential and implement them as initial chemical screening tools animal testing (*in vivo*) can be reduced. *In vitro* models such as primary cultures and continuous cell lines are well characterized high-throughput screening tools for several single compound and mixtures of endocrine disruptors [1, 2, 4]. Knowledge about endocrine disrupting chemicals (EDCs) different mode of action (MoA) and mechanism of action (MOA) has been obtained through use of batteries of *in vitro* models. Chemicals with ED properties such ethynylestradiol may act as an estrogen mimic by activating the estrogen receptor (ER) through estrogen mediated responses. Activation ofthe ER would initiate a multi-organ endocrine response in vivo, but since *in vitro* lack the full toxicokinetic and toxicodynamic ability of the intact organism, it might have a limitation in its multitude of cellular responses. The aim of this study was therefore to investigate the response in primary rainbow trout (*Oncorhynchus mykiss*) hepatocytes after short-term exposure to the estrogen mimicking chemical ethynylestradiol (EE2) using transcriptomics. Primary hepatocytes exposed to EE2 for 48 hours had a total of significantly 174 differentially expressed gene transcripts (DEG) with a concentration response curve (CRC) between EE2 concentrations, number of DEGs and enriched GOs. The gene ontology (GO) analysis showed that there is an over representation of biological processes related to the nutrient reservoir, lipid related transport and reproduction, potentially associated with production of estrogen related proteins (eg. vitellogenin) in the primary cells. Among all DEGs, 50-67.2% of the rainbow trout genes were successfully mapped to mammalian orthologs. Further, DEGs related to endocrine regulation such as glucocorticoid-, androgen-, Wnt/β-catenin-, calcium-, ERK/MAPK and apoptosis signaling were enriched in these pathways. Primary hepatocytes have shown to be a promising tool in EDC screening as it retains the innate cellular properties of the liver. Using primary hepatocytes and global gene expression as an initial screening tool would contribute to a better understanding of chemical`s MOA in the *in vitro* scenario, and potentially also refining *in vivo* testing of EDCs.

Characterization of thyroid metabolism disruption at the level of transcriptome, morphology and behavior
I. Bagci, Antwerp university / Biology; M. Heijlen, KU Leuven / Department of Biology; L. Vergauwen, University of Antwerp / Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences; A. Hagenaars, Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; V. Darras, KU Leuven / Department of Biology; D. Knapen, University of Antwerp / Biology department
Accumulating evidence indicates that a large number of environmental chemicals disrupt the normal action of thyroid hormones in human and animals. Disruption of normal TH signaling may have deleterious organismal effects on widespread biological processes. Besides the need for an efficient, low cost, and high throughput routine alternative testing tool, there is also need for further mechanistic information on the effects of thyroid hormone disruption. Using morpholino (MO) technology targeting the different deiodinases (Ds) in zebrafish embryos we provide a reference dataset at the transcriptional, morphological and behavioral level that will be used in an alternative test to identify potential TH disruptors in the environment. Analysis of the impact of D1D2MO and D3MO on a genome-wide scale in head, abdomen and tail at 3 day post fertilization (dpf) using microarrays revealed specific transcriptional patterns. GO analysis revealed that transcripts in the head region of the D1D2MO and D3MO were mainly related to

phototransduction. At the morphological level, impairment of the eye development in knockdown embryos was apparent as soon as 1 dpf, demonstrated by a significantly smaller eye surface. However, this effect persisted up to 4 dpf only in D3 morphants. Further examination of the eye phenotype revealed significantly less cone specific photoreceptors in retinas of D3MO embryos at 3 dpf compared to SCMO. Activity measurement of larvae based on video-tracking at 4 dpf revealed that D1D2 and D3 morphants were significantly less active in light following a dark period, indicating that the knockdown embryos were less sensitive to light stimuli. Besides the observed effects related to eye morphology, other prominent effects were observed in hatching success, swim bladder inflation, heart beat frequency and length. Interestingly, the phenotypes of D3 morphants showed significantly more frequent retardation and defects in early developmental processes compared to D1D2MO embryos. By integrating transcriptional and higher organismal level effects of thyroid hormone disruption we provide important insight on the mechanisms of environmental THDs. Our findings show that visual perception, eye surface, hatching success, swim bladder inflation, length and behavioral profiling are promising endpoints for identification of THDs in the environment.

Investigating the hepatic transcriptomic response of brown tout exposed to a model oestrogen, E2, and the anti-androgen, linuron, using RNA-seq

T. Uren Webster, Biosciences College of Life and Environmental Sciences; E.M. Santos, University of Exeter / Biosciences College of Life and Environmental Sciences

Brown trout are a sensitive, ecologically important species. 17β-oestradiol (E2) and the anti-androgenic herbicide linuron are two contaminants present in agricultural pollution that are likely to affect brown trout populations. We set out to investigate the global hepatic transcriptomic response of mature male brown trout exposed to E2 and linuron using RNA-seq, which is emerging as a valuable tool for conducting transcriptomics in species with limited genomic sequence information. We exposed mature male brown trout to 3 measured concentrations of E2 (1.94, 18.06 and 34.38 ng/L), 3 concentrations of linuron (2.5, 25 and 250 μg/L) and water controls for 4 days and sequenced three individual liver samples from each treatment on an Illumina HiSeq 2500 platform. Using a *de novo* approach, we assembled a hepatic transcriptome consisting of 172,688 transcripts. Transcript expression analysis revealed a total of 2113 differentially expressed transcripts in fish exposed to 34.38 ng E2/L (measured concentration) compared to the control group, but few changes in the lower treatments. The most up-regulated transcripts included well characterised oestrogen-responsive genes (vitellogenins, zona pellucida proteins, *esr1*), while up-regulated hepatic processes were associated with vitellogenesis (lipid metabolism, cell proliferation, ribosome biogenesis). 34.38 ng E2/L is in a range of values measured in sewage effluent and has been associated with peaks in agricultural pollution, thereby raising concerns for brown trout populations in the most contaminated rivers. 822 transcripts were differentially regulated across all linuron treatments. We identified a striking down-regulation of enzymes involved in cholesterol biosynthesis, possibly resulting from a disruption of androgen signalling. We also found evidence of a considerable induction of transcripts involved in cellular stress response, including up-regulation of CYP1A (up to 560 fold) by 250 μg linuron/L, as well as molecular chaperones and the antioxidant system. There were similar, less pronounced, transcriptional changes in fish exposed to 2.5 μg linuron/L which may raise concerns over the potential effects of this pesticide on wild brown trout populations. These results, which include identification of both conserved and novel toxicological effects in an ecologically important species, also demonstrate the value of RNA-seq as a sensitive and robust tool in ecotoxicology.

462

Developing a platform of environmental omics for the green-lipped mussel Perna viridis

C. Ip, The University of Hong Kong / School of Biological Sciences; P. Leung, The University of Hong Kong / The Swire Institute of Marine Science and School of Biological Sciences; J. Qiu, C. Wong, Hong Kong Baptist University / Department of Biology; L. Chan, P. Lam, City University of Hong Kong / Department of Biology and Chemistry; K. Leung, The University of Hong Kong / The Swire Institute of Marine Science and School of Biological Sciences

The green-lipped mussel *Perna viridis* is an important marine biomonitor species in pollution monitoring and ecotoxicological studies in Asia-Pacific region, and considered as a subtropical equivalent biomonitor of the temperate *Mytilus* species. However, the genomic information of *P. viridis* is still largely unexplored when compared with *Mytilus* species. This study aimed to establish a transcriptomic profile of *P. viridis* using the next generation sequencing technology and provide a good representative set of genomic information for elucidation of toxic mechanisms upon pollution stresses and identification of a suite of suitable biomarkers for monitoring marine pollution and environmental stresses. To obtain a wide spectrum of environmental-associated transcripts, adult mussels (4-5 cm shell length) were collected from different locations in Hong Kong and from those after 24-hour exposures to various challenges of physical stresses and chemical pollutants, so as to cover a wide range of stress-associated transcription patterns for future environmental studies. Two males and females from each location and from each treatment were chosen for obtaining the three target tissues (i.e., hepatopancreas, gill and adductor muscle). For each sex and each tissue type, a total RNA sample was extracted from pooled tissues from the field and laboratory treated mussels. The RNA sample was subjected to cDNA library construction, followed by the RNA-sequencing using a Solexa GAIIx (Illumina). Including the splicing variants, a *de novo* assembly of a total length of 295,064,579 base-pair (bp) contig was obtained, with 233,257 contigs assembled of an average size of 1264 bp. The 192,879 non-redundant assembled transcripts were blasted against the NCBI nr database and three molluscan EST databases, and resulted in 44,713 transcripts with at least a blast hit, and having a top match with the sequences from the Pacific oyster, *Crassostrea gigas (*27,651 transcripts). A total of 5,131 transcripts were assigned with KEGG annotation involving in 329 pathways. Based on multivariate statistical analysis, expression patterns of genes from stress associated responses and detoxification were strongly tissue-specific but the differences between genders were little. The anticipated genomic database generated from this study will further strengthen the role of *P. viridis* as a universal marine biomonitor in the Asia-Pacific region.

463

Identification of biomarkers of metal exposure by transcriptome analysis of Elodea nuttallii

N. Regier, University of Geneva / Institute Forel Earth and Environmental Sciences; L. Baerlocher, Fasteris SA; M. Muensterkoetter, Helmholtz Centre Munich; L. Farinelli, Fasteris SA; C. Cosio, Geneva University / Aquatic Biogeochemiostry and Ecotoxicology Institute FA Forel Earth and Environmental Sciences Faculty of Sciences

Gene expression analysis by recently developed RNA sequencing technology is a promising tool to be used to develop biomarkers of exposure for use in the field. A good biomarker should be specific and react dose-dependently. Rooted aquatic macrophytes are good candidates for ecotoxicological tests because they are exposed to both water and sediments. *Elodea nuttallii* is such a macrophyte. It is native to Northern America, but occurs almost worldwide as neophyte. It has been shown to accumulate high amounts of toxic metals. In the present study, we used *E. nuttallii* exposed to metals in the lab in order to identify gene signatures that can be used to reveal metal exposure in the field. Using RNA-Seq, we identified more than 60’000 expressed gene sequences, of which about 35’000 could be identified by BLAST searches and 33’000 could be functionally annotated. GO annotation revealed a broad range of biological processes and molecular functions to be present, indicating that we identified a representative gene catalogue of *E. nuttallii*. Expression analysis considering only dose-dependently regulated genes revealed 54 up- and 158 down-regulated by Cd. For Hg we found 84 up- and 86 down-regulated genes. After validating RNA-Seq for a small subset of genes by RT-qPCR, this set of genes was used for designing a codeset for Nanostring nCounter analysis. Shoots were exposed to various concentrations of Hg, Cd, Cu, to the Hg contaminated Babeni reservoir, and to a variety of other abiotic parameters i.e. salinity, cold and darkness, and gene expression signature measured by nCounter. We found two main clusters: samples exposed to high (μg/L range) metal concentration formed one group, irrespective of the metal used for exposure. The second cluster consisted of samples exposed to low (ng/L range) metal concentrations, including samples exposed in the Hg contaminated Babeni reservoir in Romania. Genes identified in the laboratory after exposure to high concentrations were successfully used as biomarkers of Hg exposure in the field in a complex environment. On the other hand, the biomarkers also responded to high concentrations of Cu and Cd in the laboratory, suggesting that more genes would be needed to discriminate between the different metals. In conclusion, we were able to show that a genomic approach is suitable for development of ecotoxicological test and that macrophytes are well suited as test organisms.

464

De novo transcriptomic profile in the gonadal tissues of the intertidal whelk Reishia clavigera

K.K. Ho, The University of Hong Kong / The Swire Institute of Marine Science and School of Biological Sciences; P.T. Leung, The Univeristy of Hong Kong / The Swire Institute of Marine Science and School of Biological Sciences; C. Ip, The University of Hong Kong / School of Biological Sciences; J. Qiu, Hong Kong Baptist University / Department of Biology; K.M. Leung, The University of Hong Kong

The intertidal whelk *Reishia clavigera* (formerly named as *Thais clavigera*) is one of the most sensitive species suffering from organotin-associated imposex in their females. However, limited information of mRNA transcriptome has restricted the molecular investigation on such endocrine disruption in this species. By means of Illumina sequencing, we obtained a global *de novo* transcriptome from the gonadal tissues from both male and female of *R. clavigera*, with 197,324 assembled transcripts and 151,684 condensed non-redundant transcripts. A blast hit results from the NCBI’s non-redundant molluscan database showed that 28,948 transcripts were successfully annotated with significant matches at an e-value of ≤ 1e-6. Among them, 1,108 transcripts were assigned to a well-defined gene ontology term.

This first transcriptomic study on the gonadal tissues of *R. clavigera* has generated the fundamental information of mRNA transcriptome that paves the path for mechanistic studies of chemical contaminants (e.g., organotins) on this common biomonitor species.

Soil Biodiversity and Ecotoxicology (III)

Revealing the effects of silver-induced selective pressure on soil microbial communities by high throughput sequencing diversity screening

S. Vasileiadis, University of South Australia / Institute of Agricultural and Environmental Chemistry; E. Puglisi, Universita Cattolica del Sacro Cuore / Microbiology; M. Trevisan, Universita Cattolica del Sacro Cuore / Institute of Agricultural and Environmental Chemistry; K. Langdon, NSW Office of Environment and Heritage; M. McLaughlin, CSIROUniversity of Adelaide; E. Lombi, E. Donner, University of South Australia / Centre for Environmental Risk Assessment and Remediation

Silver-induced selective pressure on environmental bacterial communities is likely to become increasingly relevant due to the growing use of silver nanoparticles (Ag-NPs) as antimicrobial agents in biomedical supplies and other commercial products. As Ag from many such applications is ultimately released to the environment, e.g. via the wastewater-biosolids-soil pathway it is important to understand the existing prevalence of silver resistant bacteria and the potential for Ag resistance to spread via the bacterial mobilome. We aimed to explore the effects of Ag on total soil bacterial communities and to identify key changes in relative abundance of bacterial groups after long-term exposure to silver ions. Five Australian soils covering a broad range of physical-chemical properties were exposed to silver for 2 weeks (2W) and 9 months (9M) at concentrations ranging from 50-400 mg/kg of soil while non-treated soils were maintained as controls. Total DNA was extracted from the soils in triplicates and polymerase chain reaction (PCR) based counting (real-time quantitative PCR) and partial sequencing (Illumina MiSeq platform based) of the 16S rRNA gene of Bacteria throughout 100 samples was performed. 16S rRNA gene counts had an immediate significant drop in the 2W samples which either persisted or had recovered in the 9M samples. Sequencing analysis of 1,446,210 sequences revealed an inverse relation of the α-diversity with the 16S rRNA gene counts. Minimal convergence of the community structures was found which could be attributed to the exposure time to silver and the applied dose when samples were collectively analyzed, with the samples grouping according to the soil type of origin throughout statistical tests. However, a major influence of the time of exposure to silver and the applied dose was shown when samples of each of the five soil types were analyzed separately. Distance based redundancy analysis showed that 55-78.1 % of the observed variance could be attributed to these two factors with time of exposure being the more important. Sequences classified into the mycobacterial slow growers were shown to become dominant in the 9M samples of one soil type, irrespectively of the applied dose, according to differential abundance tests. Collectively, our results show that the effects of silver on the total microbial community depend on the pre-exposed communities, and that potentially resistant pathogenic strains can be found in environmental samples.

Modification to seedling emergence and growth test to reduce quantities of test materials

H. McShane, W.H. Hendershot, McGill University / Dept of Natural Resource Sciences

Cost can be a limiting factor in testing potential toxicity of newly-emerging contaminants such as nanomaterials on terrestrial organisms. For example, the effect of potentially hazardous materials on early stage plant growth can be determined using a standard terrestrial seedling emergence and growth test (e.g., OECD Test No. 208, Environment Canada EPS 1/RM/45). In this test, multiple plants (usually 5 or 10 depending on the species) are raised in three or more replicate pots, and growth (shoot and root length and biomass) is recorded 7 or 14 d after planting. Depending on the number of replicates and test material concentrations, the test may require kilograms of soil, and the quantity of the material being tested will be correspondingly large, and possible costly. We present results of a modified terrestrial seedling emergence and growth test in which each plant is grown in a separate receptacle. With this modification, the quantity of soils and test materials required for a terrestrial seedling emergence and growth test may be reduced by more than 60 % compared to the standard growth test. Results are presented for two plant species, two natural soils, and two test materials. These results are compared to those from standard growth tests. The advantages and disadvantages of the modified test are discussed.

467

Non-avoidance behaviour to boric acid could be related with the GABAergic mechanism

C.C. Bicho, Universidade de Aveiro / CESAM Department of Biology; S.I. Gomes, University of Aveiro / Department of Biology CESAM; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; M.J. Amorim, Universidade de Aveiro / Department of Biology and CESAM

Soil invertebrates, e.g. enchytraeids, are known to to be able to avoid unfavourable conditions, which gives them an important ecological advantage. These organisms possess chemoreceptors responsible for the detection of stressors in the environment, which caninitiate body reactions to stimuli, e.g. avoidance behaviour. Avoidance can be assessed following the standard guideline for earthworms (ISO 17512-1 2008), which can be affected by chemicals. Here we foccused on the non-avoidance of boric acid case study using *Enchytraeus crypticus*, studying a selection of target genes via Quantitative Real Time PCR (qPCR) related to neurotransmission pathways: acetylcolinesterase (AChE) and Gamma-AminoButyric Acid (GABA). Results confirmed that *E. crypticus* was not able to avoid boric acid. Further, as concentration increased there was an increase in the “non-avoidance”, indicating a possible effect at the chemosensorial or transmission level. The affected pathway does not seem to be related with the cholinergic mechanism. Evidences indicated that it could be related with the GABAergic system. The gene measurements pointed to a dose-response to boric acid, which is in agreement with the increase in non-avoidance behaviour.

Keywords: mechanism of response; soil invertebrate, avoidance behaviour, neurotransmissor

468

Expression of metallothionein isoforms in embryos of the terrestrial snail Cantareus aspersus reveals early life stage adaptation to metal stress

P. BAURAND, Université de Franche Comté UMR CNRS / UMR ChronoEnvironment; V. Pedrini-Martha, University of Innsbruck / Institute of Zoology; M. Niederwanger, University of Innsbruck; N. Capelli, University of FrancheComte CNRS / UMR ChronoEnvironnement; R. Scheifler, University of FrancheComte / ChronoEnvironnement; A. deVaufleury, University of FrancheComte CNRS / UMR ChronoEnvironnement; R. Dallinger, University of Innsbruck

Metallothioneins (MTs) are ubiquitous metal binding proteins with species-specific, stress-protective and metal-regulatory functions. In adult terrestrial snails, two MT isoforms are involved in metal-specific functions like copper (Cu) homeostasis or cadmium (Cd) detoxification (Dallinger et al. 1997), whilst a third, non-specific isoform binds Cd and Cu simultaneously (Hispard et al. 2008). The gene expression of these three MT isoforms, (CuMT, CdMT and Cd/CuMT) has been explored previously in adults of *Cantareus aspersus* (syn. *Helix aspersa*) (Hispard et al. 2008; Höckner et al. 2011). It was found that the CdMT gene was significantly upregulated by Cd, whereas the two other genes did not respond to Cd or Cu exposure at all. Whilst the embryotoxicity of Cd to *C. aspersus* (hatching success after 20 days of exposure) is known (EC50 = 3.5 mg/L; Druart et al. 2012), no data are available on the expression of the three MT isoforms and their contribution to potential protection against Cd in developing snail embryos. The aim of this study was, therefore, first to look at the expression of the three distinct MT isoforms in Early Life Stage (ELS) of *C. aspersus* by detection of isogene-specific cDNAs and secondly, to quantify their Cd dependant gene upregulation by quantitative Real-Time detection PCR. Our results show that the Cd and Cd/CuMT genes, but not the CuMT gene, are expressed in snail embryos from the first day of development. The transcription of the 3 MT isoforms increased with development time, suggesting that the capacities of metal regulation and detoxification may gradually increase throughout the snail embryogenesis. In control embryos, however, the most important isogene seems to be the Cd/CuMT, whose transcription levels exceeded by far the transcript levels of the other two MT genes. This contrasts with the only minor significance of this gene in adult snails and suggests that in embryos, this isoform may play a comparatively more important function in metal physiology. This function seems not to be related to Cd detoxification. Instead, snail embryos responded to Cd exposure by an over-expression of the CdMT gene, whereas the intermediate Cd/CuMT isogene remained unaffected. Overall our data demonstrate the ability of snail embryos to respond very early to Cd exposure by MT synthesis.

Cd-sensitive and Cd-tolerant COI haplotypes couples in the standard test species Eisenia andrei (Oligochaeta)

L. Voua Otomo, NorthWest University / Zoology; P. Voua Otomo, Unit for Environmental Sciences / Botany and Zoology; C. Bezuidenhout, M. Maboeta, North West University

To test whether metal-resistant and metal-sensitive genotypes could be an inherent part of the genetic make-up of earthworm populations, we used DNA barcoding to identify the three most commonly shared COI haplotypes between 8 populations of the standard test species *Eisenia andrei*. These COI haplotypes (Hap1- Hap3) were subsequently paired up and exposed to Cd in order to assess their differences in sensitivity. A total of six couples were exposed to 0, 25, 50 and 100 mg Cd/kg for 4 weeks at 20°C. The survival, biomass variation and cocoon production of each couple were assessed weekly. Results indicated that couple 6 (Hap3 x Hap3) was

consistently the most sensitive for all endpoints whereas couple 4 (Hap1 x Hap3) was the least sensitive for reproduction. The rest of the couples showed the same responses for all the endpoints assessed. Our findings indicate that earthworm populations may carry intrinsically metal-tolerant or metal-sensitive genotypes. This may explain why a long-term metal exposed earthworm population would show increased tolerance with time. Furthermore, in the context of ecotoxicological testing, our results underline the importance of using genetically diverse population in laboratory testing as earthworm laboratory stocks have been found to be mostly genetically homogeneous. //

Ecolotoxicological evaluation of 2,5-furandicarboxylic acid (FDCA), a novel green chemical from Bio-based industry

G. Chen, Animal ecology group; T. De Boer, Vrije Universiteit / AGCI; N.M. van Straalen, Vrije Universiteit Amsterdam / Inst of Ecological Science; R. Cavill, J. Briede, Maastricht University / Department of Toxicogenomics; D. Roelofs, Vrije Universiteit / Inst of Ecological Science

2,5-Furandicarboxylic acid (FDCA) is a promising biomass-derived chemical with large market potential as an alternative ingredient for polyethylene terephthalte (PET). FDCA can be synthesized from 5-hydroxymethyl (HMF) derived from fructose or glucose. Chemicals used during this process could be released into environment. So ecotoxicological data are requested to assess the ecological impact. We measured dissipation rates of FDCA and HMF in sterile and non-sterile soil. FDCA and HMF are readily biodegradable in nature soils within days, and are suggested to be less stable than currently used phthalic acid. Subsequently, collembolan *Folsomia candida* were exposed to sterile and non-sterile soil spiked with FDCA and HMF (according ISO guidelines). The results show FDCA and HMF could only generate a significant toxic effect on reproduction at high concentration after removing bioactive microbial community in nature soil by sterilization. In the context of human health, we measured whole-transcriptome responses in the human liver cell line HepG2 exposed to concentrations that elicit 20% cytotoxicity. This analyses shows transcriptional regulation is not affected by FDCA when compared to the control. Comparing to studies on current phthalic acid, our findings indicate FDCA and HMF are biodegradable in natural soil and FDCA rarely affects human liver cells.

Community and ecosystem ecotoxicology (III)

Interaction between stress induced by competition and an insecticide on the response of aquatic invertebrates

P.J. van den Brink, Alterra and Wageningen University; S. Klein, Wageningen University; A. Rico, Wageningen University / Aquatic Ecology and Water Quality Management

In order to study the way ecological interactions influence the effects of chemicals on aquatic invertebrates we performed some experiments using the pairs of *Gammarus pulex* and *Asellus aquaticus,* and *Daphnia* sp. and rotifers as examples. This abstract will only describe the results of the experiments performed with *G. pulex* and *A. aquaticus*, but the poster presentation will address all experiments. Two experiments were performed in small aquatic microcosms. In both experiments 1.5 L glass microcosms were stocked with *G. pulex* and/or *A. aquaticus* which were exposed to 0, 0.15, 0.20, or 0.25 µg/L chlorpyrifos. Experiment 1 lasted for 7 days and included two levels of interaction, one with 10 individuals of *G. pulex,* and one with 5 individuals of *G. pulex* and 5 individuals of *A. aquaticus*. In experiment 2 the effects of intraspecific competition was studied in triplicate microcosms containing *G. pulex* in densities of 5, 10, 15, or 20 individuals, which were exposed to of chlorpyrifos for 21 days. To study the effects of interspecific competition, microcosms containing 5 *G. pulex* individuals and 5, 10 or 15 individuals of *A. aquaticus* were exposed to chlorpyrifos. In experiment 1 the mortality of *G. pulex* was higher in the presence of *A. aquaticus*. This increased mortality resulted in a lower mortality of *A. aquaticus* in the higher treatment. Visual observations confirmed that *G. pulex* and *A. aquaticus* not only compete over the same food source but that they also predate on each other. Surprisingly, both the intraspecific experiment as the interspecific experiment of experiment 2 showed a mediating effect of competition on the toxicity of chlorpyrifos on *G. pulex*. Additional experiments on e.g. the predation of the two species on each other might be performed to explain the interactions observed in both experiments. Also the experiments with *Daphnia sp*. and rotifers will be finalised and evaluated.

Effects of intra and interspecific competition on the response of aquatic species to carbendazim: the importance of ecological interactions for risk assessment.

A. Del Arco, UNIVERSITY OF JAÉN / ANIMAL BIOLOGY PLANT BIOLOGY AND ECOLOGY; A. Rico, Wageningen University / Aquatic Ecology and Water Quality Management; S.J. Crum, Alterra Wageningen University and Research Centre; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra

Ecological risk assessment (ERA) of chemicals has the need to increase its ecological relevance to achieve more realistic prediction. In this sense, single standard test organisms lack realism, first because those species may not represent all taxa to be protected; and secondly, ecological interactions are not taken into account. In addition, a fungicide was chosen for the experiments described here since there are fewer studies on theirs impacts in freshwater ecosystem. The present series of studies use two interacting species to explore how important ecological interaction mechanisms as competition influences the responses of the sensitive species to a toxicant. Experiments using small microcosms were performed to assess the ecotoxicological effect of the fungicide Derosal (active ingredient carbendazim) on two interacting populations of: 1) gastropods, *Bithynia tentaculata* and *Radix peregra*; 2) crustaceans, *Gammarus pulex* and *Asellus aquaticus*; and 3) arthropods and non-arthropod zooplankton, *Daphnia magna* and *Brachionus calciflorus*.This abstract describes the results of the first experiment, but the others are in progress and will also be presented orally. The aim of the present work is to understand better how ecological factors modulate direct and indirect population's responses exposed to a toxicant in order to better inform ecological risk assessment. The experiment was design to test the following hypotheses: a) both intra- as interspecific competition will increase species sensitivity and b) intra- and interspecific competition will have a similar impact on this increase of sensitivity. Preliminary results indicate that both, a) the interaction between competition and toxicant, and b) the type of competition have an influence on the response of B. *tentaculata* to carbendazim, although the mechanism is not yet understood. In addition, the immobility shows to have a higher potential as an endpoint to detect effects on *B. tentaculata* than mortality which is most often used. In conclusion, the study shows that more ecological aspects should be included in ERA in order to predict direct and indirect effects at higher ecological scales than the single species one.

473

Interaction between environmental gradients and micropollutants on the structure and functioning of natural phytoplankton communities

F. Pomati, Eawag Swiss Federal Institute of Aquatic Science and Technology / Aquatic Ecology; J. Jokela, Eawag Swiss federal Institute of Aquatic Science and Technology; J. Starrfelt, NIVA; S. Castiglioni, Mario Negri Inst / Environmental Health Sciences; L. Nizzetto, NIVA

Natural populations and communities in aquatic environments are continuously exposed to unnatural chemicals, discharged in waterways by human activities in amounts and rates that pose serious questions with regards to their impact on the resilience of natural systems. Our goal was to understand how the effects of these chemicals interfere with the processes that maintain biodiversity in natural communities. We used environmentally relevant scenarios, targeted multiple endpoints (physiological responses and community effects), and used natural phytoplankton communities in a field experiment. We sampled phytoplankton from a eutrophic lake and spiked communities with a mixture of 12 chemicals (including phyrmaceuticals and personal care products) in permeable membrane-based mesocosms. Treated and untreated communities were put back in the lake at different depths, over an environmental gradient in physical conditions and availability of limiting resources. Phytoplankton communities were analysed before spiking, and 7 days after the pulse of chemical stress. Experiments were subjected to selection by environmental filtering over the depth gradient, and over time due to changes in water conditions towards a more oligotrophic environment. We studied how exposure to mixtures of water-borne micropollutants interfered with the natural processes of sorting organisms based on their ecological and functional traits. We recorded community response variables, including community-wide distribution of important phytoplankton traits (such as size, fluorescence, coloniality), total biomass (productivity), and functional diversity. Analysis of the factorial experiment revealed that depth was always a significant factor, confirming the importance of this environmental gradient as a selection factor on phytoplankton community structure and functioning. Both depth and dose of micropollutants affected negatively the functional diversity of phytoplankton communities, while the mixture of chemicals induced significant increase in individual and community biomass. Interactions between depth and the mixture of micropollutants occurred frequently and appeared to be negative, indicating an antagonistic interaction between chemical stress and natural environmental gradients on our response variables. Our data suggest that in a multiple stressors context (reality), pollutants may interfere with natural environmental filters and affect biodiversity dynamics in natural systems.

474

The importance of direct toxicity and an altered food quality for fungicide effects on leaf-shredding invertebrates

J.P. Zubrod, Institute for Environmental Sciences University of KoblenzLandau / Institute for Environmental Sciences; J. Wolfram, D. Wallace, N. Schnetzer, R. Schulz, University of KoblenzLandau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

Decomposer-detritivore-systems govern the breakdown of leaf litter in streams. In this process, microbial decomposers (especially fungi) are of great importance as they increase the food quality of leaves (i.e. conditioning) for detritivorous macroinvertebrates (i.e. shredders). Fungicides may thus affect shredders by two pathways, namely direct toxicity and an altered leaf-associated microbial community, causing indirect, i.e. food quality-related, effects. To assess the importance of both pathways, the energy processing of the amphipod *Gammarus fossarum* – i.e. feeding, fine particulate organic matter (FPOM) production, and assimilation – was assessed during two 24-d lasting experiments ($n = 65$) using 2x2-factorial designs (factor 1: presence/absence of fungicide(s) in the test medium, factor 2: leaves conditioned in the presence/absence of fungicide(s)). One experiment was conducted with an organic fungicide mixture and one with the inorganic fungicide copper (Cu). Direct exposure to the organic fungicide mixture significantly reduced feeding. In addition, both direct exposure and the consumption of fungicide-exposed leaves significantly reduced the production of FPOM. Most likely this was due to compensational mechanisms to counteract a stress-induced higher energy demand and a lower food quality due to an impoverished microbial community, respectively. In contrast, direct exposure to Cu caused a significantly higher FPOM production, probably to excrete accumulated Cu in the course of detoxification, triggering also a significantly lower assimilation. Moreover, consumption was significantly lower when fed Cu-exposed leaves, which may be a reaction to the higher food quality (i.e. a higher leaf-associated fungal biomass). On the basis of previous studies by the authors, fungicide-induced microbial community changes can be assumed as trigger for the observed indirect effects. Further analyses of the leaf-associated microbial communities are underway to confirm this assumption. Moreover, also the energy reserves of preserved gammarids are analyzed to assess potential effects on animals' physiological fitness. Nonetheless, the presented results already show that besides direct toxicity, indirect, food quality-related effects need to be considered when assessing the risk of fungicides – and other antimicrobial substances – for the heterotrophic food web.

Stressor-induced biodiversity gradients: revisiting biodiversity – ecosystem function relationships

C. Mensens, Ghent University UGent / Biology Department Marine Biology Section; F. De Laender, Université de Namur ASBL / Lab of EnvToxApplEcol; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology; K. Sabbe, M. De Troch, Ghent University / Biology department

Biodiversity - ecosystem functioning experiments typically inspect functioning in randomly composed communities representing broad gradients of taxonomic richness. We tested if the corresponding evenness gradients and the resulting diversity-functioning relationships reflect those found in ecosystems challenged by anthropogenic stressors. Marine benthic diatom communities were exposed to the herbicide atrazine, and the resulting gradients of evenness and ecosystem functioning (primary production, energy content and sediment stabilization) were analysed. Atrazine exposure resulted in narrower evenness gradients and steeper diversity-functioning relations than random community assembly. The disproportionately large decrease in functioning following atrazine treatment was related to selective atrazine effects on the species that contributed most to the ecosystem functions. Our findings demonstrate how the sensitivity to stress and the contribution to ecosystem functioning at the species level combine in driving biodiversity-ecosystem functioning relationships in ecosystems experiencing anthropogenic stress.

Using stable isotope analysis in vegetated flow-through stream mesocosms to study aquatic-terrestrial subsidies

M.V. Wieczorek,

Emergence of aquatic insects provides a considerable energy subsidy to riparian food webs but may also transport contaminant residues. Therefore riparian food webs are at risk to be adversely affected by aquatic contamination. The objective of the present study was to develop an integrated stream mesocosms test design capable of identifying these inter-habit effects and, furthermore, providing a comprehensive approach for current ecotoxicological testing. We chose the widely distributed web-building spider *Tetragnatha extensa* as a representative species for riparian predators. The present study was performed at 4 of the 16 stream mesocosms at the University Koblenz-Landau, Campus Landau (Germany). Meshed cages were placed above the vegetated stream mesocosms, each comprising a strip of a terrestrial model meadow ecosystem and a part of the respective aquatic stream section. Four individuals of *T. extensa* were placed in each meshed cage for a time period of one month and emerging insects were determined qualitatively and quantitatively in separate emergence traps. The analysis of stable $\delta^{13}C$ and nitrogen $\delta^{15}N$ isotope ratios revealed the trophic relationships of the present stream mesocosm community, comprising emerging terrestrial and aquatic insect species and the predatory spider *T. extensa*. Data analysis of prey and spider samples showed that the overall emergence predominantly consisted of aquatic emergence. Evaluation of the present study indicates that the use of stable isotopes ratios in ecotoxicological stream mesocosm studies can provide a tool to identify contaminant related effects of aquatic pollution on riparian food web structure. Therefore, the inclusion of land-water interactions such as trophic cross-ecosystem linkages in ecotoxicological stream mesocosm studies might be a relevant future application to obtain and create more realistic test scenarios.

Identification and prioritisation of hazardous emerging pollutants (III)

Planar-YES in effect directed analysis

S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology; D. Spira, Federal Institute of Hydrology; K. Broeder, Bundesanstalt fur Gewasserkunder; m. schluesener, T. Ternes, Federal Institute of Hydrology; G. Reifferscheid, Biochemistry and Ecotoxicology

The identification of compounds with advers biological effects in complex environmental samples is one of the main challenges in ecotoxicology and environmental chemistry. The effect directed analysis which combines sample fractionation, biological assays and chemical analysis is one of the main strategies for the identification of bioactive substances. The high performance liquid chromatography (HPLC) is commonly used for the fractionation of complex samples. However, the usage of HPLC for sample fractionation suffers from some limitations. First, after fractionation a high number of samples have to be tested resulting in a limited sample throughput. Second, the mobile phase used for the HPLC might interfere with the biological assay. Therefore, the direct coupling of biological assays with thin layer chromatography (TLC) was proposed as an alternative approach. This direct coupling is already well established for the testing of acute toxicity using bioluminescent bacterial which are applied on the surface of the TLC-plate but not for specific bioassays like the yeast estrogen screen (YES). The objective of the presented study was to develop such a method (planar-YES, p-YES) and to test the hypothesis that the described approach is a valuable and robust screening tool for effect directed analysis. Therefore, the method is challenged with real samples which cover various fields of applications, i.e. analysis of wastewater and sediment as well as the characterization of sunscreens. The advantages of this approach lie in its rapidness compared to an EDA-approach with e.g. HPLC and a subsequent analysis of fractions for biological activity and in its robustness. The method allows for the analysis of effects in demanding matrices. The p-YES supports compound identification by the possibility to quickly falsify alternative compounds and by the direct accessibility of the compounds on the TLC-plate to a subsequent analysis by mass spectrometry. Activity profiles of samples can be generated easily which allow a comparative assessment of alternative processes for e.g. wastewater treatment without a detailed chemical analysis. Taken together, the p-YES-approach seems to have a high potential to be used as a fast and robust screening tool for various applications in effect directed analysis which can be used as a complementary approach to the more common combination of HPLC with a subsequent bioassay.

Diagnostic strains of the Salmonella/microsome assay as a potential tool in Effect Directed Analysis – application to a solution-oriented project

G.d. Umbuzeiro, FACULTY OF TECHNOLOGY UNICAMP / LEAL; D.A. Morales, UNICAMP / Leal, FT; F. Kummrow, Universidade Federal de São Paulo

The analysis of previously known mutagenic compounds is not enough to identify all the mutagenic compounds present in environmental samples. Bioassays, like the Salmonella/microsome assay (Ames test), are key elements in an Effect Directed Analysis (EDA) because they can drive the chemical identification of priority pollutants. Specific strains of the Salmonella/microsome assay as a diagnostic tool to help to identify major mutagenic toxicants in the aquatic environment. Some combined groups of strains, such as YG1041/TA98, YG5161/TA1538/TA98 and YG7108/TA1535, provide specific responses to different classes of mutagens. Benzo(a)pyrene, 1-nitropyrene and methylmethanesulphonate were already tested and the the strains showed adequate sensitivity. Water and sediment extracts will be tested in the Salmonella/microsome assay with the microsuspension protocol. The biologically active fractions will be tested in an additional set of higher tier diagnostic to support toxicant identification. The specificities of the different Salmonella tester strains will be exploited to suggest the types or classes of mutagenic chemicals that are present in environmental sample extracts, and chemical analysis will be performed for confirmation of the results. If successful, this approach will be incorporated as a new diagnostic tool in EDA. We intend to identify new mutagenic compounds using the chemical and biological tools proposed, supporting the selection of priority pollutants in an integrated risk based approach. ***Acknowledgement*** – This work is part of the SOLUTIONS Project – FP7-ENV-2013, Grant Agreement 603437

Combining MetFrag and PubMed for tackling environmental "Known Unknowns"
C. Ruttkies, Leibniz Institute of Plant Biochemistry / Stress and Developmental Biology; E. Schymanski, Eawag Swiss Federal Institute of Aquatic Science; S. Neumann, Leibnitz Institute of Plant Biochemistry IPB
Structure elucidation of molecules based on tandem mass spectrometry is becoming the method of choice in analytical environmental chemistry, e.g. to detect emerging pollutants. Computer assisted interpretation remains a challenging task that still needs improvement to deal with the huge amount of data acquired with more and more upcoming high-throughput methods. In this work MetFrag, a tool used for the structure elucidation of molecules based on tandem mass data, was combined with the number of reference information in the literature. Therefore the scoring of MetFrag was adapted to consider the number of references of PubMed for each candidate and tested on 3521 tandem mass spectra of 377 compounds originating from environmental samples acquired at the Eawag. The results showed that an increasing influence of the number references in PubMed yields an optimum of the median rank of the correct candidates and therewith improved the results of the processed data. PubMed's reference information alone showed to be insufficient to identify the correct compound. However, only the combination of *in silico* fragmentation with MetFrag and the number of references showed the greatest improvement. Additionally, this approach was used to predict the putatively correct compound for Challenge 9 of the CAMSI contest 2013.

480
The SimpleBox Solution Multi-media mass balance model to predict environmental fate and ecotoxic effects of mixtures of chemical substances in EU river catchments
D. van de Meent, RIVM / Institute of Wetland and Water Research; D. De Zwart, RIVM / Centre for Sustainability Environment and Health; K. Kramer, Mermayde; L. Posthuma, RIVM / Centre for Sustainability Environment and Health; J. van Gils,
The EU FP7 project SOLUTIONS sets out to deliver a conceptual framework for the evidence-based development of environmental water policies. This will integrate innovative chemical and effect-based monitoring tools with the realisation of an integrated system of source, emission, exposure, effect and risk models. SOLUTIONS aims to relate proven effects of chemical substances in rivers to known uses of these chemicals, in order to describe and predict (future) effects of emerging chemicals on the ecolgical water quality. We have developed a spreadsheet based mass balance model of river catchments that allows estimating the fate and transport of a wide selection of chemicals and their transformation products. As a test, we have applied our model to chemicals known under REACH to be used in the combined catchments of the rivers Rhine, Meuse and Scheldt.

Pollutants of tomorrow and developments in society
S. Moritz; D. Bunke, ÖkoInstitut eV / Sustainable Products Material Flows Division; W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis; R. Altenburger, UFC Centre for Environmental Research / Department of Bioanalytical Ecotoxicology; J. Munthe, IVL Swedish Environmental Research Institute Ltd; L. Posthuma, RIVM / Centre for Sustainability Environment and Health; J. Slobodnik, Environmental Institute; A. van Wezel, KIWA Water Research
Emerging pollutants are monitored in surface waters since the nineties. With progress in analytical chemistry it is possible to analyse these substances in low concentrations. Which pollutants can be expected if future developments in society are taken into account? Such developments are described in a broad range of scenarios. The scenarios on climate change are well known and published by the IPPC. The UNESCO- WWAP Water Scenario Project refers to future trends in water consumption and water resources. Until now, such implications are discussed only for some aspects. The study presented here is part of the SOLUTION project, a research project supported by the 7th Framework Programme of the EU. Existing scenarios for developments of society are identified and analysed, timelines on the production and consumption of environmentally harmful chemicals are evaluated. The second step assesses whether causal links can be seen between societal development and future pollutants. Potential links as well as trends in pollution and risks are discussed with experts from different disciplines with a broad view to address trends and to develop options for risk management. First results indicate several connections between developments in society and emerging pollutants. Because of demographic change, the population in Europe will have a higher life-expectancy. Concomitantly there will be an increase of pharmaceutical consumption. A second development is the change of climate. The IPPC expects a rise in temperature as well as -the increase of extreme weather events. As a result, the behaviour of chemicals in water will change which will influence the ecosystems. Mobilization of chemicals from sediments might be facilitated by erosion, flood events or rising temperatures. Substitution of problematic substances like phthalates also per- and polyfluorinated hydrocarbons (PFCs) might be a further driver which leads to changes in the pattern of pollutants. **Keywords:** emerging pollutants, scenarios, developments, prediction

Environmental risk assessment of nanomaterials: open issues, pitfalls and recommendations

482
Human health no-effect levels of (nano)particles as a function of their primary size
A. Laurent, Technical University of Denmark / DTU Management QSA division; J. Harkema, Michigan State University / Department of Pathobiology and Diagnostic Investigation; O. Jolliet, University of Michigan / School of Public Health
As nanomaterials are increasingly used in a variety of consumer products, potentially leading to the releases of engineered nanoparticles, no fully operational tools within the frameworks of risk assessment (RA) or life cycle assessment (LCA) yet exist to allow for comprehensive and robust assessments of their human health risks and impacts. The large number of potentially influential physicochemical properties and the difficulties to define a metric capturing the relationships between these properties and the toxic effects of nanoparticles are important shortcomings. In this study, we developed a methodology that comprehensively draws on the information available in relevant *in vivo* studies to investigate the possible correlations between these properties and the toxicity of nanoparticles. We apply this methodology to inhalation, ingestion and dermal exposures to TiO_2 and nanosilver particles, for which we reviewed 112 and 48 studies, respectively. For each of them, we reviewed nonneoplastic responses to identify the incidence or absence of adverse effects, and we analysed the relationships between these incidences/absences and the particle primary size using multiple linear regressions. Our results show that a statistically-significant, continuous co-variance of the animal no-observed-adverse-effect levels (NOAEL) with the primary particle size seems to exist. These findings can have important consequences for nanotoxicologists and policy-makers as human size-dependent NOAELs can thus be derived and enable refined, case-specific assessments related to occupational and consumer exposure to engineered nanoparticles. In that setting, the application of our results to specific TiO_2 exposure situations resulted in potentially important risks. Yet, these results should be used with caution as large uncertainties exist, e.g. the mismatch between the nanoparticles tested in toxicological studies and the actually released particles. Therefore, our study can be considered an important step forward for achieving consistent assessments of risks and impacts of nanoparticles, but it also highlights important research needs to be addressed before fully reliable impact and risk assessments of nanomaterials can be made.

483
Species Sensitivity Weighted Distribution (SSWD) as screening tool for ecological risk assessment of engineered nanomaterials: The n-TiO2 case study
E. Semenzin, Ca Foscari University of Venice / Department of Environmental Sciences Informatics and Statistics; E. Lanzellotto, University Ca Foscari of Venice; D. Hristozov, Ca Foscari University of Venice; A. Critto, University Ca Foscari of Venice; A. Marcomini, University of Venice / Department of Environmental Sciences Informatics and Statistics
Nanotechnology is an emerging field in the area of science and technology. Due to their unique or enhanced physicochemical properties, some engineered nanomaterials (ENMs) such as nanoscale titanium dioxide (n-TiO_2) are suitable for a wide variety of applications in many sectors (e.g. cosmetics, paint). For this reason the market of n-TiO_2 has been exponentially growing to reach 2 400 000 million tons in 2026 only in the US. At the same time, societal concerns regarding the potential environmental and health risks from this material have increased and need to be addressed trough robust risk analysis. Nevertheless, due to significant epistemic uncertainties and methodological limitations the quantitative Ecological Risk Assessment (ERA) of n-TiO_2 is still beyond the state of the art. Therefore we propose a complementary approach for screening-level ERA that provides a quantitative estimation of ecosystem effects from exposure to ENMs. The methodology further develops the Species Sensitivity Weighted Distribution (SSWD) approach by including three weighting criteria (i.e. species relevance, trophic level aboundance and data quality) to address nano-specific needs. This nano-SSWD model was tested with ecotoxicological data for n-TiO_2 including 189 ecotoxicological endpoints (e.g. LCx) for species representative of the freshwater, seawater and soil compartments. The application of the model resulted in estimation of environmental quality criteria (i.e. Hazard Concentration affecting 5% of the species) and ecological risk (i.e. Potentially Affected Fraction of species). These results were then compared to similar results from applying the conventional SSD approach to the same dataset. SSWD were also built for specific trophic levels (e.g. primary producers) and taxonomic groups (e.g. bacteria) thus allowing to identify the more sensitive ones. The SSWD approach resulted to be a valuable tool for a screening-level ERA allowing to incorporate the data quality evaluation and to obtain a cautelative risk estimation (slightly lower than the one obtained with the conventional SSD) although accounting for intraspecies variation (i.e. species

relevance criterion). However, in order to obtain more reliable results, it is suggested to test the approach to a more complete dataset, once available. Finally, further developments envisage the need to combine the weighted SSD approach with a probabilistic one in order to address a higher risk assessment level of ENMs.

484
LCA-RA combined approach by using a Bayesian model: example of the aquatic ecotoxity impact/risk of the Nano TiO2 production.
V. Adam, University of Strasbourg CNRS / Laboratory of hydrology and geochemistry of StrasbourgFrance; G. Quaranta, Université of Strasbourg CNRS / EOSTLHYGES; S. Lawniczak, University of Strasbourg CNRS / LHYGESEOST
Titanium dioxide (TiO_2) has been commercially produced since the early 20th century for its refractive index propriety "Grubb G.F. and Bakshi B.R., 2010". These TiO_2 particles are rutile of 250 nanometers (nm) to 1 micrometer (μm) in diameter. Anatase-phase TiO_2 particles (with a diameter between 1 and 100 nm) are commercialized for several years in the cosmetics industry but also for their photocatalytic properties. TiO_2 nanoparticles offer a big potential to improve the performance of final products but there are unanswered questions about their impacts on human health and the environment. To appreciate the uncertainties regarding the nano TiO_2 potential impacts and risks on the environment we combine Life Cycle Assessment (LCA) and Risk Assessment (RA) approaches. LCA is a chain-oriented tool to evaluate environmental impacts of a product during its entire life cycle, from the extraction of raw materials, via manufacturing and use, to the waste product final disposal. The data concerning the raw materials consumption and pollutants releases to various environmental compartments are identified and quantified in the life cycle inventory analysis step. These data are converted in environmental impact in the Life Cycle Impact Assessment step (LCIA). The purpose of LCIA is to express the impact in term of category indicator which is calculated multiplying the emission with the fate and effect factors of the nanoparticle. Risk is expressed as a product of an exposure probability and the probability of a resulting hazard such as a reduction in survival of a group of organisms or impaired ecosystem function "Kaplan S., Garrick BJ., 1981". LCA and RA both rely on the same type of data, that are on the one hand emissions into the environment and transfer to the different environmental compartments (fate/exposure), and on the other hand ecotoxicological data (effect/hazard). However, high uncertainties remain concerning the fate and the effect of nanoparticles, so a probabilistic approach such as Bayesian network is used in this nano TiO_2 study. The network gives satisfying results and allows direct visualization of the uncertainties. Two main steps of the Bayesian network are presented to study the aquatic ecotoxicological risk of a TiO_2 production. We focus the communication on the structure of the network, consisting of nodes (variables) and arrows (relationships between variables), and on the probability tables of each variable.

485
A proposal for regulation of nano-Ag, nano-ZnO and nano-CuO based on comparison to dissolved metals
B. Nowack, EMPA; D. Notter,
In the recent past a lot has been written about the utmost urgency to elaborate regulations based on the toxicity of engineered nanoparticles. However, developing regulations seems to be a difficult task and an ambiguous topic where errors can occur easily. Writing more reviews going through the same literature again and again will not provide new information but rather create the unfortunate situation of paralysis by analysis, because a review usually identifies new research needs. The task is definitely highly complex, but does this render impossible finding a first pragmatic valuation for regulation purpose? Our study presents a pragmatic way for a potential regulation for three types of metal and metal oxide nanoparticles with respect to their ecotoxicological hazard potential. Nano-Ag, nano-ZnO and nano-CuO are relatively easy soluble particles. We evaluated studies reporting LC/EC50 values for both the nano-form and dissolved metals for the same test system and organism. We thereby establish a database to detect nanoeffects based on total metal concentrations in the test system. For freshwater and terrestrial organisms the vast majority of the ratios is below 1. For freshwater only 9 of 262 data points (3.4%) and for terrestrial systems only 1 of 15 data points (6.7%) have a ratio above one, indicating that the nano-form is in most cases less toxic than the dissolved ion using total metals concentrations as a metric. The maximum ratio observed was 2.4 for freshwater and 1.3 for terrestrial organisms. For nano-ZnO and nano-CuO the distribution of the ratios was similar. For freshwaters the percentage of data points above one was 18.8% for ZnO and 3.3% for CuO. This comprehensive evaluation of the ecotoxicological literature shows that over all published data spanning a wide range of different organisms, different forms of the nanomaterials, test systems and exposure conditions only few combinations of parameters resulted in a toxicity of the nanomaterials that was higher than that of the same mass of dissolved metal. This evaluation shows that OVERALL the toxicity in the vast majority of the cases was les for the nanomaterials than dissolved metals based on total concentrations. Use of the existing regulations for dissolved metals is therefore able to protect in almost all systems also the organisms from nanomaterials. By using a safety factor of two we can protect almost 100% of all organisms in freshwater and terrestrial systems.

What are appropriate fate descriptors and modelling approaches to predict environmental concentrations of engineered nanomaterials for risk assessment?
A. Praetorius, ETH Zurich / Institute for Chemical and Bioengineering; M. Scheringer, ETH Zuerich / Institute for Chemical and Bioengineering; F. Von der Kammer, Vienna University / Department for Environmental Geosciences; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering
A comprehensive risk assessment of any substance requires a combination of hazard and exposure assessment. In this context, environmental fate models that predict environmental concentrations play an important role, especially in the case of engineered nanomaterials (ENMs), where measured environmental concentrations are not yet available due to significant analytical challenges. Environmental fate models are well-established tools used for decades in the risk assessment of organic pollutants. They are based on a set of essential chemical property data, namely degradation half-lives in different environmental media and partition coefficients describing a chemical's relative affinity for different environmental phases. However, due to the fundamentally different properties of ENMs compared to organic pollutants, the concepts and models valid for organic pollutants cannot simply be used for ENMs. Here we present a new concept for environmental fate models for ENMs. The environmental fate of ENMs is dominated by aggregation (homo- and heteroaggregation), transformation (e.g. dissolution, surface transformation, degradation of organic coatings) and sedimentation processes. In contrast to organic chemicals whose environmental fate is largely governed by equilibrium partitioning, the fate of ENMs is exclusively kinetically controlled, because ENMs do not reach thermodynamic equilibrium but are present in the environment as unstable suspensions. Here we provide a detailed analysis of the underlying concepts of equilibrium partitioning and colloid science. We discuss several examples from the literature that directly or indirectly prove that partition coefficients cannot be determined for ENMs. An appropriate fate descriptor that can be used however to describe the interaction of ENMs with natural particles in an environmental fate model is the attachment efficiency, α_{hetero}, which describes the surface interaction of ENMs and natural solid particles by quantifying the probability of successful attachment upon collision. In the context of risk assessment it is important to recognize the differences between conventional pollutants and ENMs and to adjust existing methods carefully and adequately to account for the ENM specific properties. The implications of wrongly using partition coefficients in fate predictions for ENM risk assessment can be significant as they misrepresent the fate processes of ENMs and lead to wrong predicted environmental exposure concentrations.

Predicting molecular properties of environmental contaminants

487
QSARINS: a new software for the development and validation of MLR models and QSARINS-Chem: Insubria datasets and new QSAR/QSPR models for environmental pollutants.
P. Gramatica, University of Insubria / QSAR Res Unit Environ Chem Ecotox Dep Theoretical Applied Sciences DiSTA; N. Chirico, University of Insubria / QSAR Research UnitDepartment of Theoretical and Applied Sciences; S. Cassani, University of Insubria / DiSTA; s. kovarich, SIN Soluzioni Informatiche Srl / QSAR Res Unit Environ Chem Ecotox Dep Theoretical Applied Sciences DiSTA; E. Papa, QSAR Res Unit Environ Chem EcotoxDep Theoretical Applied Sciences DiSTA
QSAR models, correctly developed and rigorously validated, are highly useful for screening and prioritizing chemicals without experimental data or even before their synthesis in the safe chemical design approach. Their use in regulation is suggested in the European legislation of chemicals REACH,in particular to reduce experimental costs and tests on animals. In recent years particular attention has been devoted to the validation of QSAR models, and the "OECD principles for the validation of QSARs models for their application in regulation" have been established to increase the confidence on the reliability of data predicted by QSAR models. We propose the new software QSARINS (QSAR-INSUBRIA), for the development of Multiple Linear Regression (MLR) models, by Ordinary Least Squares (OLS), and by Genetic Algorithm (GA) for variable selection. This program is mainly focused on the internal and external validation of QSAR models by various statistical parameters. Additional features implemented in QSARINS include tools for explorative analysis of the datasets by Principal Component Analysis, dataset splitting, applicability domain analysis (e.g., detection of outliers and interpolated or extrapolated predictions), consensus modelling, selection of the best model by MultiCriteria Decision Making (MCDM) and various plots. QSARINS is a user-friendly platform for QSAR modeling in agreement with the OECD Principles and for the analysis of the reliability of the predicted data. QSARINS-Chem, a module of QSARINS, includes several datasets of

environmental pollutants characterized by chemical structures (Hyperchem and Mol formats) and several end-points (physico-chemical properties and biological activities). The chemicals with the related data are accessible in different ways (by CAS, SMILES, names, etc.) and their 3D structure can be visualized. Additionally, some QSAR models based on molecular descriptors calculated by the free online software PaDEL-Descriptor are implemented in QSARINS. Among them the Insubria Persistent Bioaccumulative and Toxic (PBT) Index model for the prediction of the cumulative behavior of new chemicals as PBTs. The new PaDEL-Descriptor models can be easily applied for future predictions on chemicals without experimental data, verifying the Applicability Domain to new chemicals without data. The QMRF of all these PaDEL models is available. QSARINS-Chem can be also used as a management tool of custom datasets and models.

Predicting Equilibrium Partitioning of organic chemicals – Validation of Existing Models

K. Goss, Department of Analytical Environmental Chemistry; S. Endo, Helmholtz Centre for Environmental Research UFZ / Department of Analytical Environmental Chemistry; A. Stenzel, Analytical Environmental Chemistry

As part of the assessment of the environmental behavior of organic chemicals we need models that are able to predict equilibrium partitioning between various phases with only the molecular structure of the solute as input information. A frequently used approach to reach this goal is to predict $K_{air/water}$ (K_{aw}) and $K_{octanol/water}$ (K_{ow}) by increment methods and then use empirical correlations to predict environmental partitioning between water and other condensed phases from the predicted K_{ow}. However, octanol is not an ideal surrogate for many organic phases in the environment. Hence, it is beneficial to use more direct methods such as ABSOLV, SPARC and COSMOthermX that offer a comparably broad applicability. For none of these methods there is much of an independent validation (i.e. with data not used in model calibration) available. Especially a validation with experimental data of high quality for multifunctional complex compounds is rare. Here we present such a validation for up to 270 complex organic chemicals including pesticides, flame retardants, siloxanes and others. The experimental data used was only measured in one research group (our own) and subject to a thorough quality and consistency control. The validation systems include heptane/propylene carbonate, ethylene glycol/1,2-dichloroethane, heptane/2,2,2-trifluoroethanol, and poly(dimethyl siloxane) (PDMS)/water. Though they are not related to environmental partitioning systems, they represent all types of relevant interactions such as hydrogen bonding properties or van der Waals interactions. In our validation we found ABSOLV and COSMOthermX to perform the best with an average root mean squared error (rmse) of 0.80 and 0.79 log units, respectively. Considering the differences of the validation systems, the rmse ranges are relatively small, i.e., 0.64 to 0.95 log units (ABSOLV) and 0.65 to 0.93 log units (COSMOthermX) suggesting a system-independent prediction accuracy. We suggest that these predictive uncertainties can be used as a benchmark for ranking other predictive methods and for defining error margins in decision processes that use results from these methods.

489

Measuring logP>8.5 for risk assessment – a question of standards

F. Begnaud, Firmenich / DRAP; J. Larcinese, P. Fankhauser, U. Maddalena, Firmenich

Assessing the (eco)-toxicological effects and fate of chemical substances in the environment requires to know their physico-chemical characteristics like water solubility and logP. From these data some ecotoxicological results can be deduced by application of dedicated QSARs, which are highly desirable to avoid test on animals, reduce study cost and improve throughput of data generation. Our work focuses on evaluating the different approaches allowing to measure or estimate highly hydrophobic logP (greater than 8.5) with a satisfying accuracy. *In silico* models have been investigated, but clearly robust datasets are missing to ensure accurate results. Standard OECD procedures for logP determination encompass logP values from -2 to +8.2 (OECD 107, 117, 123). For higher logP ranges, extended HPLC measurements can be considered. However non-chemically related standards are often used, which leads to significant discrepancy and poor accuracy of the logP value. Considering a properfume (Haloscent®D) with estimated logP > 9.0 as model substance, we have investigated the possibility to extrapolate "Reversed phase-HPLC logK vs. logP" calibration curve to determine its logP and have evaluated the corresponding accuracy. The impact of the standards on the accuracy of the measurement of logP for this very hydrophobic compound has been determined and it has been demonstrated that strict homologues ensure the best accuracy in the logP evaluation. The strong correlation between the retention factor on reversed-phase HPLC and the number of carbon of the homologues demonstrates that extrapolation is feasible at least up to the target compound. From this study the logP of the properfume is 9.7+-0.3. The logP of its homologue with 8 carbons on the alkyl side chain is 7.8±0.3. Extrapolating logP values from the regression between RP-HPLC retention factors vs. logP can lead to accurate results for highly hydrophobic compounds. Using structurally related standards is key to get the best possible accuracy and limit systematic bias that may occur. This approach can be extended to other compounds to generate robust set of data for high logP and ecotoxicological endpoints estimation by QSARs.

Influence of pH and cations on the speciation, bioavailability and toxicity of uranium in Lemna minor

n. Horemans, Belgean Nuclear Research Centre SCKCEN / Biosphere Impact Studies; M. Van Hees, Belgian Nucrlear research centre (SCK-CEN); C. Willrodt, Bundesamt für Strahelschuts BfS; T. Turtiainen, Radiation and Nuclear Safety Authority STUK; H. Vandenhove, Belgian Nuclear Research Centre SCKCEN / Biosphere Impact Studies

Uranium is naturally present in both aquatic and terrestrial environments. In freshwater its average concentration typically ranges from 0.01 to 6.6 μg/L in various oxidation states and forms. Due to anthropogenic activities its concentration has locally risen to levels that pose potential ecological risks. Uranium toxicity is known to depend on its redox state, speciation and physiological form with the aqueous UO_2^{2+} and UO_2OH^+ hypothesized to be the most toxic species. To assess the impact of different cations or pH on the toxicity of uranium on plants, a growth inhibition test was set up in which *Lemna minor* was exposed to different uranium concentrations ranging from 0.05 μM up to200 μM for 7 days in varying proton or cation concentrations (Ca^{2+}, Mg^{2+}, Na^{2+}, K^+). In general OECD guidelines (226) were followed except for the phosphate concentrations that were kept to a maximum of 0.5 mg/L to limit the formation of precipitating U-phosphate complexes. Toxicity of U expressed on nominal concentrations decreased with increasing Ca concentrations. Changing Mg and K did not seem to influence U toxicity. At the time of writing experiments for different Na concentrations were still on going. Strongest effect was, however, found for the different pH values where the toxicity clearly decreased with increasing pH. The EC50 value increased from 40μM at pH of 5 (the standard pH-level used in the OECD-growth inhibition test) to 110μM at pH 6. At pH 7 and 8 the EC50 could not be established as no sufficient growth inhibition to calculate the EC-values could be obtained within the tested U-concentration range. At pH 6 and 7 U started to precipitate probably as U-phosphate complexes and as such U concentration were lower than expected at these pH values. Further, as expected from literature pH also clearly influenced the speciation of U in the test medium. As modelled by Geochemist WorkbenchÒ, uranyl (UO_2^{2+}) was the most dominant species at pH 5, at pH 7 U-phosphate complexes were mostly present and finally at pH 8 more U-carbonate was formed. The data clearly support the hypothesis that uranyl is the most toxic U-species for Lemna. Toxicity was similar between pH5, and pH6. and at pH6 uranyl levels were lower but higher UO_2OH^+ concentrations were predicted. Hence, the data further indicate that also UO_2OH^+ will contribute to U toxicity in plants. The data obtained in this study will be further used to establish a Biotic Ligand Model for U in plants.

Ecotoxicity Analysis of Cholinium-based Ionic Liquids

S. Ventura, University of Aveiro / Chemistry; J. Pereira, University of Aveiro & CESAM / Department of Biology; F.L. Silva, University of Aveiro / Chemistry; A.M. Goncalves, IMAR-Institute of Marine Research, Department of Life Sciences, University of Coimbra / Department of Life Sciences; F. Goncalves, University of Aveiro CESAM / Department of Biology; J.L. Coutinho, University of Aveiro / Chemistry

Ionic liquids (ILs) are salts with low melting points, liquid at or close to room temperature, and cholinium-based ionic liquids are quaternary ammonium salts with a wide range of potential industrial applications. Based on the fact that the cholinium is a complex B vitamin and widely used as food additive, cholinium-based ionic liquids have been seen as environmentally harmless and thus, accepted as non-toxic, although their ecotoxicological profile is poorly known. The present communication provides new ecotoxicological data for ten cholinium-based salts and ionic liquids, aiming to extend the surprisingly restricted body of knowledge about the ecotoxicity of this particular family. Furthermore, insight was gained in counteracting two widely accepted principles ruling ILs ecotoxicity, the side-chain effect until a cut-off level and the decrease in toxicity with the functionalization of the cation. Given the wide range of structures that can be engineered within the same IL family to respond to function and environmental challenges, assessments allowing the establishment of structure-activity relationships such as that performed here are of great use for the proper design of “optimal” ILs from a technical and environmental point of view, minimizing the array of final ILs undergoing mandatory and costly prospective risk assessment before licensing. The results show that not all the cholinium tested can be considered harmless towards the test organism adopted (the standard marine bacteria *Vibrio fischeri*). Moreover, data suggest that the cholinium family exhibits a different mechanism of toxicity as compared to the imidazolium ionic liquids previously described in the literature.

Estimation of toxicological properties using internet accessible models

M. Vracko, Kemijski inštitut / Laboratory of Chemometrics; A. Plosnik, Kemijeki

inštitut

QSAR methods became an important alternative to animal testing, to fill data gaps in hazard assessment and in classification and labelling of chemicals (e.g. the U.N. Globally Harmonized System for chemical labelling, or, the European chemical regulation known as REACH). The widely known public available programs are: VEGA, TEST, and OECD QSAR Toolbox. The models have been developed under consideration of OECD principles for validation of (Q)SAR models used for regulatory purposes. In the presentation an accent is placed on VEGA platform and the four toxicological endpoints predicted by CAESAR programs: mutagenicity, carcinogenicity, developmental toxicity and skin sensitization.The predictions for three data sets are discussed: the set of 27 conazoles, the set of Poly Aromatic Hydrocarbon (PAHs), and the set of compounds taken from the CosIng inventory.

Statistical challenges in ecotoxicology

493

Choice and Evaluation of Statistical Models Used to Analyze Ecotoxicity Experiments

J.W. Green, DuPont / Applied Statistics Group

Criteria are presented by which to evaluate statistical models that might be used to analyze ecotoxicity experiments. These include experimental design considerations, control variability, concentration-response shape, goodness of fit, number of parameters to estimate, normalization of responses, and model uncertainty. Distributional properties of model estimates are developed and shown to be important indicators of model quality. In particular, the ability to estimate ECx for values of x ranging from 10 to 50 is explored as a way of demonstrating capabilities and limitations of models to provide regulatory required values is explored. Special attention is given to fish early life stage, fish sexual development, mollusc reproduction, and terrestrial plant experiments. Examples of good and bad modeling strategies from guideline studies are given.

494

Generalized mixed models for ecotoxicology: avoiding pseudoreplication and unnecessary data transformations

W. White, Biology and Marine Biology; S.M. Brander, University of North Carolina Wilmington / Department of Biology Marine Biology

Ecotoxicological data present a number of challenges for analysis: 1) nonlinear responses (e.g., dose-response curves); 2) non-normally distributed data (e.g, count or proportion data); and 3) non-independence of data points. The latter issue, termed ‘pseudoreplication’ in the ecological literature, often arises when there are latent or insidious factors causing some replicates to be more alike one another, such as samples run on the same gel, or fish reared in the same growth chamber. All three of these factors violate key assumptions of traditional linear parametric statistics (ANOVA and regression). Fortunately, recent developments in statistical computing allow the use of generalized linear mixed models (GLMMs): analyses that allow for nonlinear responses with non-normal data (making it a ‘generalized linear model’) and incorporate random effects that account for differential covariance among replicates (thus a ‘mixed’ model containing both random effects and the main fixed effects). GLMMs offer a powerful alternative analytical approach with two major advantages. First, they permit fitting models to the natural distribution of the data (e.g., Poisson distribution for count data, binomial distribution for proportional data), rather than relying on elaborate transformations of dubious effectiveness (e.g., logarithmic, probit, arcsin square root) to achieve linearity and normality. This improves the predictive ability of the model. Second, they allow an explicit accounting of the true covariability structure of the data, ensuring that latent non-independence does not produce erroneous results or improper p-values. We show the advantages of GLMMs using examples from laboratory experiments on endocrine disruption in fishes, illustrating the improvements in inference and highlighting potential pitfalls in designing and fitting GLMMs.

495

MOSAIC_repro: a new user-friendly web interface to analyse bioassay reproduction data directly on-line

S. Charles, University Lyon / Laboratory of Biometry and Evolutionnary Biology; P. Veber, Université Claude Bernard Lyon 1 / Laboratoire de Biométrie et Biologie Evolutive; P. RUIZ, University of Lyon; M. Delignette-Muller, VetAgro Sup

MOSAIC stands for “*MOdeling and StAtistical tools for ecotoxicology*”. In ecotoxicology, bioassays are classically conducted to measure acute or chronic effects of potentially toxic substances on reproduction, growth and/or survival of living animals. MOSAIC is a user-friendly web interface dedicated to the mathematical and statistical modelling of such bioassay data. Its simple use makes MOSAIC a turnkey decision-making tool for ecotoxicologists and regulators. Without wasting time on extensive mathematical and statistical technicalities, users are given advanced and innovative methods for a valuable quantitative environmental risk assessment. MOSAIC is available at http://pbil.univ-lyon1.fr/software/mosaic/. Today, MOSAIC offers two operational tools : (i) MOSAIC_SSD, a tool dedicated to the species sensitivity distribution (SSD) approach aiming at defining safe levels for toxic compounds in an ecosystem through the calculation of the so-called hazardous concentration for *p*% of the species (*HCp*), even when the toxicity values are censored [1, 2]; (ii) MOSAIC_repro, which provides users with a complete statistical analysis of bioassay reproduction data simultaneously accounting for mortality all along the bioassay. For that purpose, concentration-response models are fitted within a Bayesian framework. This presentation will show all features offered by **MOSAIC_repro**, based on several example datasets, all published and chosen among those offered within the web interface itself. Only a minimal statistical background will be given for a better understanding. We will show how to simply enter a dataset by uploading a tabular file containing reproduction data under a simple text format, and also the way results are provided: (i) raw data in two separate plots: one for survival and the other for cumulative reproduction; (ii) the fitted curve superimposed to the reproduction data expressed per individual-day; (iii) parameter estimates with 95% credible intervals (also named Bayesian confidence intervals); (iv) ECx (x= 5, 10, 20, 50) median values with 95% credible intervals. A collection of MOSAIC_repro screenshots will illustrate how MOSAIC_repro is very user-friendly for any user.

496

The development and application of the probabilistic exposure-response space in describing toxicity for ecological risk assessment

W.G. Landis, Western Washington University / Institute of Environmental Toxicology; A.F. Johns, Western Washington University / Institute of Environmental Toxicology Huxley College of the Environment

Results from toxicity testing in environmental toxicology commonly are reported as point estimates either from hypothesis testing or regression analysis. In contrast, a risk analysis requires a probabilistic characterization of the exposure-response curve surrounding a target set for decision-making. We propose a derivative of the regression model, the probabilistic exposure response space (PERS), to meet the requirements. The PERS describes the probability distribution associated with a response level, the associated exposure range and the slope of the curve in this region. In PERS the exposure-responsevalue (ER_x) becomes a distribution bound by the upper and lower limits of the response axis, the upper and lower bounds along the concentration axis and the likelihood of each exposure and response combination. As a test of the approach we characterized the PERS for a set of chemicals with varying modes of action and with results of the toxicity tests to daphnia published in peer reviewed journals. Original datasets were kindly supplied by the authors of the papers. A 3-parameter log-logistic model was used to determine the regression and 95 % confidence intervals were generated. For these comparisons the ER_{20} was selected and values corresponding to the concentrations at the low and high range of the value determined. The PERS approach allowed comprehensive understanding of the exposure-response relationships. For example, the concentration of parathion corresponding to an ER_{20} value for immobilization of *Daphnia magna* resulted in effects ranging from 8 to 42 percent. Next the PERS approach was applied to describing the exposure-response relationships between mercury and fish as part of a regional risk assessment. The data from Dillon et al (2010) were analyzed with estimating the ER curve and the confidence intervals. Comparison of these effects levels to the thresholds constructed using NOEC and LOEC values (Depew et al 2012) demonstrated that these thresholds corresponded to generally unacceptable effect levels. The use of PERS allows for an innate integration of probabilistic information into the risk assessment and also places specific criteria for the design of toxicity tests to be used for environmental risk assessment.

497

Hierarchical modelling of species sensitivity distribution: a case study with diatoms exposed to several herbicides

G. Kon Kam King, Université Claude Bernard Lyon / Laboratoire de Biométrie et Biologie Evolutive; F. Larras; S. Charles, University Lyon / Laboratory of Biometry and Evolutionnary Biology; M. Delignette-Muller, VetAgro Sup

The Species Sensitivity Distribution (SSD) is a key tool to assess the ecotoxicological threat of contaminant to biodiversity. It predicts safe concentrations for a contaminant in a community. Widely used, this approach suffers from several drawbacks : i)summarizing the sensitivity of each species by a single CEC entails a loss of valuable information about the other parameters characterizing the concentration-effect curves; ii)it does not propagate the uncertainty on the CEC into the SSD; iii)the HCp only indicates the threat to biodiversity (structural response of the community), without any insight about a functional response of the community. We revisited the current SSD approach to account for all the sources of variability and uncertainty into the prediction and to assess the risk from a functional point of view. For this purpose, we built a global hierarchical model including the concentration-response model together with the distribution law for the SSD. We applied this methodology to study the herbicide toxicity on benthic diatoms from lake Geneva. The classical SSD approach is to model the EC50 distribution. Contrastingly, the hierarchical approach aims to model simultaneously the distributions of all the concentration-response curve

parameters. We work within a Bayesian framework which provides the output of the hierarchical model as a posterior joint distribution of parameters for the whole community. From this joint distribution, it is possible to compute an SSD on any x of the ECx without going back to the concentration-response curve. This SSD includes all sources of uncertainty, propagated from the original raw data. Studying the evolution of the HC5 as a function of the x of the ECx, it was found that the confidence interval on the HC5 expands wildly at low values of x. This casts doubts on the usability of the EC10, for instance, to build an SSD to estimate the HC5 setting water quality standards, although the EC10 is one of the endpoints recommended by EU's Water Framework Directive. From model simulations, it is also possible to extract a quantitative indicator of the functional response of the community to the contaminant. Using this indicator, we compared the functional and structural response of a community of diatoms and found that for low concentrations, the herbicide had a stronger adverse effect on the daily growth in fluorescence than on the biodiversity. This new approach offers new insights on SSD.

498

Quantifying uncertainty in trophic magnification factors using Bayesian inference.

J. Starrfelt, NIVA; A. Ruus, NIVA / NIVA; E. Fjeld, Norwegian Institute for Water Research; K. Borga, Department of Biosciences University of Oslo / Departmenf of Biosciences

Food web biomagnification is increasingly assessed by estimating trophic magnification factors (TMF) where solvent (often lipid) normalized contaminant concentration is regressed onto the trophic level, and TMFs are represented by the slope of the relationship. In TMF regressions the trophic levels are assumed independent and not associated with variability or uncertainty pertaining to e.g. quantification. In reality, the trophic levels may vary due to measurement error in stable isotopes of nitrogen ($\delta^{15}N$) of each sample, in $\delta^{15}N$ in selected reference baseline trophic level, and in the enrichment factor of $\delta^{15}N$ between two trophic levels (ΔN), which are all needed to calculate trophic levels. While there is a great need in taking these uncertainties into account, there is a separate demand for reducing the uncertainty with the metric itself. In this study we show that by adding knowledge about the structure of the food web we can both estimate all the relevant parameters (diets, enrichment factors etc), thus taking the uncertainty into acount, while also being able to narrow down the variability in the predicted TMF by using Bayesian inference.

Teaching and communicating sustainability – paving the way to a common understanding and meaningful actions

499

Problem Based Learning and sustainability: experiences from teaching LCA at Aalborg University

M. Pizzol, L. Soren, Aalborg University / Development and Planning; J. Schmidt, Aalborg University

Problem-Based Learning (PBL) is a style of active learning based on problem solving. PBL aims at providing university students with flexible knowledge, capacity to self-learning, and skills in problem solving and collaboration. In this context, the present study explores the advantages and challenges that the PBL model offers for developing five key competences in sustainability: (i) system thinking, (ii) interpersonal competence, (iii) anticipatory competence, (iv) strategic competence, (v) normative competences. The study draws on the experiences from PBL activities performed at Aalborg University (AAU), Denmark, and focuses on the teaching of Life Cycle Assessment as a method for sustainability assessment. The objective is providing recommendations for future LCA teaching and learning. PBL activites performed at AAU were evaluated critically to detemine to what extent they addressed and contributed in developing the five competences. Stenghts and areas for improvement were identified. The study is based on direct observation of activities of students and teachers and its scope is limited to the activities on the topic of LCA during the academic years 2006-2013. The study provided examples of how PBL-approaches were used to develop five specific competences in sustainability. It is concluded that -for the case fo LCA teaching at AAU- the PBL model included activities to develop system thinking, interpersonal competence, and normative competence. However, the PBL approach should be strenghtened regarding its application to the development of anticipatory and stragegic competences.

500

Coaching instead of teaching LCA: 20 Years of experience at universities of applied science

T. Kägi, F. Dinkel, Carbotech AG

This presentation describes how we teach or better coach LCA. We have been using this approach with success since several years in diverse courses at the level of university of applied science. It involves students in active, projectbased learning, fosters their creativity, and enables their learning in context. The exercise lends itself to developing and exercising all levels in Bloom's Taxonomy of Learning. Over the last 20 years, we have used LCA case studies on real problems with great student involvement and excitement. Our observations have highlighted to us numerous features on the value of case study based coaching. These factors of student learning are: Working with ill-defined problems, handling the unknown, asking the right questions, relevance of context in solving problems, Importance of interdisciplinary team work, responding to diversity in students, values in decision making, practical experience. In summary, the didactic method case study presents various facets of environmental science, engineering, and decision making to the student. It develops systemic thinking, technical content knowledge, interdisciplinary knowledge, decision making skills, and group interaction and communication skills. Pedagogical and motivational factors such as teaching knowledge in context, learning through trial and error, extended periods of observation, seeing the use of the material learned attract and retain all students. The case study setting also lends itself to modification for different levels and stages of students. In general, LCA provides a fertile ground for investigations of this type ranging from semester-long project or design courses to homework assignments in a general education course.

501

Teaching Sustainability in the Packaging & Graphical Industry – Experiences from Teaching in Swiss Professional Courses

R. Hischier, EMPA / Technology and Society Lab

The author is teaching sustainability since more than 10 years in various courses of the Packaging and Graphical industries in Switzerland. Then continuous education – especially by professional courses – has a high significance in the Swiss society; and is important. Switzerland is a country with a high level of apprenticeships and this dual system with a job market oriented apprenticeship is actually a factor of success for Switzerland. One consequence of the dual system – having a large majority passing via the pathway of the apprentice-ship – is that industries need to prepare themselves their future senior staff members. For this, industries established their proper professional in-service courses – like e.g. the packaging industry with the 2-year-course called „Packaging Manager", or the graphical industry with the 3-year-course „Polygraphische Akademie HF TGZ". The objectives concerning sustainability in these courses are similar – i.e. a first part is used to make students aware of the most important aspects of sustainability and the link and relevance in relation to their professional activities; a second step tells the students how to integrate the topic "sustaina-bility" in their daily business activities with respective tools and instruments. It is obvious that within the given timeframe in these courses a comprehensive treatment of the topic "sustainability" however is not possible. In the first part, the objective is to approach students on a very personal and private level – in order to raise awareness for the issue by highlighting „hot" topics like e.g. energy consumption or mobility. The second part is dealing in large parts with the topic of Life Cycle Assessment (LCA) in a way that the students can understand, and "read" such studies – not that they can establish themselves such studies. In this presentation, the author will report from his proper experiences of the more than 10 years of teaching in the two above mentioned courses. He will present similarities and differences between the two industry sectors, encountered during the various courses and highlight the specific requirements, especially in the area of LCA, that this kind of courses is asking for.

502

Using an Experiential Serious Game to Stimulate Life Cycle Thinking in Organisations and in Education

D. Caudrelier, G. Bascoul, S. Vionnet, Quantis; E. Aoustin, VEOLIA Environnement

The United Nations has served as a catalyst to the development of sustainability thinking in education with its promotion of the "Decade of Education for Sustainable Development" between 2005 and 2014. Its concrete application can be seen clearly in academic research highlighting the importance of incorporating sustainability in marketing curricula (Borin & Metcalf, 2010; Bridges & Wilhem, 2008), and the publication of numerous textbooks. The presentation will introduce a new teaching and training method based on the LCA framework. The method is designed to make managers as well as students, and especially in the marketing field, aware of the actual environmental impact of the products/services that they are orwill be dealing with and to show them the positive or negative influence that marketing decisions can have on this environmental impact. The ultimate goal is to make environmental sustainability issues and values integral to marketing decision-making. This novel pedagogical method is based on an educational game called "LCP: Life Cycle Perceptions". LCP was designed as a "serious game" (i.e., a game whose primary purpose is education as opposed to mere enjoyment; e.g., Crookall, 2010). LCP has received the approval of the United Nations Education Program for Development. The presentation will explain the different learning stages of the game. It is an experiential learning game that helps trainees begin to reconstruct the LCA of a product according to their own perceptions and, subsequently, to confront these perceptions with reality. The learning process thus results from illuminating the gap between the LCA reconstructed by the trainees and the actual LCA of the product. Once the trainees have integrated this new scope

of the product life, trainers can, throughout teaching sessions, explain the influence that marketing decisions may exert on the product's environmental impact. The presentation will illustrate why a significant widening of perspective from the traditional marketing view of the product life cycle to the LCA is needed to fully integrate environmental consciousness to marketing and marketing education. It will underline why such a perspective has to be implemented through experiential learning rather than the traditional lecture format.

Adapting teaching and communication of Life Cycle Thinking to industrial practitioners and stakeholders

M. Guiton, CRP Henri Tudor / Resource Centre for Environmental Technologies (CRTE); E. Benetto, E. Igos, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE

The broad concept of sustainable development is widespread in the terminology of academia, policy-making, industry and is part of the common vocabulary of the average consumer as well. However, the meaning of "sustainable development" is different depending on the stakeholder and decision-maker, because of a different perception of the goals and underlying actions. It is the role and responsibility of scientific experts and practitioners to ensure that the proper values are associated to the concept, through tailored trainings, tools and communication actions. Historically, sustainable development is closely linked to environmental management, supported by European and national directives. Focusing on environmental management, several approaches can be adopted. Life Cycle Thinking (LCT) has emerged as one of the most appropriate vectors of knowledge and know-how transfer to stakeholders. Regarding industrial stakeholders in particular, our past experience shows that they first need a basic know-how to manage the approaches and to define their environmental strategy, and then they require concepts and tools to support its implementation. Depending on the industrial company profile, more specific requirements arise. Small and medium enterprises (SMEs) tend mainly to focus on a short term return on investment, by deriving some immediate market benefits from the implementation of LCT to their products. For the bigger industrial groups, where often a team dedicated to LCT is available, the requirements are much more diversified and can be more sophisticated as well. For industrial stakeholders working in emerging countries, environmental management is mainly a way to improve their competitiveness on the international market. On the academic side, the requirements are mainly linked to the research and teaching activities. Teachers and researchers require a deep understanding of the LCT methodologies, tools and their final purposes. The aim of this presentation is to review a number of LCT communication and teaching strategies we have been testing with the above mentioned stakeholders' types, to identify and discuss the key elements of success as a function of the target audience and their needs.

Persistent, Bioaccumulative and Toxic (PBT) substances – identification, assessment and regulatory decision making with a special focus on socio-economic aspects

505

State-of-the-art on bioaccumulation and toxicity criteria for non-aquatic organisms within the PBT/vPvB assessment framework

S. Gottardo; N.B. Hartmann, Technical University of Denmark DTU / DTU Environment; B. Sokull-Kluettgen, European Commission Joint Research Centre / Nanobiosciences

Current international and European regulatory criteria for PBT assessment of chemical substances are mainly based on toxicity and bioaccumulation data in aquatic species. For example, bioaccumulation assessment is usually addressed by means of quantitative criteria: the BioConcentration Factor (BCF) or BioAccumulation Factor (BAF) in fish and the octanol-water partitioning coefficient (Kow). In some frameworks generic criteria are also recommended such as high (eco)toxicity and detected high levels in biota. However, no cut-off values or guidance is provided for these criteria. The regulatory frameworks and related management actions may therefore potentially fail to identify a number of substances that are bioaccumulative and/or toxic in non-aquatic food chains (exposed through soil and food), but not in aquatic. This issue has been investigated through a review of the legislative status and scientific knowledge on toxicity and bioaccumulation assessment for non-aquatic organisms at international and European level. The review reveals that some persistent, low hydrophobic and poorly metabolised organic chemicals can biomagnify in terrestrial food webs and bioaccumulate in human blood and tissues, although they do not bioaccumulate/biomagnify in aquatic environments. As both Kow and estimated/measured BCF values reflect the equilibrium partitioning of organic compounds between water and biota and do not take into account either the exposure route through the diet and the organism-to-air exchange, these substances may not be classified as bioaccumulative through the current regulatory criteria. Also with regards to toxicity there may be chemicals that are not classified as toxic in aquatic organisms but may be toxic organisms in terrestrial food chains. Although toxicity data from the aquatic system in general is considered to result in a more conservative classification, there are exceptions in the literature where higher toxicity is observed for the terrestrial system. For example, effects of substances with low water solubility may not be detectable through acute aquatic toxicity tests. Hazards may instead be identified through tests with terrestrial organisms exposed through soil or food. Here we present the state-of-the-art in this field including preliminary views on possible incorporation of non-aquatic criteria in the regulatory assessment of PBT substances. The content of this presentation refers to a JRC Scientific and Policy Report (in preparation).

506

PBT classification under EC 1107/2009: Practical issues and a case example of chlorpyrifos

K.R. Solomon, University of Guelph / School of Environmental Sciences; J.P. Giesy, University of Saskatchewan / Toxicology Centre; D. Mackay, Trent University; N.N. Poletika, Dow Agro Sciences LLC / Field Exposure and Effects Department; J. Anderson, Department of Chemistry

A number of chemicals, including several organochlorine pesticides, have been identified as persistent organic pollutants (POPs). These chemicals, particularly if they undergo long-range transport (LRT), are identified, and regulated at the global level by the Stockholm Convention. In addition several additional frameworks such as EC regulation No. 1107/2009 assess chemicals for properties that might confer persistence, bioaccumulation, and toxicity (P, B, and T). There is no explicit framework or guidance for classification other than a draft document from SANCO and, unlike other frameworks such as POPs and REACH, EC1107 does not recommend the use of Weight of Evidence (WoE) for assessing data. Using WoE, we have developed a framework to for PBT assessment of current-use pesticides (CUPs) and illustrate this with the organophosphorus insecticide chlorpyrifos (CPY). In assessing P and B for chemicals, the concern is for the general environment, not for a particular local scenario. Because extreme values that are observed in specific situations are not representative of all locations, it is more appropriate to use mean values. Moreover, because many P or B processes are driven by first-order kinetics, the geometric mean value is most appropriate for comparing triggers for classification. Strength and relevance of data were used to select the best data. Specific scoring criteria were developed for each type of exposure, including bioaccumulation in sediment-dwelling organisms, aqueous bioconcentration, dietary bioaccumulation, persistence in soil, sediment, and water. These criteria were based upon OECD methods and scores for individual criteria were summed and the total score for strength used select studies of better quality. Only studies with final scores of ≥50% of the maximum score were used to assess P, B, and T. This presentation will show how this process was undertaken and why we concluded that chlorpyrifos is not a PBT pesticide.

507

Regulation of PBT and vPvB chemicals within REACH: A stock-pollution approach to authorisation and restriction

S. Gabbert, Wageningen University / Social Sciences; I. Hilber, Agroscope ART

The European chemicals legislation REACH aims at ensuring that the risks caused by substances of very high concern (SVHC) will be adequately controlled and that these chemicals "are progressively replaced by suitable alternative substances or technologies where these are economically and technically viable". Authorisation and restriction of SVHCs are key regulatory instruments in order to achieve this goal. An important subgroup of SVHC are persistent, bioaccumulative and toxic (PBT) or very persistent and very bioaccumulative (vPvB) chemicals. For decision-making on the authorisation or restriction of SVHCs a socio-economic analysis (SEA) has to be performed, where companies (authorisation) or chemical agencies of member states (restriction) must balance positive against negative impacts of a defined policy scenario and compare the outcomes with alternative policy scenarios. The current conceptualization of the REACH authorisation and restriction process, including the setup of an SEA, ignores that PBT/vPvB chemicals are stock pollutants, causing environmental concentrations to accumulate over time, depending on the emission- and the decay rate of the chemical. As a consequence, pollution damage caused to humans or ecosystems can remain even long after a chemical, or a certain use of a chemical, has been removed from the market. Ignoring stock effects of PBT/vPvB chemicals may therefore result in erroneous and incoherent regulatory decisions on the use/non-use of these chemicals. Our paper suggests a socio-economic model that allows capturing stock effects in an SEA. We show that for PBT/vPvB chemicals the weighing of benefits against costs in an SEA translates into solving an optimal timing problem and we discuss implications for regulatory decision-making on the authorisation or restriction of these substances. By means of a case study (DDT soil pollution) we identify practical steps in order to apply and implement the approach in an SEA.

While our approach does not claim to solve immediately all empirical and practical problems related to estimating and valuing impacts, we believe that it unravels the decision problem underlying to an SEA of PBT/vPvB chemicals. In addition, it offers guidance to socio-economic analysts and decision-makers at the regulatory level on model selection, data compilation and the definition of further research needs.

508

In silico strategies for the screening and prioritization of potential SVHC substances

A. Roncaglioni, F. Pizzo, C. Cappelli, M.P. Incisivo, D. Gaddaleta, A. Lombardo, Istituto di Ricerche Farmacologiche Mario Negri; M.I. Petoumenou, Instituto di Ricerche Farmacologiche Mario Negri; A. Manganaro, Kode srl; A. Biegel-Engler, M. Brandt, Umweltbundesamt; E. Benfenati, Instituto di Ricerche Farmacologiche Mario Negri / Lab of Environmental Chemistry Toxicology

Quantitative Structure-Activity Relationships (QSARs) are methods that can be used to estimate the potential toxicity of a compound from its chemical structure. Since they represent a cost effective and fast method to assess a large amount of compound they can play an important role in screening and prioritizing potential harmful compounds. For this reason they can be a valuable instrument to identify potential PBT and vPvB compounds in the framework of the REACH legislation. We will present an integrated strategy based on a series of tools able to handle different levels of details available on the different endpoints. Thses include continuous QSAR models (e.g. for ready biodegradability), fragment based classification models, substance-based tools (by analizing chemical classes distribution with the support of read-across) to property-based tools (by assessing relevant physico-chemical properties related to the property to be modelled). Efforts are focused on the different aspects necessary to identify potential SVHC: persistence, bioaccumulation and toxicity, including endocrine disruptor issue. The final goal of this study is to produce a new flowchart integrating different pieces of information to prioritize chemicals more accurately. A crucial aspect in this integration will be to properly handle the intrinsic uncertainity related to the estiamtions obtained. This means to take into account from one side the fact the not all methods/models available have the same intrinsic reliability. On the other hand, one single model posses a compound specific reliability depending on its applicability domain.

509

Global flow of contaminants: from consumer products in North America to landfills in developing countries

G. Abbasi, University of Toronto / Geography; F. de Leon, University of Toronto / Dalla Lana School of Public Health; A. Saini, University of Toronto / Department of Physical and Environmental Sciences; E. Goosey, University of Toronto / Earth Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences

Despite the increasing concern on the adverse health effects and persistency of halogenated flame retardants (HFRs), the mass of these substances continues to grow in the environment. PentaBDE, OctaBDE and HBCD were added to the Stockholm Convention POPs list in 2009, which resulted in their replacement with other HFRs with similar physical and chemical properties. Here, we investigated the presence of HFRs in ~300 consumer products in the US and Canada. DecaBDE was the most abundant in WEEE and scrap vehicles, while PentaBDE was dominant in foam products. In newer products (< 5 years), DBDPE, TDCPP and Firemaster 550 compounds were the most abundant. Based on the number of in-use PBDE-containing products, the total mass of PBDEs in consumer products estimated to be ~140,000 tonnes in 2013. Although the mass of PBDEs in the use phase declines at the rate of 4-9% per year, it is expected that the total mass of PBDE alternatives in the use phase grows at a faster rate, as more substances in various concentrations are being added to a wide rage of consumer products. Considering that more than 50% of contaminated products are being disposed of in developing countries, more stringent controls on the use and movement of these chemicals are required.

Reduction, Replacement, and Refinement (3Rs): Animal alternative approaches in ecotoxicology and risk assessment (I)

510

Enhancement of fish toxicity QSAR models for predicting acute LC50 and chronic NOEC values for non-polar narcotics: ECHA dossier submissions as an experimental data source

T. Austin, SHELL / Shell Health; C.V. Eadsforth, M. Denoyelle, Shell International; A. Chaudry, S. Stradling, Shell Projects and Technology

Under the REACH legislation, acute toxicity test data on fish are required for chemicals imported into or manufactured within the EU in quantities greater than 10 tonnes per year. For chemicals imported or manufactured in quantities greater than 100 tonnes per year, chronic fish toxicity data are also required. The high number of tests required across the chemicals industry raises costs to both industry and consumers alike in addition to raising animal testing and welfare concerns. The REACH regulations encourage the use of non-testing methods including QSAR. ECOSAR™ is one of the most widely used models to predict aquatic toxicity to fish, daphnia and algae. The methods used to develop the models within ECOSAR™ do not currently meet best practice guidelines for QSAR development and shortcomings have been identified within the scientific literature. In light of this, updated models were developed according to best practice guidance in QSAR creation. Data were taken from multiple sources including the ECHA dissemination portal. As of November 2013, the ECHA dissemination portal contains over 10000 unique substances, with over 41000 dossiers. It has therefore become a very large experimental data source. The reliability and use of this data in model development was evaluated. The models developed meet the OECD principles, have strong internal and external validation statistics, and can provide reliable predictions of the acute/chronic toxicity of non-polar narcotic chemicals towards fish. Whilst some issues with dossier misinformation were discovered, it was found that overall the ECHA dissemination portal is a valuable and reliable data source. When queried using the eChem portal, chemical dossiers containing suitably reliable data, relevant to the endpoint of interest, could be quickly found. The ECHA dissemination portal holds great potential for future QSAR development and improvement if used appropriately.

511

Development of a high Accuracy model for determining the aquatic toxicity of mixtures

P. Thomas, F. Sahigara, CEHTRA SAS; P. Bicherel, KREATiS

Abstract To date the only recognized method available for measuring mixture toxicity is the Water Accommodated Fraction (WAF) test. In this study, organisms are exposed to a specific mixture concentration termed a “loading”. The quantity of each constituent in water can be measured at a given concentration (loading rate) but this does not always correspond to the original mixture concentration and so it is difficult to demonstrate experimentally that the technical obligations required to maintain the stability of the test substance have been met. For this reason it is difficult to replace experiments accurate model predictions. The determination is complexified by the fact that liquids may partition into each other thereby reducing bioavailability of all the constituents in the aqueous mixture. In order to create a functional WAF model, these aspects therefore needed to be accounted for. The approach used was to create a three step model: First a thermodynamic mixture algorithm was prepared which determines the actual concentration of each constituent in the aqueous phase from a given original mixture concentration; Next, the non-bioavailable phase was accounted for and excluded from the aqueous concentration; Finally, the new algorithms from the ecotoxicity QSAR were used as above to determine the relative toxicity of each constituent in terms of activity. The WAF model was validated using a series of WAF tests on fish. The results were found to be in high agreement with the experimental data.

512

A 3R compliant testing strategy to predict chronic fish toxicity

L. Vergauwen, University of Antwerp / Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences; D.L. Villeneuve, US EPA / Midcontinent Ecology Division; S. Verstraelen, VITO Flemish Institute for Technological Research; F. Dardenne, Universiteit Antwerpen; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; G.T. Ankley, US EPA / National Health and Environmental Effects Research Laboratory; H. Witters, VITO; D. Knapen, University of Antwerp / Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences

To ensure an ecologically relevant basis for environmental quality standards, whole-organism vertebrate tests are considered most suitable. Currently, the Fish Early Life-Stage (FELS) test (OECD 210) is used to estimate chronic toxicity of regulated chemicals to fish. However, the FELS test uses high numbers of animals, is a low throughput test and lacks mechanistic information. We present a workflow combining several 3R compliant testing methods such as *in vivo* alternative and *in silico* methods to develop a mechanistically based alternative testing strategy for prediction of fish chronic toxicity based on the adverse outcome pathway (AOP) framework. We put forward the 5 day ZFET (ZebraFish Embryo Toxicity) test as a valuable alternative *in vivo* test system. We consider three key elements of this alternative testig strategy. Depending on the AOP, QSARs may offer a first source of information. We performed a meta-analysis correlating acute and chronic fish toxicity data available from public databases to acute and chronic ECOSAR toxicity predictions for a set of non-polar narcotics. We observed stronger correlations between experimental and predicted toxicity data for early life-stages compared to other life-stages. We propose to use the 5 day ZFET test to confirm agreement between acute experimental toxicity and QSAR predictions for specific chemicals in order to decide whether the chronic QSARs may be applicable. Secondly, if there is a consistent relationship between acute and chronic early life-stage toxicity for a specific AOP, acute toxicity data gathered using the 5 day ZFET test may be used as a starting point for the prediction of FELS toxicity. We

constructed correlations between acute and chronic fish toxicity data of non-polar narcotics. Again, the correlations were stronger when the data was limited to early life-stages. Next to the already existing concept of acute-to-chronic ratios (ACR), we propose the acute-to-chronic surface (ACS). The ACS forms a rectangle ranging between the minimal and maximal available values of acute and chronic fish toxicity and therefore informs on the uncertainty of the ACR. Finally, to substantially increase the biological relevance of risk assessment, we propose to add a refined 5 day ZFET test including AOP-specific endpoints. We will investigate the predictive potential of endpoints in the 5 day ZFET test representing key events along AOPs.

513

Can adverse outcome pathways help to predict early life-stage toxicity in zebrafish?

S. Scholz, Helmholtz Centre for Environmental Research / Department of Bioanalytical Ecotoxicology; K. Duis, ECT Oekotoxikologie GmbH; M. Leonard, lOREAL SA; R. Schreiber, HelmholtzCentre for Environmental Research UFZ / Bioanalytical Ecotoxicology; J. Ortmann, Bioanalytical Ecotoxicology; A. Lidzba, A. Kuehnert, Helmholtz Centre for Environmental Research UFZ; R. Altenburger, UFC Centre for Environmental Research / Department of Bioanalytical Ecotoxicology

The fish embryo acute toxicity test (FET) has been proposed as an alternative to acute fish toxicity testing (OECD 203) and a test guideline (OECD 236) has recently been approved. Hence, the FET now provides the opportunity to be applied in prospective chemical hazard assessment and whole effluent monitoring for acute toxicity. However, embryonic development of fish is also an integral part of the fish early life stage (FELS) test (OECD 210), which is used for chronic toxicity assessment. Thus, it can be asked whether the information gained in early developmental stages could be used to predict effects in the FELS. To test the suitability of the adverse outcome pathway hypothesis to support such a scope, a collation of well-defined substance data including both acute fish toxicity and FELS data was performed. Ideally, acute to chronic toxicity ratios (ACR) and data for cumulative toxicity (increasing toxicity over time) would be retrieved from a single FELS test. Unfortunately, toxicity in the embryonic period during an FELS is often not easily available from publications or public databases. Therefore, we have initiated setting up a database of time-resolved FELS effect concentrations using published data and registration dossiers. At present, about 100 compounds could be retrieved with data for fish acute toxicity and FELS toxicity for the same species and fulfilling a set of quality criteria. Most data show a clear correlation of FELS and acute fish toxicity data with a systematic sensitivity shift of less than one order of magnitude towards FELS data. Outliers from this correlation (i.e. compounds with a high ratio of acute fish to fish early life stage toxicity) were identified and included, for instance, compounds with a neurotoxic mode of action. This mode of action could also be identified from fish embryo tests using behavioural analysis. Given the principally high correlation of fish embryo and adult fish acute toxicity, we suggest neurotoxicity and / or changes in embryonic behaviour as one potential indicator and predictive endpoint for enhanced chronic toxicity in the FELS to be tailored in further investigations.

514

Inter-laboratory validation of the Xenopus Embryonic Thyroid Signalling Assay

A. Sebillot, S. Mothre, Watchfrog SA; I. Hirakawa, National Institute for Basic Biology / Okazaki Institute for Integrative Bioscience; N. Teyssandier, Watchfrog SA; A. Cameron, University of Cincinnati / Department of Biological Sciences; T. Iguchi, National Institute for Basic Biology / Molecular Environmental Endocrinology; D. Buchholz, University of Cincinnati / University of Cincinnati; B. Demeneix, MNHN/CNRS; G.F. Lemkine, A.J. Tindall, D. Du Pasquier, Watchfrog SA

With support from France and financial participation from Watchfrog and the French ministry responsible for ecology, a validation plan has being developed for the Xenopus Embryonic Thyroid signalling Assay (XETA); laboratories from OECD member participate in the validation study, including laboratories from Europe, North America, and Asia. The objectives of the validation are : 1) to establish the relevance of the assay by assessing its sensitivity to detect disruption by compounds active at different points within the thyroid system, and 2) to assess the reproducibility of the assay across participating laboratories. XETA is an aqueous assay based on the genetic detection of a chemical’s impact on transgenic *Xenopus laevis* embryonic stages. This transgenic line can detect the activity of Thyroid Hormone (TH) agonists that activate TH receptors, as well as antagonists of thyroid axis that work through various mechanisms. The XETA provides a rapid response (The ring test experiments within the three participating laboratories will be completed early 2014. The lead laboratory (WatchFrog) will then collect the raw results and perform the overall statistical analyses. Reliability, reproducibility within and across labs, and sensitivity of the assay will be determined. The minimal number of tadpoles that can be utilised in the test will be determine through statistical evaluation. In addition to serving as a quick screen for thyroid active chemicals, XETA, could serve as a potential alternative method to the *in vivo* Amphibian Metamorphosis Assay (AMA - OECD guideline n°231).This test is based on the study of *X.laevis* tadpole metamorphosis after 3 weeks of exposure to a given chemical, and includes histology of the thyroid. The OECD TG 231 is the only test currently available to assess the thyroid disruption on a whole vertebrate organism. XETA could provide an alternative test that can be performed quickly, providing information that would be useful for screening. It is intended that this assay will be applied to testing in the context of REACH and other international testing programs.

What do we know about the effects of multiple stressors and community responses on aquatic ecosystems?

515

GLOBAQUA: Managing the effects of multiple stressors on aquatic ecosystems under water scarcity

A. Navarro-Ortega, IDAEACSIC / Environmental Chemistry; A. Bellin, UNITN; P. Burek, IESJRC; G. Cassiani, UNIPD; R. Choukr-Allah, IAVCHA; S. Dodelec, CNRSLEHNA; A. Elosegi, UPVEHU; F. Ferrari, AEIFORIA; P. Grathwohl, University of Tuebingen / Center for Applied Geoscience; C. Jones, SMHI; P. Ker Rault, Alterra; K. Kok, WU; P. Koundouri, ATHENA; R. Ludwig, LMU; R. Milacic, JSI; I. Muñoz, University of Barcelona / Ecology; M. Paunovic, IBISS; C. Paniconi, INRS; S. Sabater, Catalan Institute for Water Research ICRA; N. Skoulikidis, HCMR; A. Slob, TNO; G. Teutsch, UFZ; N. Voulvoulis, IMPERIAL; D. Barcelo, IIQABCSIC / Environmental Chemistry

Water is the most essential of all natural resources and consequently water and its services are major components of the human wellbeing and major factors of socio-economic development in Europe. Nowadays, freshwater ecosystems are under threat due to a great variety of stressors that can have deleterious effects on them, including pollution, geomorphological alterations, land cover change, invasive species and water scarcity. In order to properly address the effect of stressors in policy terms, a coordinated effort on the research that considers multiple perspectives is needed.Within this context GLOBAQUA project has assembled a multidisciplinary team of leading scientist in the fields of hydrology, chemistry, ecology, ecotoxicology, economy, sociology, engineering and modelling in order to study the interaction of multiple stressors within the frame of strong pressure on water resources. As one of the last FP7 projects, GLOABAQUA, with the full title “Managing the effects of multiple stressors on aquatic ecosystems under water scarcity” is a 5-year project that started on February 2014. The consortium is composed of 21 European partners from 8 countries and 2 non-EU partners from Morocco and Canada. The team includes practitioners and policymakers who will ensure that the project is highly relevant to end-user needs. By bringing together researchers with strong international experience and end-users with key expertise in the region, a critical mass of experience and knowledge is being mobilized to carry out the project activities.GLOBAQUA aims at addressing the fundamental need of connecting the occurrence of multiple stressors in a situation of water scarcity with the policy implementation in European river basins. The structure of the project into WPs allows sharing responsibilities between researchers who are specialists in their respective fields. The work performed by the different WPs expands through different scales, starting from the monitoring and modeling studies to the river basin scale. The achievement of an overall good status of European water bodies until 2015 (according to the WFD) poses a crucial challenge not only to water management agents but also to policy makers on different scales, the scientific community and the society in general. Overall, the synergy of the different groups arises from their different expertise that complements each other to get a holistic picture of the problem, as well as potential solutions.

516

Improving the WFD purposes by the incorporation of ecotoxicity tests and the assessment of pollutants availability

N. Roig, Universitat Rovira i Virgili; J. Sierra, Universitat Rovira i Virgili / Soil Science Unit; M. Nadal, University Rovira i Virgili; I. Moreno, Institute for Marine Science of Andalucia CSIC; E. NIETO, INSTITUTE FOR MARINE SCIENCE OF ANDALUSIA ICMANCSIC / ECOLOGY AND COASTAL MANAGEMENT; M. Hampel, Instituto de Ciencias Marinas de Andalucía CSIC / Consejo Superior de Investigaciones Cientificas; J. Blasco, Inst Ciencias Marinas de Andalucia / ECOLOGY AND COASTAL MANAGEMENT; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering; J. Domingo, Universitat Rovira i Virgili

According to the European WFD, ecological status is based on three quality elements: biological, physicochemical and hydromorphological, but ecotoxicological status is still not included. Biological status is not always in coherence with chemical status, maybe due to the adaptation mechanisms of aquatic organisms under chronic chemical exposure. In these situations, ecotoxicity tests could be useful to resolve these divergences. Moreover, the evaluation of the freshwater ecological status often supposes time, workforce expertise and costs, that sometimes the water management organisms can not assume. The application of ecotoxicity tests as preliminary investigation could help to reduce theses

disadvantages and optimize the freshwater quality studies. The objective is to design a methodology in order to study the ecotoxicological status of rivers that could be useful and complementary to ecological status by (1) comparing the effectiveness and viability of different ecotoxicity tests performed with freshwater sediments, and (2) evaluating the relationship between ecological status, pollutant concentrations, their bioavailability, and water and sediment ecotoxicity. Thirteen sampling sites within the Ebro river watershed were selected. At each sampling reach composite samples of sediment were collected. Data about priority pollutants in water, sediment and fish as well as biological and hydromorphological status and physicochemical characterization has been achieved. The ecotoxicity of pore water and whole sediments was evaluated by different bioassays (*V. fischeri*, *N.palea P. subcapitata*, *D. magna* and *C. riparius)*. The trace metals bioavailability was calculated by a sequential extraction according to the Community Bureau of Reference method. To distinguish the potentially toxic fraction associated to trace metals burden of sediments, an analysis of acid-volatile sulphide and simultaneously extracted metals was performed. The results indicate that the ecotoxicological approach in most of the analyzed sediments is in agreement with their ecological status. This study expects to demonstrate that the integration of chemical, biological and ecotoxicological analyses could be crucial to understand the hazard of pollutants in aquatic ecosystems, especially, in freshwater sediments, and it pretends to corroborate that cost effective and rapid screening short-term bioassays could be useful to determine the surface water ecotoxicological status.

517

Combined and interactive effects of three stressors (phosphorus, temperature and zinc) in a freshwater community

D. Van de Perre, Ghent University Laboratory of Environmental Toxicology and Aquatic Ecology / Laboratory of Environmental Toxicology and Aquatic Ecology; F. De Laender, Université de Namur ASBL / Lab of EnvToxApplEcol; I. Roessink, Alterra; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology; K.A. De Schamphelaere, Ghent University UGent / Environmental Toxicology and Aquatic Ecology

During the last decades the biological and ecological responses to a suite of stressors have been examined at different levels of biological organisation (molecular to community level). However, most studies have so far focused on the effects of single stressors, while in nature multiple stressors are usually present simultaneously. At the community level very few experimental studies have investigated the combined effects of multiple stressors. Literature data suggests that significant three-way interactions of multiple stressors on organisms are common in nature. The main objective of this study is to assess the interactive effect of three different stressors on an aquatic community. An indoor freshwater microcosm experiment was conducted in which total phosphorus (oligotrophic, eutrophic), temperature (natural conditions, global warming prospective) and zinc (control, low & high) were varied in a full 2x2x3 factorial design. During the experiment general water quality (Total P, dissolved P, NO_3, NO_2, NH_4, DOC, DIC, pH, hardness, BOD_5 and O_2) and plankton abundance (phytoplankton, protozooplankton and zooplankton) community composition were recorded weekly, starting the day before the start of the treatment. At the end of the experiment the periphyton cover of the sediment was observed. Interactive effects between the different stressors on the endpoints were determined by comparing observed values with values predicted with the independent action model. The significance of the interactions (three-way and two-way) and the main effects were tested by using ANOVA's (three and two-way) on log-transformed observed data. With three-way ANOVA, both temperature and zinc were found to have effects on phytoplankton (total chlorophyll and composition) and periphyton but the zooplankton or snails only seem to be affected by zinc (at 300 μg/l of zinc all daphnia died). After 3 weeks of exposure, significant three-way phosphorus x temperature x zinc interactions were observed at every sampling for phytoplankton total chlorophyll and composition. Significant antagonistic interactions were observed starting from 3 weeks after exposure for total chlorophyll between temperature and zinc under oligotrophic conditions. Our data clearly shows that there are significant interactions between phosphorus, temperature and zinc and the different biotic communities respond differently to these stressors.

518

Cumulative effects caused by pharmaceuticals and water intermittency on algae and bacteria living in stream biofilms

N. Corcoll; M. Casellas, ICRA; B. Huerta, Catalan Institute for Water Research (ICRA); H. Guasch, University of Girona / Institute of Aquatic Ecology; S. Rodriguez-Mozaz, Institute for Water Research ICRA; A. Serra, University of Girona; D. Barcelo, IIQABCSIC / Environmental Chemistry; S. Sabater, Catalan Institute for Water Research ICRA

Increasing concentrations of complex mixtures of pharmaceutical compounds (PhCs) are progressively detected in many rivers, but their potential toxicity risk on non-target aquatic biota still remain poorly studied. Flow interruption is common in many river systems, and this natural stressor alters the functioning and biomass of aquatic biota and may alter their sensitivity to toxicants. This study aims to evaluate the effects of a chronic exposure of a mixture of 9 PhCs at environmental concentrations on the structure and metabolic processes of algae and bacteria communities. The study also evaluates if biofilms exposed to PhCs exposure and flow interruption have a different sensitivity than those non exposed to water intermittency. In order to address these issues, an experiment was performed using artificial streams. Biofilms accumulated some PhCs such as metropolol and hydroclorothiazide, and pharmaceutical effects were expressed on the decrease of algal biomass and cyanobacteria abundance. Also changes in the structure of bacterial community (based on DGGE fingerprint analyses) and higher rates of metabolic process (such as primary production and community respiration) occurred. In addition, the algal community exposed to water intermittency became more sensitive to short-term exposure of pharmaceuticals (lower EC_{50} value) than those growing under constant flow. These findings support that synergistic effects between water intermittency and pharmaceuticals exposure occurred on algal community. In contrast, the bacterial community previously exposed to water intermittency became more tolerant to short-term exposure of pharmaceuticals (higher EC_{50}) than those occurring under constant flow conditions (co-tolerance phenomena). This study shows that i) a chronic exposure of a mixture of pharmaceutical compounds has adverse effects on aquatic communities, and ii) that water intermittency modulates the effects of chemicals on natural communities (e.g. biofilms).

Assessing the effect of salinity on stream macroinvertebrate communities despite confounding factors and salinity pulses: the use of traits and large scale family turn-over.

B.J. Kefford, University of Canberra / Department of Environmental Science; M. Krough, J.D. Miller, Department of Premier and Cabinet / Office of Environment and Heritage; R. Schaefer, University Koblenz Landau

Licensed discharges of saline effluent from coal mines and power stations occur around the world including in the Hunter River catchment, New South Wales, Australia. Since 1994 a salinity trading scheme has largely been successful at preventing salinity levels rising above target levels of 600 and 900 μS/cm in the upper and the mid-lower Hunter River, respectively. Determining whether these levels are protective of ecosystem health in the Hunter Catchment is complicated by other sources of salinity, salinity often occurring in pulses, variation in ionic proportions of salinity and salinity concentrations being confounded with other environmental fluctuations. Here we examined changes in stream macroinvertebrate traits and large-scale turn-over of families with increasing salinity in the Hunter River and adjoining catchments (Karuah River, Lake Macquarie, Tuggerah Lakes and Manning River). Increasing salinity was found to be associated with a reduction in the abundance of salinity sensitive families ($SPEAR_{salinity}$), as indicated by laboratory tests. There was also a greater reduction in the abundance of families which were both salinity sensitive and have traits making their populations likely to recover slowly from pulse disturbances ($SPEAR_{salinity\text{-}pulse}$). These results suggest that salinity, especially pulses of salinity, are potentially altering macroinvertebrate communities, although evidence that other environmental factors may also (partly) play a role will be presented. We found that as EC increased, there was significant turnover in macroinvertebrate families including below salinity levels of 600 and 900 μS/cm. In conclusion, salinity changes in the Hunter and adjoining catchments are potentially (in conjunction with other variables) affecting macroinvertebrate community structure.

520

Community responses to the interactive effect of surfactant exposure and water depth in a microcosm set-up

J. Rodriguez Gil, University of Guelph / School of Environmental Scinces; L. Lissemore, University of Guelph / Laboratory Services Division; M.L. Hanson, University of Manitoba / Department of Environment and Geography; K.R. Solomon, University of Guelph / School of Environmental Sciences

Polyoxyethylene amine (POEA) surfactants are common adjuvants in many glyphosate formulations used in Canadian forestry. Aerial application of these products can lead to exposure of small vernal pools and ponds, which do not require the protection of buffer zones. POEA has been shown to be more toxic than glyphosate alone to aquatic organisms. Additionally, the fate of POEA in the environment is not well understood. To better understand the risk posed by POEA, comprehensive exposure assessments under realistic environmental conditions are needed in order to shed light on factors such as the role of sediment adsorption or the interaction with other environmental stressors such as reduced water levels in the studied habitats. To this end, twelve microcosms (4 m diameter) with water depths of 15 and 90 cm were used to evaluate the interactive effects of depth and POEA exposure. Synthetic sediment (5% organic content) covered the bottom of each pond. Three ponds of each depth were treated with POEA at a nominal concentration of 0.520 mg/L, equivalent to the recommended application rate of 4 L/ha of VisionMax® for the 15 cm-deep ponds and three times the maximum application rate of 8 L/h of VisionMax® for the 90 cm-deep ponds. Surfactant fate, water physico-chemical parameters as well as phytoplankton (ash-free dry weight and chlorophyll a), periphyton (ash-free dry weight and photosystem II quantum

yield) and zooplankton populations were evaluated over 35 days. POEA had a short water-column half-life that was consistent with previous studies. At close-to-environmentally relevant concentrations such as the ones tested in this study, exposure to POEA did not induce significant ecological effects on aquatic communities. Depth alone had a much more significant effect on the composition and development of the studied communities. No interaction between stressors was observed. Overall, the risk posed by the POEA exposure to small, shallow pools under the studied conditions was considered minimal.

Ecosystem structures and functions and their valuation in Ecological Risk Assessment (I)

521

Defining protection goals for PPP soil ecotoxicological risk asessements based on the ecosystem services concept

P. Kabouw, BASF SE; C. Kunast, EcoSystem Consulting; M. Bergtold, BASF SE; A. Ufer, BASF SE / Ecotoxicology

What to protect, where to protect and when to protect are fundamental questions that need to be addressed before designing risk assessment schemes. Recently EFSA has used the millennium assessment initiative and the therein specified ecosystem services (EsS) concept to design risk assessment schemes. Here we use the EsS concept to design a novel and science based proposal for soil risk assessments with PPPs. As a first step we defined registration principles for a new soil risk assessment. After defining these we identified soil relevant EsS. Thereafter, we formulated relevant protection goals which were transferred into test systems. In the next step we defined a tiered risk assessment based on acceptability criteria. The registration principles we identified were that risk assessments should be workable, scientifically sound and politically acceptable. A well-structured risk assessment would have to reduce uncertainties and it should reduce data gaps concerning organism potentially at risk. A risk assessment scheme should use validated test systems only, needs to have conservative triggers, and needs clear acceptability criteria. Soil relevant EsS (e.g. food production & nutrient cycling) can be affected by PPPs. While it is relatively easy to define general protection goals it is more challenging to define specific protection goals. In the soil area protection goals are now divided in structural and functional protection goals. In our opinion structural protection goals (protecting single species) lack a clear link to protection goals derived from EsS. Functional protection goals directly correlate to EsS. Thus tests based on functional parameters will reduce uncertainties. Although several functional tests are already available we demonstrate based on an example with a fungicide that novel functional tests are sensitive. Additionally we link these novel functional tests to structural tests. The integration of functional tests substantially improves risk assessment schemes as they have a broader scope than single species tests and are directly connected to EsS. Ecosystem services and the protection goals derived from them are suitable to design a new soil risk assessment scheme. Several EsS are relevant to soil and can be affected by PPPs. Protection goals based on EsS should be complemented by validated functional tests as these, in contrast to structural tests, will more directly address protection goals and thus fulfil registration principles.

Solution-focused landscape-level eco(toxico)logical assessment and management

L. Posthuma, D. De Zwart, RIVM / Centre for Sustainability Environment and Health; C. Mulder, RIVM / Lab. Ecotoxicology; K.E. Kapo, C.M. Holmes, Waterborne Environmental Inc; A.M. Schipper; M.A. Huijbregts, Department of Environmental Science; S.D. Dyer, The Procter Gamble Company / Central Product Safety; G.A. Burton, University of Michigan / School of Natural Resources Environment

This contribution aims to show examples of a solution-oriented approach to environmental assessment and management at the landscape level. The case studies involve assessment of eco(toxico)logical impacts on species assemblages at the landscape scale, including ecosystem services, while having a specific focus on solving those problems. Evidence shows that impacts of man-made stressors on ecosystems vary in space and time and involve chemical mixtures as well as many other stressors affecting habitat quality, while prevention, management and restoration often rely on disparate scientific and practical efforts. Disparate in the sense of considering chemicals separate from mixtures, and those separate from other stressors, and species separate from functions, while the impact assessment is separate from finding effective solutions. The latter resulted in the proposal to improve the utility of risk assessment by generating the concept of solution-focused risk assessment. This contribution is built on eco-epidemiological examples, based on the vast amounts of (bio)monitoring data being collected under e.g. the Water Framework Directive. We sketch how these data can be used in both ecological and ecotoxicological models, and that those data can then serve to diagnose site-specific impact magnitudes and their probable causes on a landscape level. We show that mixture- and multiple stress analyses are possible, and identify the relative importance of mixtures and other stressors in shaping local species assemblages. The studies can be done for various endpoints, amongst which species diversity and ecosystem services. An example shows that management aiming at impact reduction requires a solution-focused definition of the desired status after restoration: the choice of restoration endpoint (species diversity, ecosystem services, other) is important for choices in the restoration strategy.

523

Assessment and valuation of ecosysem services: Ensuring Relevance

S.E. Apitz, SEA Environmental Decisions Ltd

The Ecosystem Service Paradigm (EsSP) can be used to define links between human activities and ecosystems; this can be used to evaluate, justify or optimize decisions. How EsS within various applications and frameworks are applied, defined, quantified, modelled, valued and communicated ranges widely, potentially hindering their roles as integrative tools. For the EsSP be useful for the cross-disciplinary integration, those in different fields must be clear about what is meant and assumed when terms are used, and within what context assessments are being carried out. Policy/action options of "consumers" should drive EsS valuation, and EsS-based assessments should be designed to link decision context to meaningful valuation approaches. The logic behind EsSP can be explained by a three-part, iterative Decision Cascade; Ecosystem Service Decision Analysis (EsSD) defines proposed policies or actions, and the changes under consideration in scenarios. Within this context, Ecosystem Service Assessment (EsSA) evaluates how such changes affect biophysical structure, and thus ecosystem function and services; Ecosystem Service Valuation (EsSV) then takes the results and generates valuations (which can, but do not need to be, monetary) to inform decisions; linking back to EsSD. EsS-based evaluations can expand the current risk-focused thinking behind ecological risk assessment (ERA) to consider trade-offs between a range of desirable and undesirable responses of a variety of ecosystem endpoints; understanding of such trade-offs is essential to inform decisions about more sustainable remediation, regulation and management. This paper describes "taxonomies" of various aspects of EsSP applications, based upon their decision context, perspective and assessment approach. Actions and policies available to "consumers" of EsSA are discussed. Then, a range of regulatory and management applications to which the EsSP can be applied are described. The manner in which EsS considerations can be used to inform decisions depends upon a range of issues; assessment and valuation approaches must be designed to ensure relevance to the specific questions and actions at hand. Both monetary and non-monetary valuation approaches can be applied, but how these values are derived, aggregated and communicated can have important implications for the relevance, transparency and sustainability of decisions they inform; these issues will be discussed.

524

Livestock activities as source of ecosystem services. A tool for Agri-Environment-Climate payments in Rural Development Programs 2014-2020. The case of the Autonomous Province of Trento.

A. La Notte, University of Torino / Economics

Agri- Environment-Climate payments (AEC) need a robust justification within the Rural Development Program (RDP). The new RDP 2014-2020 offers the possibility to include environmental benefits and externalities as relevant elements that drives decision-making. In fact, among the environmental and climate-related Focus Areas of interest for the RDP it is possible to extrapolate those ecosystem services (ES) that we think are relevant in the management of agriculture related activities. The target of AEC measures is to deliver environmental benefits efficiently: commitments based on environmental benefits must be justified by 'hard' evidence, such as case study and quantified impact models. The use of an ES platform is proposed to support, measure and account for AEC measures by employing impact models and, through scenario analysis, testing the effectiveness of the measures to be applied. The provisioning ES here considered are those related to food provision, specifically related to livestock. ES related to food provision have the peculiarity of being linked with human action. In the models here described there are in fact two components: biophysical elements and management practices. Considering the aim of the whole project, we need to include the amount and the way human action interacts with the environment. It is necessary to distinguish between the use of meadows to produce fodder crops and the use of pasture to graze livestock. One probabilistic model is built for meadows. For meadows the target is the production of fodder crops in big quantities and of good qualities: how these features are weighted depends on the sustainability degree of the practices applied. The models built for meadows and pasture act as source for other ES. This linkage allow to check the effect of more/less sustainable management practices on other ES. The assessment of variables related to management practices will in fact not only impact on fodder crop production (meadow) but also on water, carbon stock, rural landscape and outdoor recreation. The ES directly linked to grassland probabilistic model for this application are: carbon sequestration, water purification, aesthetic view and recreation. For carbon sequestration and water quality we use two specific deterministic models; for aestetic view and recreation we have built two ad hoc probabilistic models.

525

Relation between ecosystem-service perception and environmental performance assessed by LCA and Emergy accounting: a case study of pond farming in France

J. Aubin, INRAAgrocampus Ouest / UMR SAS; A. Wilfart, K. Chary, INRA; S. Mathe, CIRAD; H. Rey-Valette, Faculté dEconomie de Montpellier

In France, fish pond farming is performed on large areas with extensive practices, more of a traditional activity than a productive activity. Its continuation or development involves a variety of issues associated with environmental constraints, biodiversity support, landscape maintenance and economic return. However, no relations have been established between the environmental performance of farming systems and perception of their ecosystem services.Our study aims to clarify the link between ecosystem services perception and environmental performances of fish ponds assessed using LCA and Emergy accounting (EA). Our study was conducted in two different fishpond farming areas of France: Brenne and Lorraine. We surveyed 29 fish farms, combining its Life Cycle Inventory with a ranking of its ecosystem services as perceived by the fish farmer. In each farm, the ranking of ecosystem services was transformed into scores, and a LCA and EA were performed. Correlation analysis (using R software) was performed to analyze relations between the indicators and ecosystem-service perceptions. Perceptions of ecosystem services by fish farmers are driven by provisioning services (fish production) but also by regulation services (hydrological regulation and biodiversity support) and cultural services (especially recreation). Significant correlations ($p< 0.05$) appeared between perception of ecosystem services by fish farmers and some LCA impact categories and EA indicators. In particular, the sensitivity to provisioning services was positively correlated with eutrophication impacts and negatively correlated with the Emergy % of renewability, the sensitivity to hydrological regulation was positively correlated with land occupation and water dependence, the sensitivity to cultural services (e.g. hunting and angling) was negatively correlated with ecosystem quality, and the sensitivity to nutrient cycling service was positively correlated with ecosystem quality, water dependence and the Emergy Index of Sustainability. Most of these relations are explained by the inclusion of natural resources in the production system and by the relative attention farmers pay to provisioning services vs. support, regulation and cultural services. Thus, profiles of fish farming depending on production objectives can be drawn using the complementarity of targeted ecosystem services and environmental performances.

Evaluation of the ecosystem services of biocontrol and functional biodiversity in Mediterranean agroecosystems. The need for a multiple es evaluation protocol

A.F. Martinou, Cyprus University of Technology / Agriculture Food Science and Biotechnology

Cyprus is one of the most geographically isolated Mediterranean islands and a biodiversity hotspot of the world. Fourty five percent of the total island area is occupied by agroecosystems, therefore assessing ecosystem services in agricultural land is of immmense importance. Agriculture in Cyprus is characterized by both traditional low input systems such as vines as well as intensive high input systems where agricultural crops such as potatoes and tomatoes are cultivated.Agricultural intensification leads to a depletion of resources that eventually can lead to desertification. Climate change and invasive species as well as unsustainable practices are expected to further worsen desertification.A simple method using prey facsimiles was adopted in order to evaluate the ecosystem services of biocontrol and functional biodiversity within intensive tomato agroecosystems and adjacent land or field margins. The method was successful and it was shown that predation biocontrol as well as beneficial species increase five fold in adjacent natural areas compared to agricultural land, therefore its use is recommended for ES assessments in other agroecosystems. The results are discussed and the need for a multiple ES evaluation protocol is highlighted for Mediterranean and other agricultural systems.

Mechanistic toxicology of engineered nanomaterials: state of the art and future perspectives (I)

527

Species differences and the waltz of nanoparticle recognition

Y. Hayashi, T. Miclaus, C. Scavenius, Aarhus University / iNANO Interdisciplinary Nanoscience Center; K. Kwiatkowska, A. Sobota, Nencki Institute of Experimental Biology / Department of Cell Biology; P. Engelmann, University of Pécs / Department of Immunology and Biotechnology; J.J. Scott-Fordsmand, Aarhus University / Department of Bioscience Terrestrial Ecology; J.E. Enghild, D.S. Sutherland, Aarhus University / iNANO Interdisciplinary Nanoscience Center

Cells "see" the corona of biomolecules around a nanoparticle, rather than the nanoparticle's bare surface. Here we present for the first time formation, profiling and characterisation of nanoparticle-protein corona made of proteins of invertebrate origins (*Eisenia fetida* coelomic proteins; EfCP), and that this facilitated interactions with the cells from which the native proteins were harvested. We suggest that the protein corona formed of the native repertoire switches "recognisability" of the nanoparticles' biological identity and this assists the cells to interact with them. Most striking in our findings is dynamic evolution of the protein corona in the local extracellular microenvironment, where protein secretion and corona re-formation simultaneously occurred. The upshot is a three-step cycle of nanoparticle recognition, whereby 1) corona formation, 2) cellular interaction and 3) protein secretion are the key components to understand its toxicokinetics within biological systems. What appears intriguing is that such toxicokinetics of nanoparticles may not be the same even among related species of invertebrates sharing similar ecological niches, for example, between various earthworm species. This is because the protein repertoires and resulting formation of protein coronas can be species-specific. The broad implication is that the use of representative species may need careful consideration in assessing the risks associated with nanoparticles.

528

Silver nanoparticles affect the homeostasis of copper in a multi-cellular fish in vitro system

M. Minghetti, K. Schirmer, Eawag / Environmental Toxicology

Tight regulation of the homeostasis of essential elements is crucial for the life of all organisms. Several metal specific transporter proteins are necessary to allow this process. In this study we evaluate if citrate coated silver nanoparticles (cit-AgNPs) interfere with this complex machinery. Using lines of fish intestinal (Rainbow trout gut, RTgutGC) and hepatic (Rainbow trout liver, RTL-W1) cells this project aims at investigating the effect of cit-AgNPs on the homeostasis of essential metals such as copper, iron and zinc. To mimic more closely the *in vivo* scenario and allow polarization, intestinal cells were grown on transwells. Moreover, to evaluate the effect of cit-AgNPs following the intestinal uptake and metabolism, hepatic cells were co-cultured in the sub located well (or basolateral chamber). Cytotoxicity of silver (Ag) in its ionic ($AgNO_3$) and nano (cit-AgNPs) form was evaluated in both intestinal and liver cells. Doses of ionic- and nano- Ag that resulted in 15% reduction of viability after 24 hours of exposure were applied to the RTgutGC grown on transwells. Following these exposures RTL-W1 grown under the transwell did not show any reduction in viability. Metal analyses by ICP-MS indicated that, while intestinal cells accumulated similar amounts of silver following ionic or nano- Ag exposures, cells exposed ionically excreted significantly more silver to the basolateral chamber (containing the RTL-W1 cells). Messenger RNA levels of Metallothioneins (MTA and MTB), copper ATPases (ATP7A and ATP7B) and zinc transporter (ZnT1) were measured by quantitative PCR in RTgutGC and RTL-W1 cells. MTs mRNA levels were highly increased by both ionic and nano-Ag in RTgutGC. In agreement with the ICP-MS analyses, RTL-W1 indirectly (under transwell) exposed to ionic silver showed increased MTs mRNA levels. Moreover, the mRNA levels of ATP7B were increased in RTgutGC following both nano- and ionic- Ag exposure and ZnT1 were increased in RTgutGC exposed to ionic silver. Taken together this data suggests that cit-AgNPs enter the cells as efficiently as $AgNO_3$. However, ionic silver is excreted more efficiently basolaterally by RTgutGC cells. The increased expression of the Cu-ATPase ATP7B, which is known to transport silver, might have a role in basolateral silver excretion.

529

In vivo tracking of single walled carbon nanotubes and their modulation of nutrient transport and processing genes during fish feeding studies

T. Sabo-Attwood, University of Florida / Department of Environmental Global Health Center for Environmental and Human Toxicology; J.H. Bisesi, University of Florida / Environmental and Global Health; C.M. Lavelle, Physiological Sciences; L. Ferguson, Pratt School of Engineering / Department of Civil and Environmental Engineering; N.B. Saleh, University of South Carolina / Department of Civil and Environmental Engineering; N.D. Denslow, University of Florida / Physiological Sciences

Increased use of single-walled carbon nanotubes (SWCNTs) in research and consumer industries has led to a call for reliable data on their fate and biotoxicity to better evaluate their environmental impacts and potential health effects. Previous research in our lab has shown that direct exposure of SWCNTs to the GI tract of fathead minnows via gavage did not cause overt toxicity and using near-infrared fluorescence imaging were able to determine that the SWCNTs are not likely absorbed. But the highly sorptive nature of SWCNTs may limit nutrient availability in the presence of food as they move through the digestive system under feeding conditions. To investigate whether SWCNTs can impact nutrient availability and uptake in fish, we cloned a suite of genes relevant to nutrient transport and processing (PEPT1, PEPT2, CCK, LPL) from fathead minnow tissues. We then show how these expression patterns are modulated in response to SWCNTs in feeding studies. We additionally assessed the ability of SWCNTs to interact with intestinal proteins using a quantitative ITRAQ proteomics approach. For baseline studies, fathead minnows were fed a diet consisting of ground commercial fish feed or starved for 96 hrs followed by a period of re-feeding for 96 hrs. A second study was performed where fish were given feed containing SWCNTs for 96 hrs. Result of these studies show that each generevealed a specific expression profile. For

example, PEPT1 was most highly expressed in the proximal intestine and increased in starved fish compared to fed fish. Interestingly, fish that were initially starved for a period of time and then re-fed showed that PEPT1 expression levels were similar to those observed in the fed group. Conversely, starved or fed conditions had minimal impact on the expression of CCK. These results indicate the temporal nature of nutrient-related genes in response to variable nutritional conditions. We are currently assessing the impact of SWCNT exposures on the temporal expression of these genes along the intestine and generating proteomic profiles from SWCNT-protein complexes isolated from exposed fish. Using NIRF we were able to track and quantify SWCNTs in the intestinal tract throughout the exposure periods which show the nanomaterials are primarily confined in the GI tract. The results of the current study will increase our understanding of the interaction of gut nutrients, lipids, and enzymes with SWCNTs.

530

Role of Quantum Dot Surface Functionality on Uptake and Function in Fathead Minnow Ovarian Follicle Cell Primary Cultures

C.M. Lavelle, Physiological Sciences; M. Uzor, Center for Environmental and Human Toxicology / Department of Physiological Sciences; N.D. Denslow, University of Florida / Physiological Sciences

Nanomaterials (NMs) encompass a broad group of sizes, materials, and surface chemistries; raising the need to identify characteristics that are likely to influence uptake and toxicity into cells and organisms. To date, no high-throughput screening assay has been developed to identify NMs that have the greatest potential to elicit adverse outcomes on fish reproduction. Previous studies in mammalian *in vitro* systems have identified steriodogenesis as a potential target of NM toxicity. For the first time for FHM, we isolated ovarian follicle cells using a previously described method for another fish species. These primary cultures were utilized for high throughput screening of the uptake and effects of quantum dots (QDs) with different surface functionalities. Cell function was evaluated by measuring steroid synthesis/accumulation and changes in key steriodogenic genes by qPCR. We used commercially available QDs with different surface functional groups, carboxy groups (-COOH), amino groups linked to the QD with PEG (-AMINO), or PEG (-PEG) as model NMs in this study. Cells were plated and allowed to adhere for 48 hours prior to a 24-hour dosing period (10nM QDs). Following dosing the media was refreshed without QDs for a 24-hour post treatment period. At the completion of the experiment laser scanning confocal microscopy was used image cells to evaluate QD uptake. Total RNA was isolated from cells in replicate cultures for analysis of changes in STAR, CYP19A1, FSHR, and FOXL2 mRNA expression. Media from all time points and treatments was assayed for E2 accumulation. Confocal microscopy showed that QDs were internalized, and that the degree of internalization and location of NMs depended on surface functionalization. Preliminary steroid hormone analysis showed a significant decrease in estradiol (E2) accumulation in QD(-PEG) exposed cells. This is the first report of the capabilities of NMs to influence reproductive physiology of fish ovarian follicle cells. The use of high throughput screening assays, such as the assay described here, will allow for screening NMs for their cellular uptake potential as well as their ability to elicit effects on reproduction in fish. We describe here, for the first time in fish, the role surface functionality plays in QD accumulation in ovarian follicle cells *in vitro* and their effects on steroid hormone accumulation. Acknowledgement: NSF grant CBET-0853707.

Indium and ITO induce endoplasmatic reticulum stress

N.R. Brun, FHNWETH / Institute for Ecopreneurship; N. Buettiker, University of Basel / Department of Pharmaceutical Sciences; B. Wehrli, ETH Zurich; K. Fent, Institute for Ecopreneurship

Indium and indium tin oxide (ITO) find increasing use in numerous electronic equipment, particularly in flat screens. The unique properties of ITO nanoparticles, a sintered mixture of of indium(III) oxide (In_2O_3) and tin(IV) oxide (SnO_2), make it to a crucial compound in the electronic industry. Intruction into the environment occurs via spillage during production or leaching from electronics at their end of life, thus being part of electronic waste. However, very little is known on the (eco)toxicological profile of these metals in aquatic organsims. In the present study we assessed the molecular effects of indium nitrate ($In(NO_3)_3$) and ITO nanopaticles *in vitro* (zebrafish ZFL cell line) and *in vivo* (zebrafish embryos). To this end ZFL cells were exposed to different concentrations between 0.5 and 1000 μg/ml, while zebrafish embryos were exposed to 0.1, 1 and 10 mg/L of $In(NO_3)_3$ and ITO. Any cytotoxicity of ITO was noted up to 1000 μg/mL, whereas $In(NO_3)3$ was cytotoxic with an an EC50 of 741.3 μg/ml in ZFL cells. An ER stress response or unfolded protein response coupled with apoptosis and inflammation occurred at the transcription and protein level at concentrations of 500 μg/ml. Both the mRNA and protein levels of the marker gene BiP were induced. BiP can be released through three signalling pathways (IRE1, ATF6, PERK) under stressed conditions to enhance folding capacity. Indium results in a selective release of BiP through ATF6. Our data demonstrate for the first time that ER stress response is induced by indium *in vitro*. The toxicity of indium nitrate was much stronger than that of ITO. Similar effects occurred in zebrafish embryos, although at lower activity. However, we found a strong induction of TNF-α after exposure to 1 and 10 mg/L of both indium nitrate and ITO. The low solubility of indium in water, in which zebrafish embryos were exposed to indium is suggested to play the major role for reduced toxicity. This study unravels an unknown mode of action of indium that should be considered for the evaluation of its human and environmental health risks.

532

A comparison of toxicity and accumulation kinetics in Daphnia magna and Lumbriculus variegatus exposed to differently coated silver nanoparticles

K.B. Paul, HeriotWatt University / School of Life Sciences; F.R. Khan, Roskilde University / ENSPAC; L. Ellis, University of Birmingham; V. Stone, Heriot Watt University; T.F. Fernandes, HeriotWatt University / School of Life Sciences

As nano(eco)toxicology progresses it is becoming more important to gain a deeper understanding how rates of uptake and depuration, that collectively define accumulation, may relate to nanomaterial toxicity. Understanding this is crucial to refine testing protocols and in the extrapolation of data across *phyla* for the successful implementation of nanotechnology impact assessment. Here we discuss research on two model species, *Lumbriculus variegatus* and *Daphnia magna*. Ten nm PVP, PEG and citrate coated Ag NPs, in parallel with silver nitrate ($AgNO_3$), were used. NPs were characterised as prepared and in appropriate test media. Toxicity was assessed with standard *D. magna* and *L. variegatus* static non-renewal immobility tests. Unidirectional uptake and depuration rate constants were determined using experimental principles of the biodynamic model. Different coatings lead to different acute toxicities and accumulation kinetics despite similar Ag NP core size. Test organisms showed different sensitivity and toxicity ranks to the particles. *D. magna* and *L. variegatus* acute toxicities ranged between 5-13 and 64-327μg/ L, respectively. Uptake rate constants ranged from 0.87-1.65 and 0.13-0.6 65 L g^{-1} d^{-1} and efflux rate constants ranged from 0.27-2.48 and 0.0045-0.064 d^{-1} for *D. magna* and *L. variegatus*, respectively. *D. magna* showed a biphasic depuration to all particles which is indicative of NP loss after ingestion whereas *L. variegatus* fit a 1-compartment loss model. The study indicates that biodynamic modelling of water-borne exposures can be used to explain acute toxicities and derive a consistent rank order for both species based on LA_{50} values i.e. PEG-Ag NP > PVP-Ag NP > Cit-Ag NP. However caution is required when basing assumptions on water-column concentrations as toxicity rank is not conserved across *phyla*. This may suggest physiological differences between species and specific NP-organism interactions are important determinants of bioavailability and toxicity. The data also shows it is likely Ag^+ release from Ag NPs cannot fully explain their toxicity therefore using adapted Ag^+ models to predict Ag NP toxicity may have inherent shortcomings. The authors acknowledge funding from NERC and contributions from other partners in this project. \n

Applications of innovative passive sampling and dosing (I)

533

Combining equilibrium passive sampling and dosing for determining the in situ mixture toxicity of environmental mixtures

K.E. Smith, Korean Institute of Science and Technology Europe / Convergence Environment Team; Y. Jeong, C. Park, KIST Europe Korea Institute of Science and Technology; J. Kim, KIST Europe / Institute of Environmental Sciences; S. Kim, KIST Europe / Chemical Management Lab

The advantages of passive sampling for determining the dissolved concentrations of organic contaminants are well documented – *in situ* sampling, up-concentrating of compounds with low levels, plus no need for an external power source. These same characteristics also make passive sampling an attractive option for the initial sampling of environmental mixtures prior to their introduction in toxicity bioassays. However, this approach only makes sense if the environmental mixture profile, plus the dissolved levels of the individual constituents, are preserved between the field and toxicity test. In this study, a laboratory study was performed that shows that the most reliable way to achieve these dual goals is by combining *equilibrium* passive sampling and dosing. Silicone passive samplers were exposed in model aquatic set-ups, with or without dissolved organic carbon, to constant dissolved concentrations of organic compounds of different hydrophobicities. Duplicate sets of passive samplers were removed during the kinetic and equilibrium uptake phases – with one set extracted and exchanged into DMSO for spiking, and the other group used directly in passive dosing mode. The sum toxicity measured using the Microtox assay depended on whether the passive samplers were in kinetic or passive uptake mode, and also whether the compounds were introduced by spiking or passive dosing. These differences can be explained by the variations in mixture composition and test losses depending on the approach used. Equilibrium passive sampling and dosing resulted in toxicity test dissolved concentrations that were similar to those determined in the set-ups, and thus most closely reflected the true *in situ* sum toxicities.

534

Passive sampling with POCIS for contaminants of emerging concern in

drinking water

C.D. Metcalfe, Trent University / Environmental Resource Studies; E. Hoque, Water Quality Centre; T. Sultana, Trent University / Environmental and Resource Studies; P.A. Helm, Ontario Ministry of the Environment / Environmental Monitoring and Reporting Branch; S. Kleywegt, Ontario Ministry of the Environment / Standards Development Branch

Contaminants of emerging concern, including pharmaceuticals and personal care products (PPCPs) and endocrine disrupting substances (EDS)have been reported in drinking water at many locations in the USA, Europe and in Canada. The source of most of the compounds is municipal wastewater. Traditional water sampling methods often require the pre-concentration of large volumes of water to detect trace levels of these contaminants. POCIS is a passive sampling technology that has been developed to concentrate trace contaminants of emerging concern in water. However, there have been few studies to evaluate whether POCIS is suitable for monitoring these contaminants in drinking water. The purpose of this study was to determine if contaminants of emerging concern are present in raw and treated water in drinking water treatment plants (DWTPs) in Ontario, Canada. Another objective was to evaluate the use of POCIS as a monitoring tool for these contaminants in drinking water. Five DWTPs in Ontario were monitored for seven "indicator compounds" that included a non-prescription pharmaceutical, two prescription pharmaceuticals, two antibiotics, an estrogen hormone and an artificial sweetener. The cocnentrations of these compounds were estimated from amounts accumulated in POCIS deployed for 2 and 4 weeks in raw and treated drinking water at the DWTPs. These estimated concentrations were compared to the concentrations measured directly from extracts prepared from grab samples of raw and treated drinking water collected at three times during the deployment period. The indicator compounds were detected in most grab samples of raw water, but detection in treated drinking water was primarily limited to samples prepared from POCIS. Comparisons between POCIS data for 2 and 4 week deployments indicated that there may have been some loss of the indicator compounds from the POCIS over the length of the deployment period. The potential for loss of contaminants sequestered into POCIS over time was confirmed in a bench scale experiment. Overall, this study demonstrated that POCIS passive sampling could be a valuable tool for monitoring contaminants of emerging concern in drinking water, but a knowledge of the dynamics of contaminant accumulation and depuration is required to interpret the monitoring data appropriately.

535

Passive sampling as a tool for monitoring pharmaceuticals and its metabolites in marine environment at trace levels

M. Martinez Bueno, Hydrosciences Montpellier; F.H. Hélène, UMR Hydrosciences / UFR des Sciences Pharmaceutiques; A. Piram, University of Aix Marseille / Équipe MPO; D. Munaron, IFREMER Laboratoire Environnement et Ressources du Languedoc Roussillon; M. LeDreau, IFREMER; C. Casellas, Hydrosciences Montpellier; E. Gomez, Université de MontpellierCNRS Hydrosciences Montpellier UMR / Sc Environnement Sante Publique

Carbamazepine (CBZ) has been reported as a potential tracer in surface water due to its high persistence to biodegradation and poor elimination during wastewater treatment [1,2]. It has frequently been detected in wastewater effluent (up to 2.1 mg/L), in surface water (up to 1.1 mg/L) or even in drinking water (30 ng/L) [3,4]. However, little information on its detection and no data on its transformation products (TPs) in marine water are available in literature. This may be due to higher dilution rates, the complexity of the matrix (salts and ions) or/and the lack of suitable approach to detect these analytes at trace levels (ng/L). Recent studies have reported that passive samplers (POCIS) are effective samplers for qualitative and quantitative evaluation of emerging contaminants in surface water and wastewater [5,6]. In order to perform quantitative analysis it is necessary to determine the uptake rates or sampling rate (Rs) for each compound of interest in the POCIS. However, until now only some publications have reported on the application of these devices for analysis of pharmaceuticals in marine environment [1], and consequently, uptake rates have been calculated for a limited number of pharmaceuticals (approx. 25 drugs) [3,5,6]. This parameter is specific for each compound and depending on water-flow, temperature, biofouling, size of the POCIS (sorbent quantity), physico-chemical parameters (e.g., pH, dissolved organic compounds, and conductivity) as well as sampling period. Accordingly, the aim of this work was: (i) to develop and validate an analytical strategy to evaluate the occurrence and concentration of two anticonvulsants (carbamazepine and oxcarbazepine) and its related TPs in coastal water impacted by sewage treatment plant (STP) effluents; (ii) to determine the uptake rates of the target compounds under laboratory experiments; (iii) to evaluate the use of POCIS as a qualitative tool of non-target compounds (not included *a priori* in the method) from seawater.

Passive sampling method for the detection of pyrethroids and organophosphates in surface waters in the sub-ng/L range

J. Hollender, Eawag / Environmental Chemistry; C. Moschet, R. Seiz, Eawag / Uchem; H. Pfefferli, Interkantonales Labor Schaffhausen; E. Vermeirssen, Eawag / Dept of Environmental Toxicology

Most pyrethroids and organophosphate insecticides are very toxic for aquatic organisms (e.g. annual average environmental quality standard (AA-EQS) of cypermethrin: 0.08 ng/L). Although most of these substances are very non-polar ($logK_{ow}$ 4-8), critical concentrations can be reached in rivers. Thus, analytical methods are needed that can detect these substances in the sub-ng/L range. Gas-chromatography tandem mass spectrometry with negative chemical ionization (GC-NCI-MS/MS) has been found to be most efficient. However, there are problems during sampling, storage and extraction of water samples because pyrethroids efficiently sorb to plastic and glassware. Passive sampling on polydimethylsiloxan (PDMS) samplers can avoid this drawback and allow long sampling intervals for increased enrichment. Thus, PDMS passive samplers may be an efficient tool to detect non-polar pesticides in surface waters. In this study, a passive sampling method using PDMS sheets followed by an analytical method for 17 non-polar insecticides (15 pyrethroids, 2 organophosphates) using GC-electron ionization (EI)-MS/MS was developed, validated and applied to field samples. The PDMS sheets were extracted in a fast and efficient way using accelerated solvent extraction. Clean-up was performed using a combined silica gel and C18 column in order to reduce environmental matrix and sampler matrix. Good absolute recoveries (53–85 ± 8 %) and low LOQs of < 60 ng/PDMS were achieved for all substances. Back-calculation to time-weighted average water concentrations was done with sampling rates determined in the literature for PCBs. With this, LOQs in the sub-ng/L range could be achieved (0.002-0.13 ng/L), thus below AA-EQS values. To establish substance specific sampling rates, experiments were carried out in a flow channel system. To monitor in-situ sampling rates during field deployments, five pyrethroids were used as performance reference compounds . We generated 45 environmental samples with 2-week PDMS sheet deployment in five rivers during the main pesticide application period. Four pyrethroids (cypermethrin, permethrin, lambda-cyhalothrin, deltamethrin) and two organophosphates (chlorpyrifos, chlorpyrifos-methyl) could be detected in concentrations in the range of their AA-EQS values. The results show that PDMS samplers are very successful in detecting highly toxic non-polar insecticides in surface waters, which facilitates their future monitoring for compliance with EQS values.

Measurement of labile fraction of PAHs with polymeric membranes, in case of chronic or accidental pollution in rivers in France

A. Bressy, C. Lorgeoux, C. Mirande Bret, Paris Est University / Leesu; K. Cailleaud, Total Petrochemicals France / PERL; K. Lemenach, University of Bordeaux / UMR CNRS EPOCLPTC; N. Lesage, Total Petrochemicals France / PERL; C. SOULIER, Université Bordeaux; A. Basseres, TotalFinaElf / PERL; H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC; G. Varrault, Université ParisEst LEESU UMRMA UPEC ENPC AgroParisTech UPEMLV / Leesu

Over the last years, passive samplers have been used to measure the bioavailable fraction of hydrophobic organic contaminants in aquatic environments. In this paper, two main issues are addressed: (i) some methodological issues to measure the available dissolved Polycyclic Aromatic Hydrocarbons (PAHs) with polymeric membranes and (ii) the ability of polymeric membranes to measure the time-weighted average of the available dissolved concentration in water in case of variations over time (chronic or accidental pollution). To estimate the time-weighted available concentration during the exposure (TWC_{ldpe}), one first-order kinetic was used, whose the exchange kinetic parameters were calibrated in laboratory in a closed pilot. The laboratory constants were corrected from exposure conditions with the desorption of standards *in situ*. Experiments in channels bypassing the French river Gave were used to reproduce chronic pollution and accidental pollution with controlled injections of PAHs. Polymeric membranes in LDPE were deployed during 21 days in the channels. The first scenario reproduced chronic pollution by continuous injection of PAHs. The second scenario reproduced an accidental pollution by an injection of PAHs in the river during the first 3 days of the 21-day exposure. The third scenario was a discontinuous pollution with injection of PAHs during 3 periods of 3 days separated by 4 days. The same total quantity of PAHs was released in all scenario and two levels were tested: Environmental Quality Standard (EQS) level and 1/3 of the EQS level. During the experiment, grab samples of water were regularly analysed. The truly dissolved concentrations measured with polymeric membranes were compared with the actual exposure concentrations. The results have validated the laboratory calibration of kinetic parameters and the use of Performance Reference Compounds to correct *in situ* environmental exposure conditions. Polymeric membranes are overall reliable to integrate time-variations of concentrations, but the integrative performance of the tool decrease with the volatility of the compounds. To conclude, polymeric membranes are promising as alternative method to improve chemical monitoring of receiving water. They seem reliable to quantify the truly dissolved micropollutants and to integrate time-variation of concentration during pollution peak, discontinuous pollution or discharges of effluent.

Measuring and modelling chemical bioavailability in

soils (I)

Development of a Freundlich-type model predicting Cu, Ni, and Cd toxicity to earthworms

H. Qiu, Leiden University; M.G. Vijver, CML Leiden University; E. He, VU University Amsterdam / Department of Ecological Science; W.J. Peijnenburg, RIVM / Center for Safety of Substances and Products

This study aimed to develop bioavailability models for predicting Cu, Ni, and Cd toxicity to earthworms (*Lumbricus rubellus*, *Aporrectodea longa*, and *Eisenia fetida*) in a range of soils of varying properties. A Freundlich-type model, complying with the basic assumption of the biotic ligands model, was used to relate metal toxicity to the free metal ion activity and possible protective cations in soil porewater. LC50s based on the total soil metal concentration varied largely (usually >10-fold) in different soils. The relative sensitivity of the earthworms to metals in different soils followed the same order: *L. rubellus* > *A. longa* > *E. fetida*. A pH dependence of Cu^{2+} toxicity to different earthworm species was observed while only Mg^{2+} was found to significantly alleviate Ni^{2+} toxicity. Cd toxicity to earthworms showed to be driven by the free Cd^{2+} alone. The Freundlich-type model in which the corresponding toxicity-modifying factors were included, explained more than 84% of variations in Cu and Ni toxicity to different earthworm species. Predicted LC50s (expressed as free ion activity) never differed by a factor of more than 2 from the observed values. External validation of the model showed a similar level of precision, even though toxicity data for other soil organisms and for different endpoints were used. Although extrapolation of the Freundlich-type model across metals still needs more research efforts, this model, requiring fewer parameters than the BLM, proved to be a feasible framework for directly linking the porewater chemistry to metal toxicity in soils for various soil dwelling organisms and plants with different endpoints.

539

Implementation of bioavailability into the effects assessment of lead in soils

K. Oorts, ARCHE; E.E. Smolders, Katholieke Universiteit Leuven; R.P. Lanno, Ohio State University / Department of Evolution Ecology and Organismal Biology; M.J. Chowdhury, International Lead Zinc Research Organization / Assistant Manager Environment

At present, the risk assessment of lead (Pb) for soil in the European REACH registration file is based on a fixed generic predicted no effect concentration ($PNEC_{soil}$) for all soils. This provisional $PNEC_{soil}$ was derived from the 5th percentile of the distribution of the chronic NOEC and EC10 values for several plants, invertebrates and microbial processes. Although bioavailability and toxicity of metals can be strongly affected by the variation in soil physicochemical properties, the available Pb data did not allow establishing a relationship between soil properties and Pb toxicity to terrestrial organisms. This issue was addressed by measuring toxicity of Pb for 6 endpoints (2 plants, 2 invertebrates and 2 microbial endpoints) in a set of 7 soils covering a representative range of soil properties (pH, organic matter content, texture and eCEC). The effect of soil properties on bioavailability and toxicity of Pb was less pronounced compared to other metals (Cu, Zn, Ni, Co, Mo). Variation in soil properties only significantly explained variation in Pb toxicity for some endpoints (e.g. nitrification), but not for other endpoints (e.g. microbial respiration, *Folsomia candida* reproduction). Lead toxicity in field soils is generally significantly lower than in corresponding soils freshly spiked with soluble metal salts. This discrepancy was quantified by studying toxicity of Pb after 3 different contamination conditions: i) freshly spiked with $PbCl_2$, ii) freshly spiked, leached and pH corrected in order to remove salinity and pH stress, and iii) freshly spiked and aged for 5 years. Leaching and long-term aging of soils attenuated Pb toxicity significantly, confirming higher toxicity in freshly spiked soils compared to soils equilibrated under field conditions. Soils spiked with a lead salt to perform toxicity testing are therefore poor indicators for toxicity of Pb in soils gradually contaminated in the field and a correction factor of 4.0 was derived to correct for this discrepancy. A generic PNECsoil of 213 mg Pb/kg soil was derived as the 5th percentile of the log-normal distribution of 105 leached and aged NOEC and EC10 values, covering 27 terrestrial species or microbial processes. Normalization of toxicity data to a relevant range (10th-90th percentile) in soil properties across European soils yielded $PNEC_{soil}$ values between 171 and 442 mg Pb/kg.

540

Variability in the binding capacity of dissolved organic matters toward trace metals in soil: impact on predictive ecotoxicology

M.N. Bravin, t. djae, P. Cazevieille, C. Chevassus-Rosset, L. Lemal, J. Marger, M. Montes, C. Pradier, E. Doelsch, CIRAD

The development of ecotoxicological models for trace metals in soil requires the critical estimation of trace metal speciation in soil solution. This estimation is notably based on the description of the binding capacity of dissolved organic matters (DOM) whose a percentage is considered to react as a “generic” fulvic acid. This percentage of reactivity is typically fixed at a unique value for all soils while experimental evidences supporting this hypothesis are rather few. The present study thus aims at exploring the variability of this percentage of reactivity for soil DOM and evaluating the impact of this parameter on the toxic effect of copper (Cu) on soil organisms as predicted with the free ion effective dose (FRIED) model. Soil solution was recovered from 55 soil samples exhibiting a very broad range of physical-chemical properties. Free Cu activity was determined analytically and modelled with the Model VII. Free Cu activity was first computed by considering a percentrage of reactivity for DOM fixed at 65 % for all soils. This consideration led to a rough prediction of the actual Cu speciation in soil solution with deviation up to 2 pCu^{2+} unit. Free Cu activity was secondly computed by fitting the percentrage of reactivity for DOM for each soil solution individually, with percentages thus ranging between 5 to 200 %. Finally, the comparison of the toxic effect of Cu on soil organisms predicted by the FRIED model was alternatively over-estimated up to 37 % or under-estimated up to 60 % when using free Cu activities calculated with the fixed percentage of DOM reactivity. These results thus suggests that the large variability in the binding capacity of soil DOM involves (i) a substantial inaccuracy in the prediction of metal speciation in soil solution and (ii) a consequent alteration of the predictive power of ecotoxicological models when considering a unique percentage of reactivity.

541

Evaluating toxicity of metals alone and in combination to terrestrial plants (L. sativa M.) by site-specific principles

Y. Liu, Faculty of Science Leiden University; M.G. Vijver, CML Leiden University; W.J. Peijnenburg, RIVM / Center for Safety of Substances and Products

Metal toxicity is one of the principal abiotic stresses leading to potential hazardous effects to plants. Lettuce as a general eaten fresh in salads can be harmful to human health upon exposure to metals. In order to reduce the chance of metals entering the food chain, our study investigated how to identify the toxicity of common metals and their mixtures to lettuce (*L. sativa M.*) as a baseline for soil quality criteria. Hypothetical interactions with biotic ligands (BLs) and bioavailability dictated by water chemistry have been proposed to affect metal toxicity to a variety of organisms. These influences can be quantified in toxicity assessment using the biotic ligand models (BLMs). Based on the soil solution properties, hydroponic solution was selected as the test medium to mimic the ionic environment of soil. It was hypothesized that major cations in the solution would compete with added toxic metal ions for binding to the BLs. Apart from cadmium which did not present statistically significant enough to sufficiently create relationships between competing essential cations and Cd-toxicity, toxicity of the other common metals in soil was found to be obviously influenced by competing major cations (such as Mg^{2+} and H^{+}). Thus, with the known conditional stability constants obtained for copper, zinc, silver and nickel, BLMs were extended for toxicity prediction for binary metal mixtures (i.e. Cu^{2+}- Zn^{2+}, Cu^{2+}- Ni^{2+} and Cu^{2+}- Ag^{+}) by combining with toxic indexes, namely toxic unit (TU), toxic equivalency factor (TEF) and overall amount of metal ions binding to the BLs (f_{mix}). These three mechanistically based approaches all succeeded to explain mixture toxicity of common metals to lettuce. By bootstrapping method, the improvements of transforming toxic indicators were quantified. The comparison of model powers gave hints in the underling modes of action of binary-metal mixtures. The estimated coefficients were also helpful in approximately judging competitive effects of individual metal ions in the mixture and toxic potency of metal mixtures. In summary, our research expanded the usage of BLMs in assessing the potential threats of metal mixtures to terrestrial plants and broke from the limitation of TEF approach that can be only used for organic chemical classes. Keywords: metal toxicity, mixtures, biotic ligand models, plants

Bioavailability and bioaccumulation of copper by sediment rooted plant Myriophyllum aquaticum

M. Grote, A. Caillat, EDF RD / National Hydraulics and Environment Laboratory; P. Ciffroy, EDF / LNHE Department I; J. Garnier, AixMarseille Université / Cerege

When aiming environmental risk assessment of contaminated sediments, it is essential to characterize the bioavailability of compounds by either chemical measurements or biological methods. The aims of this study are (i) to evaluate how DGT measured bioavailable copper can use to predict the bioaccumulation in the aquatic plant *Myriophyllum aquaticum* and (ii) to characterise the processes involve in the uptake. For this purpose 3 different series of experments were conducted exposing small plants with roots and whorls of *M. aquaticum* to copper spiked artificial sediments and seperately to copper spiked nutrient solution. The bioavailably copper concentration in sediments was assessed by kinetic uptake experiments using a “diffusive gradient in thin films” (DGT) sampler. Measured DGT uptake was interpreted using the DGT-PROFS model providing the diffusion coefficient of metals in the sediment and the desorption rate from weak and strong particulate sites. Furthermore, pseudo interstitial water free copper concentrations were calculated taking into account local depletion of copper close to uptake phases (DGT or plant roots). In order to characterise the kinetics of the uptake into the plant roots, a series of experiments were conducted with plants exposed directly in the nutriment solution. Experimental results can be described by a

Michealis-Menten kinetic characterised by a maximum flux (F_{max}) of 1692 ng.m^{2}.s^{-1} and a Michaelis constant (K_m) of 1200 nM. Bioaccumulated copper concentrations in the plants were compared to modelled free copper concentrations. Bioaccumulation shows a similar relationship in plants with roots when exposed to the solution or to the sediment when compared on the basis of the modelled free copper concentrations. However, no clear relationship of bioaccumulation in plants exposed as whorls as proposed by the normalised protocole and free copper concentration was apparent. Possibly, the cutting of the stem and the fact that new roots have to develop modifies the uptake processes, which appears to lead to qualitatively different bioaccumulation. The study shows that DGT measured copper concentration can be used to predict bioaccumulation in entire sediment rooted Myriophyllum plants but not in the standardised biotest using whorls. Time series of DGT measurement were necessary to model sediments properties governing the copper resupply by the solid phase and to adequately estimate the bioavailability during exposure.

Mercury Biogeochemistry and Policy (I)

Mercury flux from Arctic snow – Irradiation and temperature dependence

E. Mann, Department of Environmental Science; M. Mallory, Acadia University / Canadian Wildlife Service; S. Ziegler, Memorial University of Newfoundland; N.J. O\'Driscoll, Acadia University / Department of Earth and Enviromental Science

Mercury moves to the Arctic environment via atmospheric transport, and is deposited to the surface with snow. This mercury is subject to photoreactions, which may form elemental mercury (Hg(0)) and move from the snowpack back to the atmosphere. Flux of mercury from the snowpack has been hypothesized to be dependent on incident solar radiation and temperature. Hg(0) flux from snow was measured *in situ* with coincident measurement of incident solar radiation and atmospheric temperature to quantify these relationships. Flux measurements were undertaken from March 20 to 28, 2013 in Resolute Bay, NU, Canada, using a Teflon flux chamber with a Tekran 2537 used to measure Hg(0) concentrations. A Davis Weather Station was deployed to measure air temperature every 10 minutes, and an OceanOptics USB 4000 spectraradiometer to measure incident solar radiation every 5 minutes for the duration of the study. Flux of Hg(0) from undisturbed snow was found to be linearly related to incident UV radiation (R^2 = 0.6; $p < 0.01$), while temperature may play a more complicated role. Snow from the site was collected and shipped to Acadia University (Nova Scotia, Canada) for experiments to determine temperature dependence of mercury photoreactions in snow. Snow was irradiated with 4.65 W/m^2 of UV radiation using a LuzChem photoreactor, and subjected to a range of temperatures (-2 to -20 °C). The reduction of mercury in snow was monitored using a Tekran 2537 and the kinetics of mercury reduction determined at each temperature, assuming pseudo-first order kinetics. Using the determined temperature dependence at constant UV irradiation intensity and previous work using constant temperature and varying UV irradiation intensity, a predictive model was developed for the loss of mercury from snow under given temperature and irradiation conditions.

544

Interactions between Hg in shallow aquatic environment and macrophytes

N. Regier, University of Geneva / Institute Forel Earth and Environmental Sciences; A. Garcia Bravo, Forel Institute; C. Cosio, Geneva University / Aquatic Biogeochemiostry and Ecotoxicology Institute FA Forel Earth and Environmental Sciences Faculty of Sciences

Accumulation of Hg in primary producers is the first step of Hg uptake in food web and result in the highest biomagnification step. In shallow waters the highly toxic methyl-Hg (MeHg) is formed and macrophytes – aquatic photosynthetic organisms that can be seen by naked eyes – are the predominant primary producers playing a key role in the structure and functioning of the ecosystem. The present study aimed at investigating Hg accumulation in macrophytes, and describes the role of macrophytes, in particular *Elodea nuttallii* in Hg fate that have been identified until now including Hg cycles in sediments, methylation, bioaccumulation, and biomagnification in the food chain. Shoots of *E. nuttallii* showed the highest Hg concentrations in the Babeni reservoir –contaminated by a chlor-alkali plant. Bioaccumulation factor (BAF) in shoots of submerged macrophyte was in the range 10^5 L/kg for total Hg and MeHg respectively. Up to 28% of the Hg concentration found in this species was in the form of MeHg. N and C isotope signature suggested a role of these plants as Hg source to fish of the reservoir. High Hg tolerance and fast Hg accumulation was confirmed in *E. nuttallii*. Basipetal transport of IHg from shoots to roots was evidenced, whereas MeHg was transported acropetally only, supporting the hypothesis that IHg accumulated in shoots originated mainly from the water column, while MeHg originated from sediments and water column. At the subcellular level, 65±11% of Hg was internalized in the cytosol where it is bioavailable to herbivores, whereas 45±17% was found in cell walls. To further understand how Hg is internalized in cells of the shoot, we exposed shoots to Hg and other metals including essential (Fe, Cu, Mg, Mn, Ca, K and Zn) and non-essential metals (Cd, Ni). Only Cu resulted in a significant 97.2±0.6% inhibition of Hg uptake suggesting a putative role of Cu transporters in Hg uptake. This was further supported by transcriptome analysis which revealed a putative role of EnCOPT1 in Hg accumulation. Results suggest that *E. nuttallii* created a microenvironment favorable for Hg methylation and biomagnification. This highlights the need for an increased understanding and consideration of the role of macrophytes in the Hg biogeochemical cycle in aquatic environment and in risk assessment of this metal as shallow water represent a significant surface of our planet.

545

Benthic fluxes of mercury in a highly industrialized coastal environment (Mar Piccolo, Taranto, Italy)

A. Emili, Department of Mathematics and Geoscience; S. Covelli, Dipmento di Matematica e Geoscienze / Dept of Mathematics and Geosciences; A. Acquavita; N. Cardellicchio, National Research Council of Italy

Coastal areas of the city of Taranto (Italy), have suffered from intense anthropic and industrial pressures (notably an iron and steel factory, a petroleum refinery, and the Italian Navy shipyard and arsenal) and were declared a "Contaminated site of national interest" in 1998. Previous research showed significant heavy metal contamination of the Mar Piccolo sediments, with higher concentrations in the first inlet where the Navy arsenal is located. High sedimentary Hg contents, in particular, are a cause of concern, given its possible transfer to the aquatic trophic chain and considering the widespread fishing and mussel farming activities in the area. Up to ≈ 8 µg g^{-1} of total Hg were measured in the Mar Piccolo sediments, while the concentration in seafood was below the limit established by the European Community (0.5 mg/kg w.w.) with the exception of the gastropod *Hexaplex t.*, sampled in proximity of the Navy Arsenal. As Hg is considered a priority pollutant for its toxicity, mobility, and bioaccumulation potential (especially in its organic form methylmercury), a further investigation on the role of sediments as a potential source of Hg to the Mar Piccolo aquatic ecosystem was conducted. The research was carried out in the framework of the "RITMARE - la Ricerca ITaliana per il MARE (2012-2016)" Flagship Project, financed by the Italian Ministry of University and Research (MIUR). The release of Hg from sediments was investigated by means of an *in situ* benthic chamber, as previously described for other Hg contaminated coastal areas of Italy.

546

Oxycline depth influences methylmercury production and pelagic accumulation in a small lake ecosystem

T. Perron, University of Montreal / Sc Biologiques; J. Chetelat, National Wildlife Research Centre Environnement Canada; J. Gunn, University of Birmingham; B.E. Beisner, GRIL University of Quebec at Montreal; M. Amyot,

Environmental disturbances like deforestation or climate change may influence lake thermal and oxic conditions, thereby modifying cycles of contaminants such as mercury (Hg). In a small Canadian Shield lake naturally separated into three basins, the thermocline and oxycline of an experimental basin were experimentally deepened by 4 m and 3 m respectively with a lake mixer to study the effect on the methylmercury (MeHg) production and accumulation. Passive heat transfer from the experimental basin to an intermediate basin caused a 2 m thermocline decrease in a second basin without affecting its oxycline depth. When thermocline and oxycline deepening occurred together, MeHg aqueous concentrations decreased by up to 90% in the hypolimnion, by 30 to 50% in zooplankton, and by approximately 30% in some fish species. A multiple linear regression indicated that oxycline depth significantly influenced hypolimnetic MeHg concentrations, with no significant effects of thermocline depth, anoxic water volume, nor the interface area of oxic-anoxic water and sediment area in contact with anoxic water. Fish MeHg decline varied among species, with a greater response for low oxygen-tolerant bottom-feeding bullhead compared to littoral creek chub. Increased pelagic primary and secondary production likely cause MeHg decreases in zooplankton and fish via algal and growth dilution. Environmental changes leading to oxycline deepening are therefore predicted to cause a decrease in MeHg bioaccumulation in similar lakes. If associated ecosystem impacts related to application of thermocline and oxycline deepening are deemed acceptable, this experiment provides a potential remediation method in small lakes confronted with elevated MeHg accumulation.

547

Effect of oxygen, nitrate and aluminium addition on methylmercury efflux from mine-impacted reservoir sediments

M. Beutel, Washington State University / Civil and Environmental Engineering; R. Duvil, Washington State University; D. Drury, Santa Clara Valley Water District

Mercury (Hg) mines are sources of Hg pollution to downstream aquatic environments. This study presents results of laboratory sediment-water interface experiments to assess the effects of oxidant and sorbent amendments on methylmercury (MeHg) efflux from reservoir sediments contaminated with Hg as a result of upstream mining activities at the New Almaden Mining District in northern California, USA. Study sites included Guadalupe Reservoir, a 25-m-deep, 30-ha reservoir near the headwaters of Guadalupe Creek, and Almaden Lake, a 13-m-deep, 24-ha quarry lake. Study sites are located in the Guadalupe River

Watershed, a complex hydrologic system that includes six reservoirs and over 100 km of rivers and streams, south of the San Francisco Bay. In the first study, 4 chambers were collected from each site and incubated in the laboratory under aerobic conditions for 10 days followed by anaerobic conditions for 17 days. Chamber water overlaying sediments was monitored with time for a range of constituents. Fluxes of MeHg, manganese and orthophosphate from sediments were significantly lower under aerobic conditions. But sediments responded in differently in important respects. Under aerobic conditions Guadalupe sediment released total Hg, MeHg, iron and sulphate. In contrast, these constituents showed negative fluxes (uptake) in Almaden sediments under aerobic conditions. This indicates that while aerobic conditions lowered MeHg flux from sediment, aerobic sediments were a source of ionic Hg. We hypothesize that the mechanism for this observation was the oxidation of cinnabar and pyrite in Guadalupe Reservoir sediment, which being closer to the mining district, may have had more mine-related mineral ores in surfacial sediments compared to Almaden Lake. In the second study, 16 chambers were collected from the deep site in Almaden Lake. Chambers were incubated in quadruplicate under four treatments for 24 days: anaerobic control; aerobic; anoxic with nitrate addition; anaerobic with buffered sodium aluminate addition. MeHg flux from sediment was significantly lower in the aerobic treatment (0.5 ± 0.6 μg/m^2·d; mean plus/minus standard error; n = 4; flux based 10 day incubation) and the nitrate treatment (0.2 ± 1.4 μg/m^2·d) relative to the anaerobic control (17.4 ± 6.6 μg/m^2·d). However, the sodium aluminate treatment (10.5 ± 1.9 μg/m^2·d) was not significantly different from the control.

548

Methanogens as principal methylators in tropical areas

W. Lazaro, UNEMAT; A. Schimanko Ceccatto , . Alves IgnÃcio, UNEMAT / Centro de Estudos em Limnologia Biodiversidade e Etnobiologia do Pantanal; S. Diez, CSICIDAEA / Environmental Chemistry; J. Guimaraes, Universidade Federal do Rio de Janeiro UFRJ

The periphyton is considered one of the main Hg methylation sites in the aquatic environment. Methylation is attributed primarily by sulfate-reducing bacteria (SRB), however, recent studies report that other microorganisms can methylate inorganic mercury. In this context, this work has two objectives: (1) measure the periphytic MeHg net primary production rates in a tropical flooded river plain system of high ecological value, (2) Identify the main bacterial strains involved in Hg methylation by addition of metabolic inhibitors in the area. The Guapore River is located in the Mato Grosso state, and is part of the Amazon basin. Samples were taken in March 2013. A total of 160 field replicates samples of aquatic macrophytes rhizomes with their associated periphyton were sampled. Physico-chemical parameters were measured *in situ*, along with water samples for dissolved organic carbon, total nitrogen and total phosphorus. Water samples were spiked with $^{203}HgCl_2$ (~ 25,000 DPM each). Each sample group consisted of 3 replicates and 1 control, killed with 1 ml of 4 N HCl, being: (1) Control (without addition of metabolic inhibitors), (2) BESA (2-bromoethane sulfonic acid, a methanogenesis inhibitor), (3) DCMU (3-(3,4-dichlorophenyl) -1,1 dimethyl urea, a photosynthesis inhibitor) (4); molybdate (sodium molybdate, a sulfate reduction inhibitor), and (5) CC (chloramphenicol, a bacteriostatic inhibitor). Extraction was carried out using acid leaching and extraction in toluene. With no inhibitors, the primary methylation rates ($Me^{203}Hg$ as % of total added ^{203}Hg) varied between 14% and 26%, with an average of 18 %. There were no significant differences in $Me^{203}Hg$ production between lakes (p=0.232). When the net methylation rates where compared among groups, the treatments with the lowest rates were chloramphenicol (4.4B0.1), BESA (6.9т0.7), molybdate (10.6т1.6), and DCMU (12.9%т3.0). The $Me^{203}Hg$ produced in different treatments were significantly different (p = 0.001). In PCA, only the first axis resumed 90% of data variance. We found no significant relationship (Rт = 0.042, p = 0.113) between the production of MeHg and the first PCA axis.. Our study may indicate indirect contributions by autotrophic prokaryotes in Hg methylation and strongly suggests that methanogens rather than sulfate reducing bacteria were likely the primary methylators in the periphyton of our study area. **Keywords:** mercury, methanogens, radiotracers, wetlands.

Toward sustainability: benchmarks, certification and LCA (I)

Global Principles and Practices for Hotspots Analysis

J.A. Fava, PE INTERNATIONAL Inc; M. Barthel, WRAP / Product Sustainability Forum; P. Strothmann, Strothmann Consulting; C. Harnanan, PE INTERNATIONAL Inc

Hotspots analysis is a relatively new analytical tool that is being used as a pre-cursor to developing product sustainability information. It allows for the prioritization of resources and actions in industry sectors, product portfolios, product categories or individual products that really matter by virtue of their environmental, social and ethical impact profile and /or their physical trading volumes and economic sales in the economy. While hotspots analysis is proving to be a helpful and effective tool that assists in the identification of areas to be prioritized for further research or action by relevant stakeholders, there is currently no common global approach to hotspots analysis; nor has there been any effort to bring together or share best practice amongst those product sustainability initiatives currently involved in hotspots analysis. Neither do any accepted principles or guidance exist on how to translate and apply the results of this analysis into meaningful product sustainability information for use by industry, governments and other stakeholders In order to address this gap, the project will involve the organization of a global process with the following **four** over-arching objectives: To develop a common understanding of and map hotspots analysis approaches currently in use and to share the learning and experiences derived from these analyses; To develop, agree and pilot a commonly agreed methodological framework for 'hotspots' analysis approaches based on identified global principles and practices, as a means of accelerating and prioritising international action on product sustainability; To build and share the knowledge base derived from existing hotspots analysis world-wide to support the development of a richer and more global view of the product categories and individual products that offer the most opportunities for performance improvement by tackling the hotspots associated with them; and To develop and agree on a guidance document on the consistent and appropriate use of the product sustainability information derived from hotspots analysis. The presentation will provide insights into the existing challenges with regards to hotspot analysis and outline the process of how to overcome these challenges. It will make the case for stakeholders involved with hotspot analysis methodologies as well as study results to become involved in the project.

Creating a pilot eco-label assessment matrix based on life cycle assessment

M. Locher, University of Applied Science NorthWestern Switzerland / now at Weleda; A. O Rourke, DEKRA / Sustainability and Performance Excellence; G. Sonnemann, University of Bordeaux / The Life Cycle Group CyVi

A growing number of different eco-labels exist, spanning a wide variety of product categories and serving different markets. While intended to represent the environmental preferability of a product they are applied to, the exact scope of environmental and social attributes that eco-labels address is oftentimes opaque to users. Whether or not the eco-label covers the most critical environmental and/or social impacts associated with a product over its life cycle is also not well understood nor communicated. In this article, eco-labels are examined from the perspective of life cycle assessment (LCA). We describe the creation of an pilot eco-label assessment matrix that seeks to analyze eco-labels' criteria against the sustainability "hot spots" of a product as indicated by LCA. A test application of the assessment matrix was conducted for ecolabels applied to two agricultural product categories: beef and cotton. These were selected, as they are known to have significant sustainability impacts. Information was gathered on known impacts for these two product categories and a basic LCA was conducted. A set of "hot spot" indicators was constructed then compared to the criteria laid out by three prominent eco-labels. The pilot testing reveals some critical gaps and differences in approach between the eco-labels assessed and the LCA results. We discuss the strengths and weaknesses of the draft eco-label assessment matrix and it's potential applicability in different contexts. The article also highlights ways in which eco-labels, LCA and LCIA data may be improved and be made more accessible. The findings demonstrate the utility of taking a structured approach to the assessment of Eco-labels serve as "trust marks", providing users with information on sustainability-related issues associated with that product, and enabling them to make a more informed purchasing decisions. **\n**

LCA-related benchmarking process as part of environ-mental performance assessment for buildings – a contribution to sustainable construction works

T. Luetzkendorf, M. Balouktsi, Karlsruhe Institute of Technology KIT / Chair of Sustainable Management of Housing and Real Estate

The involvement with the issue of sustainability has led to considerable efforts also from the side of the real estate industry. As a result, an understanding of sustainability has been created and is reflected in standards such as ISO 15392:2008. Thus, a sustainability assessment of construction works includes based on the fulfillment of technical and functional requirements, the assessment of the social, economic and environmental performance. As a result of standardization activities (ISO TC 59 SC 17 and CEN TC 350) there are now available among others appropriate foundations for the selection of criteria, the calculation process as well as the data requirements for an assessment of environmental performance. The criteria were derived from the areas of protection, for whose elaboration SETAC played a significant role. By using methods of LCA, a transition from qualitative to predominantly quantitative assessment of environmental performance as an aspect of sustainability was possible. Through the publication of EPD's for construction products and the availability of databases (e.g. the Ökobau.dat in Germany) the practical applicability in the processes of planning and sustainability assessment has been improved. It is now possible the building related resource use and the effects on the environment to be calculated for the full life cycle, and be included in comparisons of variants or a sustainability assessment already during the planning phase. For the national systems of sustainability assessment in

Germany (BNB and DGNB) these calculations are an integral part. A sustainability assessment requires, in addition to the calculation of the energy and material flows, the results to be able to be classified based on benchmark values. This topic has not yet been treated in standardization. Currently the foundations for the development and application of LCA-related benchmarks for buildings are discussed. It is, among others, a question of securing the completeness of the description of the building and its life cycle, ensuring the comparability based on a description of the functional equivalent, defining the limit and target values and the development process of benchmarks (e.g. on the basis of average values or reference buildings). By performing life cycle costing as a necessary part of the sustainability assessment new possibilities arise for plausibility checks.

552

Applying PEF in practice - challenges related to the development of PEFCRs and benchmarks

A. Lehmann, Technische Universitaet Berlin / Department of Environmental Engineering Chair of Sustainable Engineering; V. Bach, Technische Universitaet Berlin / Chair of Sustainable Engineering; M. Berger, Technische Universitaet Berlin / Chair of Sustaiable Engineering Office Z; M. Finkbeiner, DaimlerChrysler AG / Chair of Sustainable Engineering

The identification of benchmarks and classes of environmental performance for certain product groups is one of the targets of the Product Environmental Footprint (PEF). Within a three-year pilotphase (started in Nov 2013), product group-specific rules (Product Environmental Footprint Category Rules – PEFCRs) should be set up and validated as well as different B2B and B2C communication vehicles should be identified and tested. The intended environmental performance benchmarks for particular product categories will describe the range in which the results could be seen as not being significantly different in comparisons or comparative assertions. In order to test the applicability of the PEF methodology and to follow up the ongoing developments in the pilot phase, especially the development of benchmarks, a case study on plastic products, specifically a comparison between bio-based and conventional plastics (Cellidor vs. PMMA) is conducted. The study includes translating existing LCA studies into a PEF – leading to 'test PEFCR' which could apply for the category 'manufacture of plastic products' (CPA/ NACE code 22.2) – and determining benchmarks and environmental performance classes for the particular product category. Regarding the development of benchmarks, as a first step the uncertainities common to the product category are analyzed. First results already indicated significant differences of up to 150 % for some impact categories due to the very different product systems of the two plastic products. As a next step, a "test-PEFCR" for the product category will be developed and five environmental performance classes will be defined, ranging from A to E with C describing the benchmark and A and E the best and worst cases. Results of this analysis, with a focus on the developed benchmarks and identified challenges will be presented at the SETAC-conference. Hence, this study helps to clarify how to deal with specification of benchmarks within the PEF methodology.

553

Agricultural production guidelines as a basis for impact assessment – a case study of Indian silk production

M.F. F. Astudillo, Zoology; G. Thalwitz, F. Vollrath, University of Oxford / Department of Zoology

The environmental impact of agriculture and textile production is of growing interest for legislators and consumers that demand environmental credentials of products and services. As but one example, the European Commission is updating the Ecolabel criteria for textiles, to inform consumers, set public procurement policies, and promote a market for green products. Because this voluntary scheme covers a wide range of products, a life cycle assessment (LCA) approach is used to detect the phases with the highest environmental impact in order to determine product specific criteria. The majority of primary production for textiles takes place in non-OECD countries and accurate data on local production practices can be difficult to acquire. Exemplifying this, despite its long history and importance as a textile, LCAs of raw silk production are lacking although preliminary results indicate high embodied energy. In order to establish a benchmark for silk impacts and identify areas with major contribution to environmental impact, we performed an outline LCA of Indian raw silk based on recommended practices and comparing it with available data on farm practices. We constructed life cycle inventories for raw silk production, categorised by production stage. Included were mulberry cultivation, silkworm rearing and silk reeling. The funcional unit is one kg of raw silk at factory gate and the impact assessment method employed was ReCIPe Midpoint (E) v.1.06, as implemented in Simapro V. 7.3.3. For the majority of the indicators, burdens are concentrated in mulberry production. When compared with other natural fibers on a mass basis, environmental impact of silk is significatly higher. Results indicate that environmental impact of guideline values and recommended practices can vary greatly, depending on the category. We argue that, while they may not be representative of the actual farm practice, LCAs based on best practice recommendations (from e.g. agricultural extension institutions) can serve as a baseline for evaluating the environmental sustainability of products for which comprehensive data is lacking or not easily accessible. This is especially relevant for silk and other products produced exclusively at small scale in low- and middle-income countries with a large proportion of impact at farm stage.

554

Comprehensive environmental sustainability assessment on Pampers baby wipes including supply chain specifics

G. Van Hoof, Procter Gamble Services / Environmental Stewardship Organizatino; A. Weisbrod, Procter Gamble PG / Global Product Stewardship

P&G uses Life Cycle Assessments (LCA) to learn of potential product category impacts on the environment, guide the sustainable design of products, and develop justified claims. Pampers recently innovated their baby wipes in Western Europe (WE) and North America (NA) thanks to a novel making process, allowing significant reduction in dry product weight (-19% in NA, -14% in WE). We conducted a cradle-to-grave LCA study to compare wipes from 2007 with 2013 to better understand the potential environmental impacts of the new process and optimized weight. Since the majority of relevant environmental indicators for baby wipes are driven by the production of the wipe raw materials, this innovation resulted in an improvement to all relevant environmental impact indicators ranging between 10 and 40%. Agricultural land occupation for WE is the only indicator that shows no significant change (+4%). Because life cycle impact assessments do not account for all environmental impacts, we also explored other potential environmental aspects in the supply chain. For example, sustainable forestry is not always covered well in life cycle inventory data sets. The supplier of a major wipe material achieved a total sustainable forestry certification of 75% of their fibers from tree woods. Both the smaller environmental footprint identified from LCA, and the fiber certifications, are useful checks internally and are helpful to communicate to reassure stakeholders externally. Net, this study shows that comprehensive sustainability assessments use LCA insights coupled with supply chain management and associated sustainability certification systems.

Developments in Environmental Quality Standards: bridging the gap between science and practical regulatory implementation (I)

555

Gaps in sediment quality guidelines: Incorporation of sediment physicochemical characteristics in assessing uranium bioavailability

S.E. Crawford, University of Saskatchewan Toxicology Centre / Toxicology Centre; K. Liber, University of Saskatchewan / Toxicology Centre

Sediment Quality Guidelines (SQGs) have been criticized for overlooking the important role of bioavailability and the modifying factors that control the behaviour of metals in aquatic ecosystems. However, our understanding of the factors and mechanisms controlling the bioavailability of some metals is still incomplete. In particular, there is limited information regarding the bioavailability and toxicity of sediment-associated uranium (U) to freshwater benthic invertebrates. The tendency of U to accumulate in sediments makes benthic invertebrates among the most highly exposed organisms. Benthic invertebrates are also an important group of organisms used for the evaluation of metal impacts in aquatic environments, and for the development of SQGs in Canada and equivalent criteria around the world. Where SQGs exist for U, the true risk of U exposure to benthic communities is often over- and under-predicted. Recommendations for improvement of SQGs, include the incorporation of bioavailability correction factors or consideration of the dissolved fraction as an indicator of bioavailability. It is known that sediments are important in metal sequestration and associated changes in exposure to aquatic organisms, but few studies have worked with U-spiked sediments and of those that have, only a few have used benthic invertebrates as the test species. This research focused on quantifying the changes in U bioavailability for organisms exposed to U-spiked formulated and field sediments respective to the physicochemical characteristics of the sediment (i.e., particle size and total organic carbon (TOC) content). Additionally, comparisons between U concentrations measured in the solid and dissolved phase were investigated to determine if alternatives to total contaminant concentrations in sediment could be used to better predict U bioavailability. Results from these studies have shown that with similar concentrations of U in sediment, the actual amount of U available for biological uptake is influenced by the composition of the sediment. Formulated and field sediments consisting of higher amount of clay or organic carbon content significantly reduce bioaccumulation of U to exposed *C. dilutus* larvae. This demonstrates that the current SQG approach of using total sediment concentrations as a basis for predicting U effects downstream of U mining areas, is not reliable and incorporation of sediment factors that modify U bioavailability should be considered.

556

Applicability of sediment quality standard derived using standardized equilibrium partitioning method for the assessment of water bodies' status

S. ANDRES, A. PAPIN, INERIS; D. Amouroux, LCABIE IPREM / UMR CNRS; H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC; M. Chevreuil, LHEEPHE Université Pierre et Marie Curie; C. Cren, ISA; F. Botta, INERIS

In the implementation of the Water Framework Directive, quality standards (QS) may be derived in the most appropriate matrix, including sediment for e.g. hydrophobic substances which are barely detected in water. The EU Technical Guidance Document on EQS (TGD) recommends in certain circumstances to apply the equilibrium partitioning (EqP) method to derive a standard in sediment based on the standard derived in water. The TGD provides default values, in particular for Total Organic Carbon (TOC) content. This method is generally believed to be rather protective, except for highly hydrophobic compounds for which an additional factor has to be applied. This method was applied at national level in order to allow the derivation of QSsed for a large number of chemical to be investigated in an exceptional survey in which 85 chemicals were analyzed at about 110 sampling points together with TOC. The selection of chemicals to be investigated in sediment took place within a larger priorisation exercise among 2400 compounds considered as potential candidate substances; of which more than 400 are pharmaceuticals and associated metabolites, and about 70 are chemicals used in personal care and household products. The rest are mainly pesticides, biocides and industrial chemicals. The results of the monitoring campaign contributed to the selection of substances to be integrated in the monitoring programmes of the water agencies in the various river basins. Substances for which a risk of degradation of the quality of the water body was identified were prioritised. This risk was calculated using EqP method with both default and site specific values for TOC. The results show that for a significant number of stations, the estimation of the risk may be different depending of the use of default or site specific TOC. This result is substance-dependant. In addition, for those sampling sites with a TOC profile which differ significantly from the default EU sediment, the overall estimated risk is evidently more impacted. It is also to be noted that default values proposed in the TGD for the application of the EqP method at EU level are not protective in a majority of the stations investigated in this campaign. In order to increase the understanding of *in situ* toxicity, TOC as an indication of bioavailability is used to interpret the differences observed between the so-called chemical status and biological status based on biological indicators determined on the same sampling sites.

557

HBCD diastereomer levels in fish and suspended particulate matter from European freshwater and estuary sites - environmental quality standard compliance and trend monitoring

H. Ruedel, Fraunhofer IME Institute for Molecular Biology and Applied Ecology / Environmental Monitoring; J. Nowak, J. Mueller, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; M. Ricking, Department of Earth Sciences, Hydrogeology, Geochemistry; Free University Berlin; M. Quack, Trier University / Biogeography; R. Klein, Trier University

Hexabromocyclododecane (HBCD) is a brominated flame retardant applied mainly in polystyrene foams used as building insulation, and to minor extents in flame-retarded back-coats, e.g., for upholstery textiles and in high impact polystyrene (HIPS) used in electrical and electronic equipment. An environmental monitoring project was initiated to assess the impact and relevance of emission control programmes that have been implemented by HBCD producers and users during recent year. It is designed to assess temporal trends at different sites across Europe and focuses on compartments which are expected to be sinks for HBCD (based on its physico-chemical properties and the life cycles of products containing HBCD). Samplings cover fish (bream; annually since 2007) and suspended particulate matter (SPM; every second year). Selected sites are at the rivers Tees/UK, Mersey/UK, Western Scheldt/NL, Götaälv/SE, and Rhône/FR and at Lake Belau/DE. The later was selected as site with little anthropogenic influence. For fish, annual pooled samples of usually 15 fish per site were prepared. SPM samples were collected at river sites with sedimentation traps during 4 periods of 3 months per campaign. HBCD analyses were performed applying an LC/MS-MS method that allows quantification of major diastereomers (alpha-, beta- and gamma-HBCD). Based on the results from 6 years of fish monitoring it can be concluded that at sites with diffuse exposure characteristics the concentrations of HBCD are decreasing. For example, the HBCD level of bream from the Rhône declined by about 80 % until 2012. This decrease of HBCD fish levels seems to be mirrored by a decline of HBCD levels in SPM from the Rhône site. HBCD levels of the Scheldt SPM revealed no change although HBCD levels of fish also decreased significantly. Only at one site impacted by a former point source (i.e. Tees) no decreasing concentrations could be observed so far and at one site (Götaälv/SE) an increase of HBCD fish levels was observed between 2007/2008 and 2012 (no continuous sampling at this site). In general, decreasing environmental HBCD concentrations in fish seem to be consistent with the implemented emission control measures. In the revised EU directive on aquatic environmental quality standards (EQS) for surface waters (2013/39/EU) an EQS for HBCD levels in fish was set (167 μg/kg wet weight). Fish muscle HBCD levels at all sites were below this EQS with the exception of the Tees site.

558

Identification of threshold values of accumulated metals for the protection of the aquatic ecological status. A comparison among four different species.

L. Bervoets, M. De Jonge, University of Antwerp / Biology; E. Van Ael, University of Antwerp / Department of Biology; C. Belpaire, Research Institute for Nature and Forest INBO; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology

Monitoring of micro pollutants in aquatic ecosystems is still mainly based on measurements in the environment (water column and/or sediment). However, these measurements only reflect the momentary pollution status and do not take into account differences in bioavailability, affected by abiotic factors such as pH, water hardness, temperature and biotic factors such as feeding habits. As a consequence, current water or sediment quality criteria for micro pollutants are not necessarily adequate and well related to effects on aquatic communities observed in the real world. Direct measurement of pollutants in biota could tackle these problems. Recent studies have demonstrated that accumulated micro-pollutant levels in some aquatic invertebrates (e.g. Hydropsychid caddisflies, zebra mussels) or levels in fish (e.g. eel and gudgeon) can be potentially used to predict ecological effects of micro contamination on aquatic communities and to derive safe pollutant levels. The aim of this study is therefore to compare the applicability of different aquatic species to derive safe tissue levels for metals in relation to ecological relevant responses. For four different species, two fish species and two invertebrate species, accumulated levels are related to effects at the community level. Selected fish species were eel (*Anguilla anguilla*) and gudgeon (*Gobio gobio*) whereas macro invertebrates were represented by larvae of the non-biting midge (*Chironomus* sp. gr. *thummi*) and the zebra mussel (*Dreissena polymorpha*).. Metal levels in eel muscle from were related to the Ecological Quality Ratio (EQR) assessed at the same site in the same period. For gudgeon we related metal levels in liver to the IBI. Metal levels in midge larvae or zebra mussels were related the Belgian Biotic Index (BBI). For most metals threshold values could be derived above which ecological quality. For example, safe levels for Cd were 0.2 μg/g dw in eel muscle but 10 μg/g dw in liver of gudgeon and *Chironomus sp.* and *Dreissena sp.*. The much lower safe level for eel can be attributed to the fact that levels were measured in muscle. We could conclude from this study that for most metals safe tissue levels could be derived that are protective for aquatic communities. However, care should be taken in the selection of the organisms. Concerning metals, fish muscle will give much lower safe levels compared to liver or whole invertebrate organisms.

559

UK fish biomonitoring highlights issues with priority substances, such as mercury and PBDEs

M.D. Juergens, Centre for Ecology and Hydrology; A.C. Johnson, CEH Wallingford; A. Lawlor, J. Crosse, Centre for Ecology and Hydrology; D. Hughes, K.C. Jones, Lancaster University / Lancaster Environment Centre

Wild-caugh fish are very suitable for monitoring persistent pollutants because they accumulate pollutants over their lifetime thus: - icreasing the concentrations compared to the water and therefore improving the chance to be able to measure it - reducing the variability by integrating over a number of years - and last but not least, providing a MEANINGFUL measure of pollution with regards to risks to fish themselves and/or their predators (including humans) The usefulness of biota (fish) environmental quality standards has been appreciated in the recent revision of the EU Priority substances legislation (Directive 2013/39/EU), which includes 11 biota water quality standards (previously only 3) Already, since 2007, CEH and the English Environment Agency are building an archive of frozen fish tissue samples which will allow for retrospective monitoring in the future as well as giving an insight into the present (or recent past) chemical state of English rivers. Data from a subset of these fish will be presented on mercury, PBDEs and others The mercury EQS was exceeded in the majority of samples, suggesting some concern for predators, and a trend towards higher contamination in larger (ie. older) individuals was noticable. All fish analysed exceeded the PBDE standard of 0.085 μg/Kg for the sum of six indicator PBDEs by several orders of magnitude. The standard has, however, been set extremely low, which does not seem to be justified from the available toxicity data and would be almost impossible to monitor if the concentrations were actually that low - by contrast, the measured levels of hexachlorobenzene, and hexachlorobutadiene were always below the EQS As the Fish Archive grows it will become possible to determine temporal and spatial trends of these and other substances recent publication: Jürgens, MD, et al. (2013). "The presence of EU priority substances mercury, hexachlorobenzene, hexachlorobutadiene and PBDEs in wild fish from four English rivers." Science of the Total Environment **461–462**: 441-452.

560

Protection goal directed monitoring strategy to implement Environmental Quality Standards (EQSs) for biota

P. Lepom, Laboratory for Water Analysis; C. Heiss, general aspects of water and soil protection; J. Koschorreck, Umweltbundesamt; H. Ruedel, Fraunhofer IME Institute for Molecular Biology and Applied Ecology / Environmental Monitoring

Directive 2013/39/EU lays down biota EQSs for eleven priority hazardous

substances. Where two different standards were derived for biota, i.e., one for the protection of top predators from secondary poisoning, and another one for the protection of human health from consuming fisheries products, the lower of the two was adopted as the overall quality standard. This practise may cause difficulties in implementation of the biota standards, as different protection goals require different monitoring strategies. Therefore, we propose a protection goal directed monitoring strategy. For protection from secondary poisoning, the strategy includes (1) identifying the relevant fish-eating top predator, (2) examining prey composition and size range, (3) sampling a 'prey basket' and (4) analysing the priority substances in whole fish. For protection of human health from consumption of fisheries products, a different approach has to be applied. In that case commercially important local fish species need to be sampled and the filet analysed. In a pilot study, mercury concentrations were determined in muscle and whole fish samples from three fish species collected at Lake Großer Stechlin, a reference site some 70 km north of Berlin, in September 2013. The data were used to evaluate the impact of the selected species or 'prey basket', the selected length range, and the analysed tissue on the assessment of compliance with the biota EQS for mercury. Furthermore, we will present results from mercury monitoring in fish conducted within WFD monitoring programmes in Germany by the competent authorities of the Federal States and will evaluate these data in view of compliance assessment and the suggested protection goal directed monitoring strategy. Our results will feed into the work of the EU group drafting a guidance document on chemical monitoring in biota with focus on compliance checking, which was recently established under the Common Implementation Strategy for the WFD.

Endocrine Disruptors: Exposure, Hazard & Risk Assessment (I)

561

Multi-generation study - reproductive effects of 17β-dihydroequilin, estrone, and 17β-estradiol in Japanese medaka (Oryzias latipes) following combined protocols OECD 229 and OECD 234

L.A. Constantine, Pfizer Inc / Pharmacokinetics Dynamics and Metabolism

Two separate studies were conducted to understand the endocrine effects of 17β-estradiol and Conjugated Estrogens (CE), specifically, estrone (E1) and dihydroequilin (DHE) on three generations of Japanese medaka. In the multigeneration life-cycle test, medaka were exposed to nominal concentrations of 1.0, 7.5 and 75 ng a.i./L each of E1 and DHE, for total exposure of 2.0, 15 and 150 ng a.i./L in combination, a positive control of 100 ng a.i./L E2 and a negative control. Two additional dosing groups were exposed; one to 1.0 ng a.i./L E1 alone and the other to 1.0 ng a.i./L DHE alone. Following a pre-exposure period of 26 days to identify actively spawning fish, spawning groups of 5 males and 5 females were formed and exposed for 21 days under flow-through conditions to evaluate reproduction of the parental generation (F0) as per OECD 229, Fish Short Term Reproduction Assay (FSTRA). Following the FSTRA, an evaluation of sexual development in the F1 generation using eggs from the F0 generation carried through 83 days post hatch (dph) was conducted as per OECD 234, Fish Sexual Development Test (FSDT). Following the 83 day exposure of the F1 generation, most of the treatment groups were terminated in keeping with the FSDT. However, exposures in the 2.0 and 15.0 ng a.i./L E1/DHE combination doses, as well as the negative control were continued through reproduction (22 days) and hatching of the F2 generation embryos (4 dph). A similar study was conducted to evaluate 17β-estradiol at nominal concentrations of 2.75, 8.8, 28.2 and 90.1 ng/L. Survival, growth, reproduction (fecundity and fertility), hatching success, sex ratio and VTG data will be presented for these three endocrine disrupting compounds.

562

Proposal of how to update the standard information requirements in REACH, PPPR and BPR – a testing strategy for identification of endocrine disruptors

H. Holbech, University of Southern Denmark / Department of Biology; P. Bjerregaard, University of Southern Denmark / Biology; U. Hass, S. Christiansen, Technical University of Denmark DTU / Division of Toxicology and Risk Assessment

This presentation is based on a project prepared by the Danish Centre on Endocrine Disrupters (CEHOS) for the Danish EPA. The project aim to provide a science based input to the on-going work in EU with regard to endocrine disruptors, i.e. the development of criteria for identification, REACH review on EDs and the revised strategy for the future work on endocrine disruptors, focusing on adequate detection of substances with endocrine disrupting properties under various legislative frameworks, including REACH (EC No 1907/2006), the Plant Protection Products Regulation (PPPR) (EC No 1107/2009) and the Biocidal Products Regulation (BPR) (EC No 528/2012). There are currently no specific information requirements or testing strategies with regard to endocrine disruption in REACH and other relevant legislations. However, in relation to biocides and recently also to plant protection products, indications of endocrine disrupting properties of a substance trigger additional information/testing requirements. With regard to plant protection products a new regulation from 1 March 2013 (EU 283/2013 (active substances) + EU 284/2013 (products)) sets out the general data requirements from 1 January 2014. According to these, new test methods that include endocrine sensitive endpoints have been included with regard to human health and the environment. Similar data requirements and new test methods that include endocrine sensitive endpoints are included in the guidance on Regulation (EU) No 528/2012 on how to fulfil data requirements for biocides. To a limited extent in vivo test methods that include endocrine sensitive endpoints have also been included in the standard information requirements for substances regulated under REACH. The existing information/data requirements in REACH, PPPR and BPR are not sufficient to adequately detect substances with endocrine disrupting properties. Proposals for changes in the existing REACH, PPPR and BPR information/data requirements are therefore provided. The proposals include enhancement of standard test methods as well inclusion of new methods and recommendations are given for a testing strategy. For all substances (prioritized by tonnage and exposure scenario), QSAR studies and testing using in vitro assays for interaction with different ED modalities e.g. ER, AR and steroidogenesis interference, should be conducted to elucidate whether there are alert(s) for further testing for ED effects.

563

Mind the gap: Concerns using endpoints from endocrine screening assays in risk assessment

J.R. Wheeler, Dow Agrosciences; L. Weltje, BASF SE / Agricultural Centre; R. Green, 3National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs)

Endocrine *in vivo* screening assays not only provide mechanistic information on the potential of a substance to interact with the endocrine system, but also data potentially relevant for risk assessment. However, these screening assays have a number of limitations that should be considered before the direct use of such data for risk assessment purposes. This paper discusses the limitations that should be considered for both human and environmental risk assessment. A proposal is made to provide an objective and transparent process in order to consider which endpoint(s) might be incorporated into a risk assessment, and when more definitive studies may be of value. Such an approach is necessary to ensure the appropriate use of screening data, and to enhance our understanding of the (eco)toxicological profile of substances undergoing screening.

564

MTBE and endocrine disrupting potential: An hypothesis-driven weight of evidence analysis

E.M. Mihaich, ER; A. de Peyster, San Diego State University / Graduate School of Public Health

Methyl tertiary-butyl ether (MTBE) is a fuel component used in gasoline production to increase combustion efficiency and bring associated environmental benefits, with some minor specialty uses as a solvent in closed systems. Impacts on endocrine system endpoints have been noted in several repeated exposure rodent toxicology studies using very high doses of MTBE. In addition, a study performed with zebrafish suggested that MTBE might be estrogenic. Resolving whether or not MTBE should be considered an endocrine active compound is important given increasing worldwide concern about endocrine disrupting substances accumulating in the environment and their potential for causing adverse effects on public health and wildlife. Evidence is presented for/against the idea that MTBE has potential to interact with key endocrine pathways in mammalian and non-mammalian organisms. A weight-of-evidence (WoE) analysis was conducted, focusing on specific hypotheses related to disruption of estrogen, androgen, and thyroid hormone pathways, steroidogenesis and also specifically aromatase, the enzyme that converts androgens to estrogens. This WoE procedure involved systematic consideration of each endpoint observed in one or more study designs and a semi-quantitative weighting of relevance of each type of endpoint to a given hypothesis to reach scientifically justified conclusions based on the totality of the evidence. Studies performed at extremely high doses in rodent studies in some cases confound the identification of direct endocrine system responses. However, maximal use of all existing relevant and reliable information and consistent observations in multiple studies increase support for or against a given mode of action (MoA) hypothesis. While the MTBE database continues to grow and its evaluation is ongoing, a systematic and transparent WoE assessment of the results from a wide variety of mammalian and fish studies suggest that MTBE is not primarily impacting endocrine pathways.

Do concentrations of ethinylestradiol and estradiol in European rivers exceed proposed EU environmental quality standards?

A.C. Johnson, CEH Wallingford

This study used a geographic based water model to predict the environmental concentrations of 17a-ethinylestradiol (EE2) and 17b-estradiol (E2) throughout European rivers. The work was prompted by the proposal of the European Community (COM(2011)876) to consider these chemicals as candidates for future control via environmental quality standards (EQS). National drug consumption information, excretion, national water use, and sewage removal rates, were used to derive per capita sewage effluent values for the European countries . For E2, excretion rates of the natural hormone and national demographics were also included. Incorporating this information into the GWAVA model allowed water concentrations throughout Europe's rivers to be predicted. The mean concentration from the expected sewage discharge scenario indicated that 12% by length of Europe's rivers would reach concentrations greater than the proposed 0.035 ng/L EQS for EE2. For several countries, between a quarter and a third of their total river length would fail such an EE2 EQS. For E2, just over 1% by length of rivers would reach concentrations greater than the 0.4 ng/L proposed EQS.

Investigation of Health Effects Associated with Indirect Potable Reuse Water

E.J. Routledge, Brunel Universty / Institute for the Environment; E. Lawton, Brunel University; P. Antczak, University of Liverpool; F. Falciani, The University of Birmingham / Institute of Integrative Biology

Population growth and urbanisation drives unquenchable demand for ever larger volumes of clean safe drinking water. In some countries suitable sources of drinking water are becoming so scarce that they will not be able to satisfy future demand. In 2007, the Southeast of England was classified as experiencing 'serious' levels of water stress. Consequently, there is a need to find alternative sources of safe drinking water that can be used for potable supply or to augment current sources. Advanced water treatment methods are now being examined to investigate whether treated domestic sewage effluent can be treated to drinking water standards and discharged near a drinking water abstraction point; a process known as Indirect Potable Reuse (IPR). Technological solutions to address the water sustainability problem must be shown to remove biologically active chemicals, including endocrine active chemicals, to levels below which they no longer pose discernible hazards to human health. In this presentation, we outline new research on the health risks associated with exposure to Indirect Potable Reuse water using developmental assays in zebrafish. We show that short-term developmental assays in zebrafish combined with genomic analysis (microarrays) can be used to identify potential health outcomes associated with exposure to chemicals present in treated sewage effluent before, during and after advanced treatment. When applied to IPR, this approach can be used to determine the extent of treatment needed to remove chemicals to levels where developmental and/or genomic effects associated with potential health outcomes compared to the control water are no longer seen. Such information is needed to inform decisions about the application of advanced treatments that could be used to ensure the sustainability of potable drinking water.

Reduction, Replacement, and Refinement (3Rs): Animal alternative approaches in ecotoxicology and risk assessment (II)

An alternative testing strategy for neurotoxicity using zebrafish

J. Legradi, P. Cenijn, VU University Amsterdam / Institute for Environmental Studies; S. Tufi, VU University, Institute for Environmental Studies; M. Brouns, VU University Amsterdam / Institute of Health Sciences; P. Leonards, VU University Institute for Environmental Studies / Chemistry Biology; J. legler, Institute for Environmental Studies

Recent epidemiological studies have indicated that exposure to low doses of environmental contaminants during human development can have deleterious effects on cognitive development in childhood. The EU project DENAMIC aims to develop better and sophisticated tools, procedures and testing methods to screen compounds for (developmental) neurotoxicity and to improve assessment of exposures and effects (more information on www.denamic.org). As part of the project, a new alternative assessment strategy is under development to prioritize compounds for further in vivo rodent testing. To this end, hazard characterisation of pesticides and environmental pollutants at the molecular and cellular level is carried out, with emphasis on adverse effects during neuronal development. Test chemicals are selected based on their environmental relevance, known neurotoxicity and different modes of action. Experiments are performed with acute or subchronic exposures. Zebrafish larvae are used as an alternative animal model to study neurotoxicity in vivo. To this end developmental toxicity as well as altered behaviour is monitored. Compounds inducing behavioural effects are then studied in more depth to investigate the underlying mode of action. We have developed a new testing regime to better understand behavioural effects in zebrafish and link them to toxic mode of actions. A subset of the investigated chemicals is selected for further in vivo testing in mice and rats to validate the alternative assays.
Behavioural tests in rodents are the standard test used for neurotoxicity testing. This study will ultimately demonstrate the usefulness of zebrafish embryo assays as an alternative testing strategy for developmental neurotoxicity testing.

Development of an In Vitro Approach to Assess Disruption of Steroidogenesis in Native Fish Species

S. Beitel, University of Saskatchewan Toxicology Centre / Toxicology Centre; J.A. Doering, S. Patterson, University of Saskatchewan / Toxicology Centre; M. Hecker, University of Saskatchewan / School of the Environment Sustainability and Toxicology Centre

There is concern regarding exposure of aquatic organisms to chemicals that interfere with the endocrine system. One critical mechanism of endocrine disruption is impairment of steroidogenesis that can lead to altered or delayed sexual development, and ultimately reproductive failure. To enable objective risk assessments of environmental contaminants, it is critical to identify the sensitivity of species native to the environments in question. However, to date little is known about the sensitivity of fish native to northern ecosystems to disruptors of steroidogenesis. One of the main challenges with assessing the effects of contaminants to native species of interest is that they are often difficult to culture or maintain under laboratory conditions. *In vivo* studies to characterize endocrine effects are also labour, resource and time intensive. Furthermore, some of the species of interest are endangered or threatened in their ecosystems. The aim of this study was to develop an *in vitro* gonadal explant assay enabling the assessment of endocrine disrupting chemicals on sex-steroid production in wild fish species. Northern pike (*Esox lucius*), walleye (*Sander vitreus*), and white sucker (*Catostomus commeroni*) were sampled from Lake Diefenbaker, Saskatchewan, Canada at pre-spawn and multiple post-spawn time-points. Gonads were excised and exposed for 24 hours to a model inducer (forskolin) and inhibitor (prochloraz) of steroidogenesis. Concentrations of 11-ketotestosterone (11-KT) and estradiol (E2) in plasma and media were quantified using ELISA. Tissues exposed to forskolin showed a concentration dependent increase in 11-KT and E2. Exposure to prochloraz resulted in a decrease of 11-KTand E2. Results illustrate that the gonadal tissue is undergoing steroidogenesis in an *in* vitro setting that is reflecting reproductive seasonality, and is also responsive to chemical exposure in a concentration-dependent manner. White sucker were found to be the most responsive species, with the seasonal time-point of greatest sensitivity differing between sexes. When exposed to 3 μM forskolin, white sucker males and females produced up to 15-fold greater 11-KT and 15-fold greater E2, respectively, when compared to the solvent controls. In conclusion, seasonality of reproductive function represented a critical factor that needs to be considered when using this here-established *in vitro* explant assay to assess responses of native species to disruptors of steroidogenesis.

Physiologically based toxicokinetic models for in vitro-in vivo extrapolation of receptor-mediated effects in rainbow trout

M. Brinkmann, RWTH Aachen University Institute for Environmenta / Institute for Environmental Research; k. Eichbaum, RTWH Aachen University / Institute for Environmental Research; S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology; G. Reifferscheid, Biochemistry and Ecotoxicology; T. Bui, IVL Swedish Environmental Research Institute Ltd / Natural Resources Environmental Effects; A. Schaeffer, H. Hollert, RWTH Aachen University / Institute for Environmental Research; T.G. Preuss, Bayer CropScience / Institute for Environmental Research

The European REACH regulation was established by the European Parliament and the Council to prospectively avoid the negative effects of industrial chemicals on humans and the environment. To meet this mandate, the chemical industry must provide toxicological and ecotoxicological data, potentially requiring a large number of animal experiments. To minimise the use of animals, however, the 3R principle (i.e., reduction, replacement, refinement) demands that animal experiments should be substituted with appropriate alternative test methods whenever possible. Many dossiers submitted to the European Chemicals Agency for the authorisation of chemicals have attempted to provide the required data without performing new experiments, relying heavily on *in silico* methods (e.g., quantitative structure-activity relationships, read-across, grouping or weight-of-evidence approaches); *in vitro* assays were scarcely used. Here, we propose a methodology that uses physiologically based toxicokinetic (PBTK) models to extrapolate *in vitro* data to the *in vivo* level. We collected experimental results for *in vitro* and *in vivo* ethoxyresorufin-*O*-deethylase (EROD) and vitellogenin (Vtg) induction in rainbow trout (*Oncorhynchus mykiss*) following chemical exposure (either via the aquatic exposure medium or intraperitoneal injection) and compared those results with model predictions. We found that the predictive power of aqueous chemical concentrations was limited; median effect concentrations (EC50s) based on internal concentrations in fish correlated far better with *in vitro* EC50s (97 % of the values deviated less than one order of magnitude from the regression of *in vivo* and *in vitro* data). The present study demonstrates that PBTK models can be used to ordinate important biochemical markers of mechanism-specific effects (i.e., EROD and Vtg) to correlate with experimentally derived *in vitro* data. We believe that the presented non-experimental *in silico* methods for *in vitro-in vivo* extrapolation have the potential to achieve an overall reduction in the number of toxicological and ecotoxicological experiments with live animals when combined with experimental *in vitro* test methods while maintaining an equal level of protection.

A 3D spheroidal fish liver model alternative to better understand bioaccumulation in ecotoxicology
M. Baron, Plymouth University / School of Biological Sciences; K. Mintram, R. Cumming, AstraZeneca Safety, Health & Environment; W. Purcell, S. Jackson, Plymouth University / School of Biomedical & Biological Sciences; S. Owen, AstraZeneca / Safety Health Environment; A.N. Jha, Plymouth University / Biological Sciences
The use of three-dimensional cell culture models (spheroids) are becoming more widely used in toxicological research, particularly in the fields of pharmaco-toxicology, cancer and food research. This is due to their ability to simulate the *in vivo* environment more effectively than standard *in vitro* models, which lack the 3D micro-environment of intact tissue.We recently developed and characterised a method to produce primary hepatocyte spheroids from rainbow trout that provides long term cultures. This new model has the potential to pre-screen xenobiotic compounds and measure whether they can be metabolised by fish. While *in-vitro* systems do not fully replace the requirement for *in vivo* studies, they can be useful adjunct models with a higher throughput that can support the ecotoxicological evaluation of the potential risk of aquatic pollutants, offering an alternative to animal testing. Spheroid models offer additional functionality over conventional *in vitro* cultures, in particular defined *in-vivo* like tissue architecture and good cell-cell and cell-matrix interactions are longer-lived. As such they can be developed to offer a new *in vitro* screening tool for environmental toxicological monitoring. Here we report the development of a Loss of parent assay used to determine the rate at which parent compounds were lost from spheroid cultures over a period ≤ 72 h and monitored the appearance of some primary metabolites. Compounds were selected on the basis of their physicochemical properties, existing comparable datasets and known toxicity profile. The system was fully characterised and validated with the non-selective β-blocker propranolol to establish a positive control compound and the rate of metabolism K_{met} values were calculated for all compounds. Our results compare well with data from the literature and demonstrate a current predictivity of ~70 %, suggesting that this new model is worthy of further dedicated study for its application in accumulation studies. Keywords: 3Rs, bioaccumulation, alternatives cell culture\n\nAbstract type: Poster

Predicting bioconcentration of benzo-a-pyrene in fish based on different fish cell lines
J. Stadnicka-Michalak, EawagSwiss Federal Inst of Aquatic ScienceTechn; F. Weiss, Eawag Swiss federal Institute of Aquatic Science and Technology; M. Knöbel, Eawag Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology; K. Schirmer, Eawag / Environmental Toxicology
Quantification of chemical toxicity continues to be based mainly on measurements of external exposure. Yet, in order to understand, interpret and extrapolate toxic effects, using internal concentrations of chemicals is more suitable. Though these can be measured, being able to predict them would be much more efficient and feasible. Predicting chemical internal concentrations accurately is, however, still challenging as biotransformation processes can strongly influence the extent to which chemicals accumulate in fish. For this reason, toxicokinetic models, which link *in vitro* biotransformation data to the whole organism bioconcentration of chemicals, have been developed. However, these models thus far are based on the assumption that biotransformation in the body solely occurs in fish liver. Since this is unlikely to be true, this assumption may result in underestimating the biotransformation of chemicals in fish. In our study we measured biotransformation in rainbow trout cell lines of liver (RTL-W1), intestine (RTgut-GC) and gills (RTgill-W1). Acknowledging that the liver is the main site of biotransformation whereas gills are not, we assumed that the gill cell line can represent cells also from other richly perfused tissues. We distinguished the intestine and pyloric caeca from richly perfused tissues in order to account for biotransformation occurring in the intestine as an important environment - organism barrier. The highly hydrophobic (log K_{OW} = 5.99) polycyclic aromatic hydrocarbon, benzo-a-pyrene (BaP), served as model chemical. It had previously been shown to be quickly biotransformed by fish which resulted in over 1000-fold differences in measured versus predicted bioconcentration factors (BCFs). The biotransformation of BaP in all cell lines was incorporated into the Physiologically Based Toxicokinetic (PBTK) model for rainbow trout. All applied fish cell lines biotransform BaP; however, the biotransformation in gill cells took more time than in other cell lines. BCF estimated by our PBTK model assuming biotransformation only in liver, was around 3000. However, taking into account also biotransformation in other tissues based on cell lines data reduced BCF further to 1000. This value is very similar to measured BCF (920). Thus, building a virtual fish based on different cell lines can help improve predicting BCFs of highly biotransformed compounds.

Passive and active uptake of pharmaceuticals by a primary fish gill cell culture model
L.C. Stott, Kings College London / Division of Diabetes and Nutritional Sciences; S. Schnell, Division of Diabetes and Nutritional Sciences; C. Hogstrand, Kings College London / Division of Diabetes and Nutritional Sciences; S. Owen, AstraZeneca / Safety Health Environment; N.R. Bury, Kings College London / Division of Diabetes and Nutritional Sciences
Traditionally, whole organism studies are used to assess the bioconcentration of compounds from the water. If we are to replace or reduce the large numbers of fish used in these regulatory tests then an effective and realistic *in vitro* screen is required. The gills of fish are continuously bathed in water and are a principle site of both xenobiotic uptake and efflux. The current study uses an *in vitro* rainbow trout primary gill cell culture system, which forms a polarised epithelium with high transepithelial electrical resistance (TEER; >20 KΩ cm^{-2}) and low paracellular permeability that tolerates apical freshwater exposure as *in vivo*, to assess pharmaceutical uptake and efflux. Bidirectional studies of seven pharmaceuticals (propranolol, metoprolol, atenolol, formoterol, terbutaline, ranitidine and imipramine) showed that all were transported across the epithelium in both directions. Concentration equilibrated conditions with equivalent concentrations of drugs on both sides of the epithelium revealed the active transport of propranolol and imipramine from the apical to the basolateral compartment. Further assessment of the non specific β_1/β_2-adrenergic antagonist, propranolol, revealed at very low environmentally relevant propranolol concentrations (ng L^{-1}) transport is saturable before higher concentration exposures show increased passive uptake and a concentration dependent rate of transport. Known inhibitors of drug transport proteins (e.g. SLC22, 47, SLCO, ABCBs and ABCCs); cimetidine, MK571, cyclosporine A and quinidine inhibited propranolol uptake, whilst amantadine and verapamil were without effect. Together, our results suggest that there is passive transcellular uptake of the natural form of propranolol that is enhanced by water, and the active uptake of the cationic form is perhaps via OCT2 and an MRP transporter. The uptake and efflux of propranolol *in vitro* using this gill cell system correlates with predicted *in silico* and measured *in vivo* plasma concentrations, further validating the use of this model as a potential complement or surrogate to refine, reduce or replace the numbers of fish used in bioconcentration studies.

Ecosystem structures and functions and their valuation in Ecological Risk Assessment (II)

573
How widespread are effects of organic toxicants on ecosystem functions?
R. Schaefer, University Koblenz Landau; E. Malaj, Helmholtz Centre for Environmental ResearchUFZ / Department of EffectDirected Analysis; K. Peters; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis; M. Grote, EDF RD / National Hydraulics and Environment Laboratory; P.C. Von der Ohe, UFZ Helmholtz Centre for Environmental Research / Department of Ecological Chemistry
The decomposition of allochthonous organic matter and primary production are key ecosystem functions that provide energy to aquatic ecosystems and are therefore crucial for ecosystem services of freshwater ecosystems. Organism groups involved in these processes include invertebrates, bacteria, fungi, macrophytes, phytobenthos and phytoplankton. Studies addressing the effects of organic toxicants on these ecosystem functions are relatively scarce, but several investigations have been conducted focusing on effects on the involved organism groups. Our talk targets two questions: At which concentrations may ecosystem functions be affected? How widespread are potential effects? To evaluate the thresholds at which effects at ecosystem functions may occur, we reviewed existing studies on the effects of toxicants on ecosystem functions. In addition, we derived effect thresholds for the different organism groups that are involved in the functions (e.g. invertebrates, primary producers) based on a literature survey. These thresholds were then used to evaluate the concentrations of organic toxicants in surface water in the European Union using data from more than 4,000 monitoring sites. We found that more than one third of studies on the effects of organic toxicants on ecosystem functions indicated reductions in ecosystem functions at concentrations that are assumed being protective in the regulatory context. The reduction in allochthonous organic matter decomposition was more pronounced in the presence of invertebrate decomposers compared to studies where only microorganisms were involved. Moreover, organic chemicals were likely to exert acute lethal and chronic long-term effects on sensitive invertebrate and algae species in 16% and 42% of the 4,000 monitoring sites, respectively. Pesticides were the major contributors to the overall chemical risk. The risk increased with the number of ecotoxicologically relevant chemicals analysed. As most monitoring programs only included a subset of these chemicals, our assessment still underestimated the actual risk. We discuss several aspects of the relationship between structural effects and their consequences for ecosystem functions. In addition, we highlight research needs for future studies on ecosystem functions. We conclude that organic toxicants are occurring widespread in concentrations that affect organisms involved in critical ecosystem functions.

574

Effects of fungicides on leaf decompostion in vineyard streams
D. Fernández, University KoblenzLandau / Quantitative Landscape Ecology; K. Peters; J.P. Zubrod, Institute for Environmental Sciences University of KoblenzLandau / Institute for Environmental Sciences; E. Vermeirssen, Eawag / Dept of Environmental Toxicology; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; R.B. Schäfer, RMIT University / School of Applied Sciences
Organic matter decomposition (OMD) is central for river ecosystem functioning. However, pesticides can impair this function in agricultural streams. Only a few studies have examined the effect of fungicides on OMD, and if so mainly in the laboratory. In this study we quantitatively analysed the effects of fungicides on decomposer communities and OMD in a German vineyard area. Exposure to polar organic pesticides (16 fungicides and 4 insecticides) was evaluated during four different rainfall events using passive samplers (Empore™ SDB-RPS disks), and the required calibration information was generated in a microcosms experiment. Event-driven water samplers (EDS) were also collected for comparison with the time weighted average concentrations (TWA) provided by the passive samplers. Sampling sites were located in river reaches along a gradient of fungicide exposure, and leaf litter bags were deployed for two weeks. Monitoring included also inorganic copper in stream sediments, decomposer communities (macroinvertebrates, fungal biomass, fungal diversity and bacterial density) and physico-chemical variables. The two fungicide sampling systems were in good agreement for most compounds. TWA mean and maximum concentrations for individual compounds ranged from 0.01 to 0.18 μg/L and from 0.02 to 1.72 μg/L, respectively. EDS concentrations exceeded TWA concentrations on average by a factor of six. Fungicide exposure led to changes in the structure and composition of fungal and macroinvertebrate communities. A decrease in fungal biomass and an increase in bacterial density were found along the increasing exposure gradient. Despite these changes translated to a detectable decrease in microbial OMD rate, we did not find an impact on macroinbertebrate OMD rate. This may be explained by the abundance of gammarids in most of the sites regardless of the fungicide pollution. Our main findings were that passive sampling is suitable to quantify episodic exposures from polar organic pesticides and that functional redundancy in microbial decomposer communities do not buffer effects of fungicides on microbial OMD.

575
Hyporheic zones are important for the attenuation of pharmaceuticals – myth or fact?
M. Radke, Stockholm University / Department of Applied Environmental Science ITM; U. Kunkel, Federal Institute of Hydrology / Department of Water Chemistry; M.P. Maier, Helmholtz Zentrum Munchen / Institute of Groundwater Ecology
Hyporheic zones are well recognized for their contribution to processing of nutrients and organic matter in streams. With respect to organic micropollutants, the role of hyporheic zones for the attenuation of these contaminants has yet to be defined. In this contribution, we will present a compliation of field and laboratory studies that allows a thorough and critical evaluation of the role of hyporheic zones in the attenuation of organic micropollutants. The environmentally relevant pharmaceutical diclofenac will be used as an illustrative example. Three experimental approaches were used in the laboratory: 1) static water/sediment tests along the lines of the of the OECD 308 guideline; 2) recirculating sediment columns that provided more defined and controllable advective exchange and redox conditions; and 3) experiments in a bench-scale flume where the complex mixing between surface water and the hyporheic zone can be simulated. In the field, we carried out mass-balancing studies at two German wastewater-impacted rivers. The results from the laboratory experiments provide clear evidence that hyporheic sediments have the potential to biotransform many pharmaceuticals. In flume experiments, the diclofenac dissipation time (DT_{50}) ranged from 3 to 9 days, depending on the experimental conditions. The two more simplified test systems provided useful for determining upper and lower threshold values of the DT_{50}. The field studies showed an efficient elimination of diclofenac in one river, while it was not attenuated in the other river. This is in contrast to findings from the laboratory experiments where the elimination was similar in sediments from both systems. The overall comparison of our studies shows that we are currently lacking methods to transfer results obtained in the laboratory to the field. This is predominantly caused by a lack of methods for quantifying hyporheic exchange on the scale of at least 10-20 km. This constitutes the major knowledge gap that prevents converting lab-derived transformation rates into reach-scale elimination rates of pharmaceuticals and other organic micropollutants. Overall we conclude that hyporheic attenuation of pharmaceuticals can indeed be an efficient elimination pathway in rivers. But favorable hydraulic conditions are required and at rivers with limited hyporheic exchange even a high transformation potential in the hyporheic zone does not provide substantial elimination of pharmaceuticals from the surface water.

576
Actively use sediments in groundwater pollution management
M.H. Wagelmans, N. van Ras, S. Lieten, Bioclear
At various sites in the Netherlands further migration of contaminated groundwater plumes is prevented by seepage of contaminated groundwater to surface waters. During this discharge in surface waters, the redox conditions in which the contaminations are present undergoes a change from anaerobic to aerobic, and the contamination passes a sediment layer (especially sludge) at the bottom of the surface water. These processes are favourable for natural degradation of several contaminants like chlorinated ethenes and BTEX. This decontamination process is an important ecosystem service that can actively be used in pollution management. In the cities Amersfoort, The Hague and Haarlem groundwater polluted with chlorinated ethenes already seeps to surface water. It is expected that natural attenuation processes occur in the sediment. In order to gain insight in which layer the capacity for biodegradation is present, different sediment layers have been sampled at the sites. In the sediment samples both chemical analyses and molecular analyses have been performed. Our research has shown that in general in most studied sediments within the flowpath of the pollution the capacity for biological degradation (both reductive dechlorination and aerobic degradation) is present. However, the activity of the ecosystem service depends on the thickness of the active layer because this determines the size of the 'in situ bioreactor'. This has implications for the dredging managent in this specific canal. Dredging of the canal will, at least temporary, decrease the dechlorinating capacity as shown. This causes an increase in chlorinated ethenes in surface water which, at high incoming concentrations, might result in ecological risks during a certain period of time.

577
Assessing river bank filtration with micropollutants
E.H. Hoehn; W. Labhart, Geologisches Büro; W. Blüm, AWEL Zürich State Office for Water Energy Air
A 2012/13 study of AWEL (Zurich State Office for Water, Energy & Air) investigated on the contamination risk of micropollutants from 7 waste water treatment plants (WWTPs) in the perialpine River Glatt valley, Northern Switzerland, to River Glatt (average flow rate at 2 sampling stations: 4 and 8 m3/sec) and to ad-jacent ground water (8 drinking-water wells) of an alluvial sand-and-gravel aquifer (hydraulic conductivity ~80 m/day; groundwater flow velocities 1 - 5 m/day). River Glatt loses continuously water along much of its reach. The ground-water study focused on benzotriazole, carbamazepine, sulfamethoxazole, and the artificial sweetener ace-sulfame. These contaminants revealed groundwater concentrations in the range of ng/L, ex-cept for ace-sulfame (μg/L; 1 – 2 orders of magnitude higher than those of carbamazepine). The con-cent-rations in the ground water did not vary significantly throughout a one year's period. Compared to those in the WWTP outlets, fractional con-centrations were at less than 15 per cent. Carbamazepine and ace-sulfame were considered mobile and persistent in the studied subsurface. Fractional bank-filtrated water was cal-cu-lated from concentrations and mass flow rates of these two contaminants. Values were found to be in the order of 50-70 per cent. The mixing equation allowed us to quantify further the infiltration mass flow of river water to ground water, for various realistic scenarios, including bank-filtration rates from flow-meter measure---ments, and the assumption of zero acesulfame contribution from ground water not of bank filtration origin.

Invertebrate traits and trace metals in the impact assessment of an exceptional river reservoir flushing
D. Hug Peter, Institut Forel University of Geneva / Institute Forel Earth and Environmental Sciences and Institute of Environmental Sciences; E. Castella, University of Geneva / Institute Forel Earth and Environmental Sciences and Institute of Environmental Sciences; V.I. Slaveykova, University of Geneva / Institute Forel Earth and Environmental Sciences
The Integration of the functionality of ecosystems and their services into Ecological Risk Assessment is one of the main challenges in current ecotoxicology. There is growing evidence that threshold values obtained in laboratory are not protective of ecosystem function in the field. Our study explored the impact of the flushing of a run of the river reservoir. We studied trace metal concentration and speciation and the consequences on biodiversity and species traits of benthic macro-invertebrates in a secondary channel. The response variables included taxonomic richness and a diversity index (rarefied richness). The affinity of the individuals in the community to certain traits (eg. percentage of individuals in the community breathing with gills) was compared before and after the event. Suspended particulate matter concentrations increased up to 80 times during the flushing. In consequence, the concentration of metals bound to SPM increased as well. In the dissolved fraction, there were increased concentrations of Al, Mn, Co and Ni while Cu showed a clear decrease. Both taxonomic and rarefied richness decreased after the event. The trait profiles did not change, indicating that there was no measurable impact of the flushing. This led to the conclusion that the use of traits to study exceptional events has to be further investigated and that it is important to consider several, complementary response variables.

Mechanistic toxicology of engineered nanomaterials: state of the art and future perspectives (II)

Surface functionality dependent toxicity of graphene nanomaterials in the nematode Caenorhabditis elegans: A systems ecotoxicology approach

J. Choi, School of Environmental Engineering Graduate School of Energy and Environmental system Engineering; J. Yang, N. Chatterjee, University of Seoul; H. Eom,

Graphene is a single-atom-thick sheet of sp2-bonded carbon atoms in a closely packed honeycomb two-dimensional lattice structure, isolated from its three-dimensional parent material, graphite. As it has great potential for wide range of application due to attractive physicochemical properties, their possible environmental health and safety impact raised considerable concern. In this study, the potential hazard of graphene nanomaterials, was investigated in the nematode *Caenorhabditis elegans* exposed to graphene oxide (GO) and reduced graphene oxide (rGO) using an integrated systems toxicology approach. We first compared the toxicity of GO and rGO to *C. elegans* at the organism level, using survival and reproduction as endpoints and found that GO led significant decrease of reproduction potential. To understand the mechanism of differential toxicity, we conducted microarray followed by pathway analysis on GO and rGO exposed C.elegans. We tried to link GO-induced gene expression to reproduction decline using the *C. elegans* functional genomics tool. The pathway that popped up from the microarray and pathway analyses was selected and loss-of-function mutants of these genes were exposed to GO and rGO and their responses were compared with that of *wildtype*. We demonstrated that the distinct oxidation states regulate the nature of dispersibility of GO and rGO and in turn their nano-bio interactive effect which was reflected from differential toxicity. Here we combined toxicogenomics - pathway analysis with functional genomics tools based on *C. elegans* mutant libraries, which enhance and complement the predictive power of toxicogenomics and pathway analysis. This systems-based integrated approach is particularly valuable for investigating the toxicity of new chemicals, whose mode of action is not fully understood or incompletely characterized, such as with graphene nanomaterials, since it provides a comprehensive insight into the mechanism of toxicity.

Highthroughput genomic and proteomic effects of silver nanoparticles in tissues of the marine ectothermic mollusc Mytilus galloprovincialis

I. Saggese, University of Piemonte Orientale / Dipartimento di Scienze dell'Ambiente e della Vita; L. Boatti, University of Piemonte Orientale; F. Dondero, Università del Piemonte Orientale Avogadro / DiSIT

Marine mussels show optimal features to assess ecotoxicological effects of nanomaterials due to their filter feeding behaviour, biogeographical distribution and ecological position within coastal and estuarine environments. In this study we used a combined highthroughput genomic and proteomic approach to analyze the effects of silver nanoparticles and silver ions in tissues of mussels challenged for 28 days day in microcosm exposures. Specimens of M. galloprovincialis were maintained in 10 L microcosms, fed algae daily and exposed to silver nanoparticles (5 nm, paraffin coated, Amepox, P) and silver nitrate at nominal levels of 0.2 10^-3 mg/L ; 2.0 10^-3 mg/L and 20.0 10^-3 mg/L per day. Specimens falling within same level (LOEL) for scope for growth were used for further analysis (20.0 10^-3 mg/L for silver nanoparticles and 2.0 10^-3 mg/L for AgNO3). Transcriptomic (pathways) analysis in digestive gland showed the involvement of genes with a role in heavy metal homeostasis (ferritin and metallothioneins), molecular chaperons (mainly HSPs), mitochondrial functions and different proteolytic pathways for either silver forms. A higher implication of cytoskeleton and intracellular part (membrane-bounded and non-membrane-bounded organelles) related genes was observed for the nanosilver form. Main results obtained so far by means of immunoblot analysis of 2D gels have showed increased protein oxidation (cysteine carbonylation) and protein ubiquitination in the digestive gland tissue of the 5 nm nanoparticle treatment class. Furthermore, enhanced heat shock activity was recorded in same tissues as judged by means of western blot using polyclonal anti-HSPA1A antibodies. The analysis of tissues from silver nitrate exposed specimens is currently under investigation. Our results showed the occurrence of overlapping and specific molecular responses due the challenge of Ag ions and metal nanoparticle. We conclude that common molecular traits between the two silver forms (i.e. homeostasis, oxidation and protein breakdown) are be due to the chemical reactivity of Ag ions which can eventually dissolve from nanoparticle while different traits should depend on the different way silver is presented, imported and further handled into the cell. *Acknowledgement*- This research was granted by CP-FP 247739 NanoFATE

581

A microarray and qRT-PCR study on the effects of metal-containing nanoparticles (CuO, CdS and Ag) on mussels M. galloprovincialis.

N. Duroudier, University of the Basque country UPVEHU / Zoology and Animal Cell Biology Research Centre for Experimental Marine Biology and Biotechnology PIEUPVEHU; E. Bilbao Castellanos, UPVEHU / Zoology and Animal Cell Biology; D. Gilliland, Institute for Health and Consumer Protection, European Commission - DG JRC; P. Reip, Intrinsiq Materials Ltd Cody Technology Park; M. Cajaraville, University of the Basque country UPVEHU / Zoology and Animal Cell Biology Research Centre for Experimental Marine Biology and Biotechnology PIEUPVEHU

Nanotechnology is a rapidly growing field which involves research and development of nanosized materials. Among them, metal-containing nanoparticles (NPs) such as CuO, CdS and Ag NPs, are widely used in different industrial processes and thus may finally reach the environment. However, little information is available on the behaviour of nanosized materials in aquatic environments and potential toxicity to aquatic species. The study of alterations in gene transcription levels could provide an early warning of the potential toxicity of NPs due to the rapid response of genes to environmental alterations. With the aim of assessing transcription level effects caused by metal-containing NPs in aquatic organisms, mussels *Mytilus galloprovincialis* were exposed to uncapped CuO (10 μg Cu/ l), glutathione capped CdS (50 μg Cd/ l) and maltose capped Ag (0.75 μg Ag/ l) nanoparticles (CuO NPs, CdS NPs and Ag NPs, respectively) for 1 and 21 days. A 8x15 custom mussel microarray containing 2900 identified genes and about 3000 unknown sequences was used and transcription levels of several target genes was studied by quantitative Real Time PCR (qRT-PCR) using TaqMan® or SYBR®Green methods. Based on LIMMA statistical analysis (not adjusted p-value< 0.001), different transcription patterns were found depending on the NP used: 42 different genes were regulated after 1 day of CuO NP exposure but only 4 were regulated 21 days after, including the defensive agent *fucolectin 6*. CdS NPs significantly regulated 69 different genes at day 1 of exposure and 25 genes at 21 days, being among them genes coding for metal ion binding proteins, such as metallothioneins, and proteins involved in the immune system, in protein degradation and in apoptosis. Ag NPs significantly regulated 20 different genes at day 1 and 13 genes at 21 days. Transcription level of most of the significantly regulated genes measured by qRT-PCR showed the same trend as in microarrays. Overall, transcription patterns were differently altered depending on the type of NP and exposure time. Alterations were more marked after 1 day of exposure, suggesting a successful adaptation to exposure conditions. Funded by EU 7th FP (NanoReTox, ref CP-FP 214478-2), Spanish Ministry of Science and Innovation (NanoCancer CTM2009-13477), Basque Government (Consolidated Research Group GIC IT810-13) and UPV/EHU through the Unit of Formation and Research "Protection of Ecosystem Health" (UFI11/37).

Interactive effects of n-TiO2 with other contaminants on immune and digestive gland function of the marine bivalve Mytilus

L. Canesi, T. Balbi, University of Genova / DISTAV; A. Smerilli, University of Genova; C. Ciacci, University of Urbino; R. Fabbri, G. Gallo, University of Genova / DISTAV

The increasing use of manufactured nanoparticles-NPs (e.g. in industrial applications and consumer products) will lead to their release into the aquatic environment, where NPs will mix and interact with other common environmental pollutants, such as organic xenobiotics and heavy metals. Hence the importance of studies directed towards elucidating the interactive effects of NPs and other co-existing contaminants, possibly leading to changes in toxicity and/or bioconcentration. Suspension-feeders have been shown to represent important test organisms to evaluate the biological impact of NPs. However, data on the interactive effects of NPs with other pollutants in marine organisms are still scanty. The effects and mechanisms of action of different types of NPs heave been widely investigated in the model marine organism *Mytilus*; these studies underlined the importance of the immune and digestive gland function as main targets for the impact of NPs in marine invertebrates. Here recent data on the effects of n-TiO_2, one of the most widespread type of NPs in use, in combination with TCDD and Cd^{2+}, chosen as models of common and persistent organic and inorganic contaminants, respectively, on *Mytilus galloprovincialis* will be summarized. The results demonstrate that combined exposure to n-TiO_2 and other pollutants exerted mainly antagonistic and synergistic effects on both immune and digestive gland biomarkers, depending on type of contaminant and the endpoint measured. These data reveal complex and often unexpected interactive responses of NPs with other pollutants from the molecular to the organism level, as well as differences in bioaccumulation, in marine bivalves.

584

Interaction of engineered nanoparticles with PAHs: Could they act as "Trojan-horses" to induce biological responses in marine species?

Y. Di, S.N. Al-Subiai, Plymouth University; V.M. Arlt, Kings College London; J. Readman; B. Stolpe, University of Birmingham / Facility for Environmental Nanoparticle Analysis and Characterisation; J. Lead, University of Birmingham; D. Schorder, Marine Biological Association; A.J. Moody, University off Plymouth; A.N. Jha, Plymouth University / Biological Sciences

Little is known about potential impact of manufactured or engineered nanoparticles

(ENPs) either alone or in combination with other environmental contaminants on aquatic species. Using marine bivalve: *Mytilus sp.*, we assessed the biological responses following exposure to C_{60} fullerene (C_{60}) and two different model polycyclic aromatic hydrocarbons (PAHs): fluoranthene and benzo(a) pyrene (B(a)P). An integrated approach, which included determination of 'clearance rates' (at individual level), histopathological alterations (at tissue level) and DNA strand breaks (comet assay: at cellular level) was adopted to determine the potential impact. Transcriptional alterations of a range of genes involved in DNA damage and stress responses and in classical signalling pathway (i.e. *cyp4ya, jnk, mdm, bax, rad51, p53, ras*) were also determined by real-time quantitative PCR in tissue specific manner for the assessment of impacts following C_{60} either alone or in combinations with PAHs. Combined exposures with fluoranthene and B(a)P provided conflicting results for 'clearance rate' and DNA strand breaks, in terms of whether the responses were additive or not. Consistent histopathological abnormalities were however clearly found in selected organs (i.e. adductor muscle, digestive gland and gills) for both exposure scenarios. For the exposure to B(a)P and/or C_{60}, a significant induction for transcriptional activation of genes involved in classical signalling pathway showed tissue and chemical-specific pattern with large tissue-specific and inter-individual variations. Formation of DNA adducts however could not be detected for any exposure conditions. Overall, biological responses at different levels showed variable sensitivity. This integrated approach could be used to determine the impact of ENPs with other environmental toxicants in the complex environment.

Applications of innovative passive sampling and dosing (II)

Passive sampling of organic ions with ion exchange membranes - Application for the determination of freely dissolved concentrations in protein binding experiments

L. Oemisch, Analytical Environmental Chemistry; S. Endo, Helmholtz Centre for Environmental Research UFZ / Department of Analytical Environmental Chemistry; K. Goss, Department of Analytical Environmental Chemistry

Equilibrium dialysis has been used as a standard method to study the sorption of organic compounds to suspended or dissolved materials such as humic matter, phospholipid liposomes and proteins. Because dialysis experiments have several disadvantages, many alternative methods have been developed. A novel tool for the determination of the freely dissolved concentration in aqueous suspensions is passive sampling with polymeric materials. Due to limited availability of convenient sorption materials only a few attempts have been made so far to adapt this technique to ionic compounds. The aim of this work was to test the applicability of ion exchange membranes (IEMs) for passive sampling experiments with organic ions. IEMs are expected to have various advantages for passive sampling of ions such as high affinity and permeability for ionic compounds having the opposite charge. In this study the sorption properties of two types of IEM (a cation exchange membrane for cations and an anion exchange membrane for anions) were characterized, and their applicability for the measurement of the freely dissolved concentration in binding experiments with bovine serum albumin (BSA) was investigated. For experiments three anionic and three cationic compounds with different ionisable groups were chosen. IEM-water partition coefficients and the equilibration time with the IEMs were determined. Equilibrium between IEM and water was reached quickly within a few hours for the anionic compounds and within 1 to 3 days for the cationic compounds. Binding isotherms to IEMs were measured for three compounds and were found to be non-linear. Furthermore, the sorption to the IEMs was independent of pH, but highly influenced by the salt concentration of the medium. BSA-water partition coefficients were investigated with the passive sampling method and, for comparison, also with equilibrium dialysis. Both experiments yielded very similar results. Additional tests indicated that the ion exchange sites of the IEMs are hardly filled by BSA. Overall, the IEMs were found to be a useful passive sampling material for organic ions. The main advantages of the passive sampling with IEM were the high enrichment of the test compounds in the IEM and the short equilibration time for anionic compounds. The non-linear sorption of the test compounds to the IEMs and the dependence on the salt concentration of the medium may be critical factors that need attention.

Application of passive dosing to the evaluation of toxicity of reactive hydrophobic organic chemicals

J. Kwon, Korea University / Division of Environmental Science and Ecological Engineering; J. Roh, Environmental Research Institute / Dividion of Environmental Science Ecological Engineering

Passive dosing is an emerging technique that controls free concentration of hydrophobic organic chemicals in a desired experimental system. Various successful applications include the determination of partition coefficients and water solubility of sparingly soluble chemicals and the evaluation of toxicity of single chemicals or mixtures. However, the majority of studies on the evaluation of toxic potential of hydrophobic organic chemicals aimed at the evaluation of baseline toxicity or receptor binding that can be explained by equilibrium speciation. Because a constant exposure condition for highly hydrophobic chemicals can be easily achieved by passive dosing, its applicability could be extended to the evaluation of toxicity of chemicals that undergo metabolic transformations. In this presentation, we introduce cytochrome p450 family protein 35A gene expressions of *Caenorhabditis elegans* exposed to chlorpyrifos as an example application of the ecotoxicity of hydrophobic chemicals at lower doses. Gene expression results obtained using the conventional spiking method passive dosing. A simple toxicokinetic model that includes metabolic transformation of chlorpyrifos was also proposed to explain the apparent gene expression of *C. elegans*. Because metabolic transformation of chlorpyrifos is regulated by P450 family genes, it was assumed that metabolic transformation rate is proportional with the increased gene expression. The proposed model qualitatively explained the observed gene expression under two experimental conditions although it is needed to measure body residue concentration for further validation of the model. In conclusion, passive dosing would be a powerful technique when combined with sensitive markers such as gene expression that involve chemical transformations.

Is equilibrium sampling applicable in routine sediment monitoring?

S. Schaefer, German Federal Institute of Hydrology; C. Antoni, Goethe University; C. Moehlenkamp, Federal Institute of Hydrology; E. Claus, Federal Institute of Hydrology BfG; G. Reifferscheid, Biochemistry and Ecotoxicology; P. Heininger, Federal Institute of Hydrology; P. Mayer, Technical University of Denmark / Department of Environmental Engineering

Freely dissolved concentrations (C_{free}) of hydrophobic organic contaminants in sediments are considered to be the effective concentrations and are more indicative of potential exposure of aquatic organisms than total concentrations (C_{total}). Passive equilibrium sampling approaches can be used to measure C_{free} in sediment pore water. Thereby, glass jars with silicone coatings of few μm thickness are very convenient for routine monitoring campaigns since the risky and time-consuming equilibration is done in the laboratory. Tedious time-serious measurements are avoided by incubating sediment sub-samples in coated glass jars with different thicknesses of silicone for validation of equilibrium sampling. Though the German Federal Institute of Hydrology has regularly monitored sediments from the German part of the River Elbe for total concentrations of, e.g., polychlorinated biphenyls (PCBs) and Dichlordiphenyltrichlorethane (DDT) and their metabolites since the 1990s, C_{free} in these sediments are largely unkown. Coated glass jars were applied to sediments from the River Elbe in order to measure C_{free} of PCBs as well as DDT and their metabolites. For this purpose, sediments were sampled at ten stations within the German part of the River Elbe from the Czech border to the wire near Geesthacht. Sediments were incubated in silicone coated glass jars for two weeks in the laboratory, the silicone was extracted and analysed by GC/MS/MS detection. Analyte amounts in silicone were proportional to the amount of silicone for all investigated contaminants and sampling sites confirming equilibrium sampling. C_{free} were in the pg / L range for PCBs and up to the lower ng / L range for DDT metabolites. Patterns of PCB accumulation in equilibrium samplers with highest values primarily for PCB 138 and PCB 153 were similar to C_{total} quantified by traditional exhaustive extraction and analysis. Though, C_{total} of p,p'-DDT are high in the River Elbe, p,p'-DDT was rarely detected in equilibrium sampling extracts and could only be quantified in sediments from two stations hinting at a strong binding of p,p'-DDT to sediment particles. In comparison with other DDT metabolites, C_{free} of DDD isomers were highest. Overall, C_{free} of PCBs and DDT metabolites clearly reflect the contamination of the river Elbe. For PCBs, estimated concentrations in biota ($C_{sed, lipid}$) obtained by equilibrium sampler data highly correlate with bioaccumulation in fish.

588

Coastal Bothnian Sea sediments as a source of dissolved PCDD/Fs and PCBs to water

A. Sobek, Applied Environmental Science ITM; K. Wiberg, Swedish University of Agricultural Sciences SLU / Department of Aquatic Sciences and Assessment; K. Sundqvist, ÅF AB; P. Jonsson, Stockholm University / Department of Applied Environmental Science ITM; G. Cornelissen, NGI

The aim of this study was to investigate whether coastal sediments in the Bothnian Sea act as a sink or source of dissolved PCDD/Fs and PCBs to bottom water. High levels of organic contaminants in Baltic Sea biota have been a matter of great concern during the last decades. Concentrations of PCDD/Fs and dioxin-like PCBs in lipid-rich fish of the northern parts of the Baltic Sea (Bothnian Sea) exceed the EU quality standard for food and feed of 4 pg toxic equivalents (TEQ) /g fw. Sedimentation of particulate organic matter is the most important removal process for PCDD/Fs in the Baltic Sea. We used polyoxymethylene (POM) passive samplers to measure the freely dissolved concentrations of PCDD/Fs and PCBs in pore water and bottom water in eight different areas along the Swedish coast of the Bothnian Sea. The study areas represent various ongoing and historical industrial activities. We also investigated the importance of local sediment contamination for observed concentrations of PCDD/Fs and PCBs in stationary juvenile perch caught

in the same areas. Activity Ratios (calculated from concentrations in pore water and bottom water based on chemical activity ratios) for PCDD/Fs were higher than one at all stations (average 27; stdev 22) implying higher fugacity in the sediment and that the sediments have a high potential to act as a source of dissolved PCDD/Fs to the water column. Activity Ratios for PCBs varied between 0.3 and 17(average 2; stdev 4). The concentrations of PCDD/Fs and PCBs in bottom water correlated positively with concentrations in juvenile perch. We know from recent studies that actions have to be taken to reduce atmospheric transport and deposition of PCDD/Fs to reduce levels in the Baltic Sea in general and in herring specifically. Still, the results presented here suggest that contamination of PCDD/Fs and PCBs in the lower trophic levels of the aquatic food web in Bothnian Sea coastal areas may be strongly affected by contamination in sediments. The results from this study thus imply that continued efforts to reduce the levels of PCDD/Fs and PCBs in coastal sediment will have positive effects on concentrations of these contaminants in the lower trophic levels of the coastal ecosystems.

589

Initial laboratory validation experiment: comparing the accumulation of organophosphorus flame retardants in passive samplers and mussels (Mytilus edilus) during continuous exposure.

T. Fisher, Cefas / Ecotoxicology and Chemical Risk Assessment; J. Brant, Cefas; J. Barber, Lancaster University; A. Papachlimitzou, D. Sheahan, Cefas

A number of field studies have been conducted in recent times using passive samplers in the aquatic environment and more recently integrated assessments using both biomarkers and passive systems. In this study a flow through dosing system was used to expose mussels (*Mytilus edilus*) and silicon rubber passive samplers to relevant organophosphorus flame retardants (OPFRs) which are largely recognised as priority hazardous substances in the marine environment. The experiment ran for a total of 28 days and included a depuration period during which the concentration decline in both samplers and mussels was monitored. The flame retardants with the higher K_{ow} values generally accumulated to a greater extent in the mussels and the passive samplers. For the majority of OPFRs tested there was faster uptake in the samplers but during the depuration phase there was a higher loss from the mussels most likely due to metabolism. However TPrP despite having a low K_{ow} was detected in the mussels all be it at a low concentration. The following compounds were below detection limits in the mussels but were present in the samplers: TCEP, TCPP and TBEP and all had a log K_{ow} value < 4. Based on these results it appears that the samplers could be more appropriate to use when there are pulsed or episodic environmental exposures as they are more likely to be detected. In general mussels are the preferred monitoring tool when the assessments involve food-chain effects and give a more realistic indication of actual exposure and effects and likely levels of contamination within organisms. As integrated field monitoring using both biomarkers and samplers increases laboratory derived data like those produced during this experiment will become ever more important to ensure that the appropriate methods are used to monitor accumulation of contaminants in the marine environment. Currently we are investigating the use of these samplers post exposure in ecotoxicological assays using other relevant species for example marine algae to assess toxicity of environmentally relevant concentrations.

590

Legacy Persistent Organic Pollutants Have Reached the Remoteness Place on Earth: the Antarctic Plateau

C. Ana; G. Caballero, IDAEACSIC / Environmental Chemistry; R. Larramendi, Viajes Tierras Polares; J. Albar, Proteomics Unit Centro Nacional de Biotecnologia CNBCSIC; J. Dachs, IDAEACSIC / Environmental Chemistry

The Antarctica is usually perceived as a symbol of the last great wilderness and remoteness. Although natural "barriers" such as oceanic and atmospheric circulation protect this region from lower latitude water and air masses, previous assessments on concentrations of persistent organic pollutants (POPs) such as polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs) evidence its ubiquitous presence in air, snow, water, vegetation or food webs organisms in the Maritime Antarctica, thus, the outermore region of Antarctica. The occurrence of these man-made synthetic chemicals in Polar Regions is just another manifestation of the multiple anthropogenic perturbations on the composition of the biosphere. Their long half-lives facilitate repeated cycles of volatilization and deposition resulting in progressive movement away from temperate and tropical source regions towards colder climate areas and remote regions. Ultimately, these compounds may experience "cold-trapping" at the Polar Regions, where the colder temperatures further prolong persistence and enhance their accumulation in snow. In addition, this cold trapping in the outermost regions of Antarctica could prevent or retard their transport to the Antarctic Plateau. The extreme persistence, semi-volatility, biacummulation potential and adverse effects of some POPs in wildlife and humans have led to develop international protocols regulating their use (Stockholm Convention). Most of the studies available in the antarctic atmosphere reporting data of PCBs and OCPs were mainly performed using active samplers mostly located close to research stations since power supply is usually a limiting factor. This limitation together with the extreme conditions of performing an atmospheric sampling campaign over the Continent result in a lack of information regarding the levels of PCBs and OCPs, or any other POPs, over the Antarctic Plateau. Therefore the main objectives of this work are: i) to assess for the first time, in an Antarctic Expedition, the occurrence of PCBs and OCPs over a latitudinal gradient, from Novolazarevskaya Station (75 km from the coast) to Glaciar Union crossing the South Pole during 35 days (total 3500 km) using a passive sampler coupled to an exclusively wind-power kite-drawn sled and ii) to prove if the eco-friendly vehicle developped by Larramendi and moved with big comets could be a useful a tool for adventorous Antarctic research.

Measuring and modelling chemical bioavailability in soils (II)

Effect of various cations in phosphate-based washing solution on toxicity of washed arsenic-contaminated soils

S. Jeong, Department of Civil and Environmental Engineering; E. Jho, Seoul National University / Department of Civil and Environmental Engineering; K. Nam, Seoul National University / Dept of Civil and Environmental Engineering

Arsenic contamination of the smelting area has been a major concern, as it could impose adverse impacts on the surrounding ecosystem. Soil washing using phosphate-based reagent is often used to remove heavy metal from soils as a more environmentally-friendly alternative than acid-based washing. Although phosphate can effectively remove arsenic from soils through phosphate-As competition ion exchange, the residual heavy metal after soil washing or the soil washing procedure itself that could deteriorate the soil qualities could still impose toxic effects on the ecosystem when the treated soils are put back. The aim of this study was to determine the toxic effects of the As-contaminated soils before and after laboratory-scale phosphate-aided soil washing treatment. The As-contaminated soils was collected from the former Janghang smelter site in Korea. The contaminated soil samples were collected from two different locations (A and B) of the site. The soil samples from the location A were sand with 33.2±10.8 mg kg^{-1} of As, while the soil samples from the location B were silt loam with 31.1±14.5 mg kg^{-1} As. Two soil samples was mainly contaminated with As, and other heavy metals were also found in soils. For soil washing, 0.5 M ammonium phosphate ($(NH_4)(H_2PO_4)$) is to be used at the soil to solution ratio of 1:5 for 2 h, which was determined based on the preceding study results. The Microtox® assay using *Vibrio fischeri* was performed to determine the toxic effects of the soils before soil washing and the toxic efects after soil washing are to be determined. From ammonium phosphate-aided soil washing results, about 24% of As was mainly removed in both of soils located from site A and B, showing most of soils achieved the concentration level provided by Korean Act. However, Microtox® results showed that the toxic effects could not be correlated to the As concentration in soil samples, suggesting that other heavy metals could have effect on toxicity of washed soils. It is expected that the toxicity of washed soil caused by the other heavy metals can be reduced by competition with cations in phosphate washing solution. Thus, soil washing using the other phosphate-based solution such as KH_2PO_4, $Ca(H_2PO_4)_2$, and $Mg(H_2PO_4)_2$ will be also conducted to compare the toxic effect of washed soils with ammonium phosphate washed soils. Based on this result, the most suitable phosphate-aided washing solution is to be selected for the site application.

592

In vivo and in vitro tests of the bioavailability of dioxins and polycyclic aromatic compounds in field-contaminated soil

S. Josefsson, Swedish University of Agricultural Sciences / Dept of Aquatic Sciences and Assessment; S. Lundstedt, Umea University / Department of Chemistry; L. Ahrens, Swedish University of Agricultural Sciences SLU / Dept of Aquatic Sciences and Assessment; M. Tysklind, Umea University / Department of Chemistry; Y. Volchko, Chalmers University of Technology / Department of Civil and Environmental Engineering; K. Wiberg, Swedish University of Agricultural Sciences SLU / Department of Aquatic Sciences and Assessment

Contaminants present in soils are only partially available for biological uptake, due to sequestering or strong sorption to soil particles. However, the methodologies for taking bioavailability into account during risk assessment of contaminated sites are not established. In this study, four different tests of the contaminant bioavailability were applied to soils from two contaminated sites. The contaminants investigated were polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDD/Fs, also known as dioxins), and polycyclic aromatic compounds (PACs). PACs includes polycyclic aromatic hydrocarbons (PAHs), but also more polar PACs such as the oxy-PAHs and azaarenes. These substances can be formed in the same processes as PAHs, but can also be produced as a result of PAH transformation in the environment. The oxy-PAHs and the azaarenes are generally more polar than the PAHs, and may therefore display a different behavior at contaminated soils, for instance in bioavailability and leachability. In this study, the seventeen 2,3,7,8-substituted dioxins, 16 PAHs, 11 oxy-PAHs and 4 azaarenes were included, thus covering a wide range of substances of importance at sites contaminated with organic

pollutants. Four tests were used to investigate the bioavailability of the contaminants. These were two *in vitro* tests – extraction using Tenax and extraction mimicking human gastrointestinal uptake (oral bioaccessibility) – and two *in vivo* tests – uptake by the worm *Eisenia fetida* and by the zucchini *Cucurbita pepo*. The aim of the study was to determine the bioavailable fraction and investigate how it varies over the contaminated sites, how well the results of the different tests correspond to each other, and to what extent the bioavailability according to the different tests correlates to soil parameters such as organic carbon, black carbon, nitrogen and phosphorous.

593

Integrating mechanistic modelling in estimating metal accumulation in plants

Y.T. Le, Radboud University Nijmegen / Environmental Science; F. Swartjes, National Institute for Public Health and the Environment the Netherlands; B. Groenenberg, P. Romkens, Wageningen University and Research Centre The Netherlands; J.A. Hendriks, Radboud University Nijmegen / Department of Environmental Sciences

Vegetable consumption is the most important contributor to human body burden many metals. In available human exposure models, metal concentrations in the edible parts are empirically estimated from the total concentration in root, using Bio-Concentration factors or regression equations. A mechanistic method, consisting of three steps: speciation, root uptake modelling, and root-to-shoot translocation modelling, was developed to assess metal accumulation in plants. Firstly, metal concentrations in soil solution were estimated from total metal concentrations in soil using multi-surface complexation models (speciation). Uncertainties in this step are induced by lacking data on soil properties. Secondly, metal accumulation in roots was estimated using the WHAM-HA modelling, i.e., humic acid was considered a surrogate to roots. Uncertainties in this simulation are associated with the wide variations in equivalent site density of roots. Thirdly, root-to-shoot translocation was modelled to predict metal concentrations in the above-ground parts of plants. The translocation depends on shoot growth and xylem loading, which are driven by passive diffusion or mediated by transporters. These factors are, in turn, influenced by plant characteristics. Therefore, plant characteristics are the most important source of uncertainties in this step. When data on soil properties were available, the estimates of soil solution concentrations were generally within one order of magnitude of the measurements. Based on generic soil properties, such deviations remained for metals for which their sorption can be simulated well by intensive data in the models such as Cu only. Higher uncertainties were seen for others, e.g., four orders of magnitude for Ni. Based on the available value of the equivalent site density, the predicted total concentrations of metals (i.e., Cu, Ni, Mn, Cd, and Zn) were in general within one order of magnitude of the measured values. The variations in the total root concentrations equal the variations in the equivalent site density of plant roots (a factor of 2). The estimates of shoot concentrations were within one order of magnitude of the measurements. Metals are mainly retained in roots while only a small amount was transported to the above-ground parts.

594

An in silico model of ingestion bioaccessibility for selected polycyclic aromatic hydrocarbons in coking works soil using gene expression programming

D.J. Beriro, J. Wragg, British Geological Survey; K. Carlson, Division of Toxicology and Risk Assessment; R.J. Abrahart, University of Nottingham; P.C. Nathanail, University of Nottingham

A new in silico predictive model has been produced for in vitro human ingestion bioaccessibility of heavy molecular weight (HMW) polycyclic aromatic hydrocarbons (PAH) (≥4 ring) using gene expression programming (GEP). GEP is an evolutionary algorithm that searches for patterns in data and expresses them as transparent symbolic regression equations. Findings suggest that GEP can be used to identify meaningful complex relationships between soil properties and PAH resulting in the production of a site-based predictive model for the bioaccessibility of HMW PAH. The identification of these relationships indicates that physico-chemical properties of soil and PAH are important determinands of bioaccessibility at the site which may be used to develop further research hypotheses. The in silico model is based on twenty-nine input variables for sixty-four soil samples from a former coking and chemical works located near Chesterfield in Derbyshire, UK. Samples were freeze dried and sieved to ≤250 mm prior to quantification by GC-MS for parent PAH (sixteen defined by the United States Environmental Protection Agency as priority pollutants) and bioaccessible concentrations of HMW PAH, extracted using the FOREhST method. Near infra-red (NIR) and mid infra-red (MIR) diffuse reflectance spectroscopy (DRS) was completed on all soil samples to determine their chemical bonding characteristics. Principal component analysis of the raw MIR and NIR data was used to create a sub-set of model input variables. Total organic carbon and pH were also determined given their influence on contaminant sorption. The completed dataset was randomly partitioned into training and testing data (70:30) and used for GEP modelling. Evolved models were evaluated using visual summaries (scatter plots and residual plots), goodness-of-fit metrics (mean percentage absolute error, R^2 and relative root mean squared error) and one-at-a-time response function sensitivity analysis. The preferred model shows good agreement between measured and predicted data, emphasising the applicability of the in silico approach to predicting the bioaccessibility of HMW PAH using selected physico-chemical soil properties. The model is not supposed to be a replacement for existing in vitro extraction methods, but instead a site-specific complementary tool for human health risk assessment of land contamination.

595

Use of diffuse reflectance mid-infrared spectroscopy for rapid prediction of physico-chemical properties of sediments

J. Soriano Disla, CSIROUniversity of Adelaide; L. Janik, S. Forrester, M.J. McLAUGHLIN, CSIRO Land and Water; W.G. Brumbaugh, USGS

The rapid and inexpensive determination of physico-chemical properties (e.g. particle size, cation exchange capacity (CEC), total organic carbon (TOC)) that mitigate the toxicity of both inorganic and organic contaminants in sediments could be useful for assessing the "susceptibility" to contamination. Techniques based on diffusive reflectance mid-infrared Fourier-Transform (DRIFT) spectroscopy have been successfully used for the prediction of many soil properties. This study describes the development of partial least squares regression (PLSR) models combining DRIFT spectra and reference analytical data for the prediction of sediment properties, relevant to determining contaminant toxicity. A total of 79 sediment samples were collected from streams and lakes of central and western USA during several independent investigations. All samples were dried at 40ºC and ground (< 100 μm) prior to scanning and laboratory analysis of up to 51 analytes. Calibration models developed by PLSR were tested by leave-one-out cross-validation. The MIR-PLSR models successfully predicted 35 of the 51 available analytes, based on the ratio of standard deviation to root mean square error of the cross-validation being greater than 1.5. For the major properties, PLSR models were successful (in order of accuracy) for Ti, K, Al, Fe, TOC, CEC, loss of ignition, P, Mg, Ca, silt, Mn and sand, and unsuccessful for Na, acid volatile sulphide and clay. Minor elements, Ga, Y, Cu, Li, Cs, V, Be, Bi, I, Rb, As, Sc, Cr, Ba, U, Zr, B, Sr, Co, In, Mo and Sn were also successfully predicted, but poorer predictions were obtained for Ge, Tl, Pd, Pb, Se, Ag, Cd, Br, Ni, Hg, Sb, Zn and Nb. Successful calibrations were dependent on the presence of analytes (e.g. Al, Ca, Fe, Mg, TOC) in known MIR absorbers e.g. minerals and organic matter, or due to their correlations (e.g. As, Cr, Cu, Ga, CEC, particle size) with MIR-active components. Unsuccessful models were due to a low number of diverse samples, low concentration, or absence of relationships with MIR absorbers. Thus, DRIFT-PLSR has the potential to simultaneously and rapidly (< 1 min) predict a range of properties of sediments, and might be adapted to field use with hand-held DRIFT instrumentation. The method therefore offers the opportunity to screen sediment samples for properties that are likely to affect toxicity of both inorganic and organic contaminants. Additional studies are in progress to better define the applicability of the method.

596

Non-extractable residues (NER) from xenobiotics in soil: a new classification and relevance in the risk assessment

K.M. Nowak, RWTH Aachen University / Institute for Environmental Research Biology V; M. Kaestner, Helmholtz Centre for Environmental Research UFZ / Dept Environmental Biotechnology; A. Miltner, Helmholtz-Centre for Environmental Research / Department of Environmental Biotechnology; S. Trapp, Danmark Tekniske Universitet / DTU Environment; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research

Anthropogenic organic chemicals are deliberately (e.g. pesticides) or unintentionally (e.g. polyaromatic hydrocarbons, chlorinated solvents, pharmaceuticals) released in major amounts to nearly all compartments of the environment. Soils and sediments as complex matrices provide a wide variety of binding sites and are the major sinks for these compounds. Xenobiotics entering these complex systems may undergo various turnover processes. They can be degraded chemically (e.g. photolysis), biologically by microorganisms, volatilised leached to the groundwater or taken up by living organisms or immobilised in the form of non-extractable residues (NER). NER formed during degradation of an organic contaminant in soil are commonly divided into two binding modes: *sequestered* (*type I*, adsorbed or entrapped) within the soil matrix or *chemically bound* (*type II*) via covalent bonds to SOM. However, recent studies with readily biodegradable compounds ($^{13}C_6$-2,4-D, $^{13}C_6$-ibuprofen, $^{13}C_3{}^{15}N$-glyphosate) showed that the NER identified by isotope mass balance are of biogenic origin. Therefore, the actual NER classification needs to be extended to a new classification scheme in terms of compounds forming the NER: into *xenobiotic NER*, which are composed of sequestered or bound parent xenobiotic and / or xenobiotic metabolites (*type I* and *II*) and into *biogenic NER* (*type III*, *bioNER*) containing natural biomass compounds. It is necessary to distinguish between the three types of NER in order to access properly the respective xenobiotic degradation rate and to estimate its potential risks for human and environment. For instance, biogenic NER which are composed of biomass compounds pose no risk for the environment. BioNER should be therefore clearly distinguished from the xenobiotic NER of type I and II, since the processes of abiotic NER and biotic NER

formations are competing processes. The relative importance of each of them will vary depending on environmental conditions, degradation kinetics, and sorption properties of the compound in question.

Mercury Biogeochemistry and Policy (II)

Mercury contamination in Lake Maggiore in the vicinity of a chlor-alkali plant: contamination of sediments and aquatic organisms

L. Marziali, IRSACNR Brugherio; D.A. Vignati, CNRS / LIEC UMR; P. Guilizzoni, Italian National Research Council Institute of Ecosystem Study CNRISE; M. Camusso, L. Guzzella, Italian National Research Council Water Research Institute CNRIRSA; G. Tartari, Italian National Research Council Water Research Institute CNRIRSA / UOS Brugherio

A mercury-cell chlor-alkali plant in Lake Maggiore basin (North Italy) has severely affected the aquatic environment between the 1940s and the 1970s, with high levels of Hg contamination in sediments. The chlor-alkali plant is located on the river Toce, a tributary of the lake which flows into the Bay of Pallanza and drives contaminated sediments. Monitoring activities are carried out by the International Commission for the Protection of Italian-Swiss waters (www.CIPAIS.org), who collected data on contamination over a period of 15 years. Our objective was to investigate mercury contamination in the aquatic ecosystem of Lake Maggiore, with trend analysis of concentrations in sediments and biota in the last 15 years, in order to assess the potential risk for aquatic food chain and possibly for human health. THg concentrations were analyzed in lake sediment cores, in the bivalve *Dreissena polymorpha* and in fish specimens of *Coregonus lavaretus*, *Alosa fallax lacustris* and *Rutilus rutilus*. Samples were analyzed with AMA254 Automated Mercury Analyzer. Peak values up to 25 mg kg^{-1} d.w. were measured in a sediment core sampled in the Bay of Pallanza. Current Hg levels remain in the range of 0.5–1 mg kg^{-1} d.w. in the Bay of Pallanza and in the southern part of the lake. Values in *D. polymorpha* are higher in the Bay of Pallanza (up to 0,2 mg kg^{-1} d.w.) than along the N-S axis of the lake (up to 0,1 mg kg^{-1} d.w.) and concentrations have remained stable over the last 15 years. Values in fish are higher for *Alosa fallax lacustris* (0.096-0.266 mg Hg kg^{-1} w.w.) than for *Coregonus lavaretus* (0.070-0.111 mg Hg kg^{-1} w.w.) and *Rutilus rutilus* (0.059-0.147 mg Hg kg^{-1} w.w.). Concentrations in fish have remained stable in the last 12 years and are above the EQS of European Directive 2013/39/UE for Hg (0.02 mg Hg kg^{-1} w.w.), with potential risk for top predators of the food chains. Future monitoring programs will focus on understaning the persistence of Hg contamination in the biotic compartement. On this basis we conclude that the possible issues are: 1) remobilization of Hg from the river Toce during high flow events, 2) Hg inputs coming from a diffuse contamination of the whole watershed, 3) changes in methylation rates due to re-oligotrophication of the lake.

598

Retrospective monitoring of mercury in fish of European freshwaters

B. Knopf, R. Nguetseng Ngueguim, IME Fraunhofer / Environmental Specimen Bank and Elemental Analysis; M. Quack, Trier University / Biogeography; H. Ruedel, Fraunhofer IME Institute for Molecular Biology and Applied Ecology / Environmental Monitoring

For the implementation of the water framework directive (2000/60/EG) a European quality standard was defined with 20 µg/kg mercury (Hg) in fresh weight of aquatic organisms (EU-directives 2008/105/EG, 2013/39/EU). Although inorganic Hg and organic Hg (mainly monomethylmercury, $MeHg^+$) have to be assessed differently because of their different chemical behaviour and ecotoxicity - $MeHg^+$ is of special relevance concerning a secondary poisoning of predator organisms (organisms of a higher trophic level) -, only determination of the total mercury concentration in organisms is required. According to the literature the fraction of organic Hg in relation to the total Hg is for example in muscle of bream 95%, and 75 – 90% for eelpout, pike, perch, pikeperch and bream, respectively. Within a monitoring program to investigate the changes of HBCD concentrations in the environment a sampling campaign started in 2007 to collect samples of bream (*Abramis brama*) in different European rivers. Bream were collected in the period 2007-2012 from the rivers Tees/UK, Mersey/UK (no sampling 2009-2011), Götaälv/SE (no sampling 2009-2011), Western Scheldt/NL, and Rhône/FR as well as from Lake Belau/DE. The latter represents a site with little anthropogenic influence. The muscle tissue samples of 15 fish per site were homogenised and pooled. Samples of the homogenised bream muscle tissue from the different sampling sites as well as sole (*Solea solea)* muscle tissue from the sampling site Western Scheldt were analysed for their total mercury concentration by cold vapour- AAS (Direct Mercury Analyser) as well as for their monomethylmercury concentration by SID-GC/ICP-MS (species-specific isotope dilution - gas chromato-graphy - inductively coupled plasma-mass spectrometry). The results of this project should answer following questions: 1) Is the EQS in fish samples of European freshwater – as in bream samples of Germany (see data of the Environmental Specimen Bank operated by the German Environmental Agency; www.umweltprobenbank.de) – clearly exceeded for mercury? 2) How far are the concentration of mercury exceeded in fish of European freshwaters in contrast to samples of bream of the reference site Lake Belau (Germany)? 3) Are there any temporal trends in the concentration of inorganic and organic mercury? 4) Is the ratio of monmethymercury to the total Hg concentration at the different sampling sites and during the time constant?

599

Critical Review of Mercury Toxicity Reference Values (TRV) and Sediment Quality Values (SQV) for Protection of Fish and Benthic Invertebrates

J.M. Conder, ENVIRON International Corporation; P.C. Fuchsman, ENVIRON International Corp; E. Bizzotto; M.H. Henning, ENVIRON International Corporation; M.T. Sorensen, ENVIRON International Corporation / Senior Science Advisor; V.S. Magar, ENVIRON / Ecology Sediment Management; F. Colombo,

Mercury is a naturally occurring element that has been released from geologically stable forms into the environment through human activities. Mercury biomagnifies through the food web, and also has the potential for direct toxic effects on lower trophic levels, including benthic invertebrates. Risks posed to benthic invertebrates by chemicals in sediment are often initially screened by comparing chemical concentrations in sediment to sediment quality values (SQVs; also known as sediment quality guidelines or sediment quality benchmarks). SQVs are often developed as paired concentrations of chemicals in sediment, typically with a lower bound statistic that is believed to be associated with the absence of an effect (i.e., no effect) and an upper bound statistic that is believed to be associated with an adverse effect. During the presentation, we will present a recent reviews of mercury SQVs developed for characterizing mercury risks to benthic invertebrates (Conder et al., 2013). For comparison, data relevant to understanding causal relationships between mercury concentrations and sediment toxicity were also reviewed.

600

Identification of artisanal gold mining as a mercury pollution source in South Africa

V. Somerset, NRE

Mercury (Hg) as a hazardous metal has caused serious episodes of environmental pollution globally and disastrous human health distresses in the last decades. Mercury undergoes a series of transformations in the environment and is converted into inorganic and organic mercury. Methylmercury as the organic form, is listed high on the list of environmental pollutants, especially since it bioaccumulates through the food chain. In South Africa the magnitude of Hg pollution was relatively low on the agenda in 2000, although a study by Pacina *et al.* [1] has ranked the country as the second highest anthropogenic emitter. This data was largely based on the Hg emissions from coal combustion and artisanal gold mining, reporting that South Africa contributes more than 10% to the global Hg emission budget. South African Scientists have since then conducted further investigations and have reported that Hg emissions are significantly lower than previously reported [2]. In 2013, the UNEP Global Mercury Assessment Report [3] has identified artisanal gold mining as the latest source contributing the most to the global mercury budget. This presents South Africa with another challenge to fully understand its Hg footprint, as the area around Johannesburg was the main hub of artisanal gold mining activities from the 1880s until the 1910s [4]. The focus of this paper is to understand the role Hg has played in artisanal gold mining activities during the early stages of gold mining in South Africa. By quantifying the amount of Hg present in historical gold mining wastes, it is hoped that a possible prediction of Hg mobilisation, re-emission and persistence in the environment can be made [5]. Thus, more information is needed of the different stages in which Hg is applied, during amalgamation processes, to extract gold in order to evaluate rates of environmental Hg losses during the past mining operations. It is further hoped that by establishing emission factors, using data from previous and / or related studies, it will be able to estimate Hg loss rates from gold production rates. In doing so, it is also hoped that the Hg pollution footprint from artisanal gold mining in South Africa will add to better understanding the fate and transport of Hg pollution in the country's Water Resources. **Keywords**: Mercury Sources; Artisanal gold mining; Human health; South Africa; Water Resources.

601

Mercury Pollution, Population Declines and Species Loss: A Review of the Evidence

M.S. Bank, University of Massachusetts / Department of Environmental Conservation

Contaminants such as mercury and its effects on species have been relatively well studied. Recent research investigations have identified methylmercury exposure as an overlooked environmental stressor that can cause negative effects on wild animal populations, even in remote areas. Species sensitive to environmental degradation hold great potential as eco-indicator species. However, eco-indicators are often merely monitored over time without recognizing the processes and mechanisms related to the factors that reduce the overall health and performance of local populations. Mercury contamination in the United States is a well-documented "contaminant biology" example and continues to be an environmental and public-health issue of great concern for certain sectors of the

global human population. Documentation of the pervasiveness of this contaminant is a first step toward understanding the potential environmental health and ecological implications of mercury pollution, including species loss and potential population decline of biological organisms. Using weight of evidence approaches I synthesize and evaluate variation in mercury bioaccumulation and distribution across a broad gradient of physical, climatic, biotic, and ecosystem settings to identify the environmental conditions and ecosystem types and species that are most sensitive to mercury pollution. Implications of this work as it relates to the UNEP mercury convention will also be discussed.

602

Calculating mercury risk and evaluating remediation actions using Bayesian networks for the South River, Virginia, USA

A.F. Johns, Western Washington University / Institute of Environmental Toxicology Huxley College of the Environment; K. Kolb Ayre, Western Washington University / Institute of Environmental Toxicology; J.M. Stinson, Institute of Environmental Toxicology; H. Summers, Integral Consulting / Institute of Environmental Toxicology and Chemistry; W.G. Landis, Western Washington University / Institute of Environmental Toxicology

Ecological managers are required to implement one or more management options to reduce risk to ecosystem services without the direct integration of risk assessment and evaluation of management alternatives. Throughout the decision making process a manager must consider multiple physical, chemical and biological stressors on an endpoint as well as the interactions of these stressors and the resulting effects. In this study, we use Bayesian networks (BNs) in a relative risk assessment framework to assess risk to four biotic endpoints and four water quality endpoints and evaluate remedial options for the mercury contaminated site, South River, VA. Bayesian networks explicitly describe the effects of mercury toxicity on these endpoints, as well as the interaction between mercury and other stressors. Through communication with decision makers for the South River, we identified two management options for the site: bank stabilization and agricultural best management practices (BMPs). The management goals for the South River reach beyond simple mercury remediation. The primary goal expressed by managers is "no regrets." In other words, the managers do not want to make the site worse in any way, such as reducing mercury levels at the detriment of habitat, loss of other species or other environmental parameters. The BNs are able to represent the expected effects of a management option and potentially unintended consequences. We have integrated these remedial options into our BNs separately, as well as combined, for the biotic and water quality endpoints. We used the South River total maximum daily load (TMDL) modelling to estimate that 45-75% of nutrients and bacteria come from agricultural land. Agricultural BMPs either slightly reduce risk or do not change risk to endpoints. Even if total phosphorus or bacteria inputs are zero, there is little change in the risk distribution output because these parameters are not risk drivers for any endpoints. We are currently completing model parameterisation for bank stabilization. Our work provides the managers of the South River with a tool that describes how management options are expected to change mercury levels, as well as overall risk. As with many mercury contaminated sites, management for the South River is not a one-time decision. Our BNs can be updated with new monitoring data to inform future decisions for the site, which is important because the South River will be managed for another 70 years.

Toward sustainability: benchmarks, certification and LCA (II)

603

MEASURING THE ENVIRONMENTAL PERFORMANCE OF THE UK CHEMICAL INDUSTRY – A LIFE CYCLE APPROACH

I.B. Ekang, University of Manchester / Chemical Engineering; A. Azapagic, The University of Manchester

The UK chemical industry is one of the largest manufacturing sectors in the UK and is pivotal for many other industries. The sector is a major export source with a turnover of over £60 billion projected to grow by 16.3% in 2016. The chemical industry is characterised by large production volumes, complex technologies and vast distribution networks with environmental consequences such as natural resource depletion, emissions to air and water as well as waste generation. These environmental impacts are potentially significant but are currently unknown. \nLife cycle assessment (LCA) was used in this study to provide insight into the environmental impacts associated with this industry with emphasis on some of the key chemical sub-sectors. A "cradle to gate" approach was used to evaluate the environmental burdens of the sub-sectors. The methodology involved the identification of some of the key chemical sub-sectors and their individual component elements and an assessment of the average environment impacts of each of these sub-sectors. A subsequent estimation of the total environmental impacts of each chemical sub-sectors over five years was performed using production data sourced from the UK Office of National Statistics. The LCA data were sourced from Ecoinvent and GaBi 6® software was used for LCA modelling. The environmental impacts were calculated using the CML 2001 method. \nThe results give an insight into the hotspots along the supply chains and indicate opportunities for improvements. The use of LCA as a decision-support tool in the sector is also discussed.

604

Evaluation of ILCD Data Network Entry-level and PEF data quality requirements in LCA databases

P. Masoni, P. Porta, M. Tarantini, A. Zamagni, ENEA / LCA and Ecodesign Laboratory; M. Recchioni, F. Mathieux, EC JRC IES; R. Pant, European Commission

In its 2013 Communication on "Building the Single Market for Green Products", and in response to commitments in the Communication on "A resource-efficient Europe – Flagship initiative under the Europe 2020 Strategy", the Commission adopted a Recommendation on the use of the Environmental Footprint as methods to measure and communicate the environmental performance of products and of organisations. The ILCD Data Network (ILCD DN) on the data infrastructure that is critical for further uptake of these and other life cycle based methods for their successful implementation in business and policy decision support. It is a web-based infrastructure aimed at providing access to consistent and quality-assured life cycle inventory (LCI) datasets from various providers. To be part of the network, datasets have to fulfil ILCD DN entry-level quality requirements. Indeed, data quality requirements have been also developed for datasets to be used in studies that are in line with the PEF/OEF, many of which are common to PEF quality requirements, but others differ in the degree of strictness. This contribution describes the approach adopted for analysing the extent to which life cycle datasets available in LCA databases meet ILCD DN entry-level and PEF data quality requirements, together with key issues emerged from the analysis. The analysis has been carried out on a sample of datasets of ECOINVENT v3.0, GaBi and EIME databases and the findings have then been extrapolated to the database level and to other third-party databases.

605

Evaluation of the importance of impacts from potential deforestation for fiber-based products in the context of life cycle assessment for non-certified products

C. Guignard, Quantis; A. Deschryver, ETH; V. Rossi, S. Vionnet, Quantis; S. Price, PEFC; A. Kounina, Quantis EPFL; S. Humbert, Quantis

Deforestation and land degradation is a major cause of environmental impacts, often associated with logging, mining, and crop or pasture land need. However, current inventory databases often do not contain information about potential deforestation in the background of wood-, fiber- and agro-based products. The goal of this study was to evaluate the importance of impacts from potential deforestation for fiber-based, and explore different ways to introduce this information in current life cycle inventory database. The impacts of 1 ha of deforestation were modelled starting from the ecoinvent process 'clear-cutting primary forest to arable land'. A specific process was modelled for deforestation associated with logging to account for carbon stored in the logs themselves. In order to evaluate the impacts of deforestation potentially associated with logging, we worked in collaboration with the Programme for the Endorsement of Forest Certification (PEFC). On a global scale, 13'000'000 ha are deforested per year and it can be assumed that 10% of deforestation relates to wood extraction. Therefore, there is approximately 1'300'000 ha deforested that is attributed to wood extraction. As a starting point, if overall deforestation associated with wood extraction is allocated equally among the entire wood extracted, one gets approximately 3.5 m2 of deforestation per m3 of wood extracted. Assuming that certified wood can be excluded from wood associated with deforestation, one gets an average of 4.66 m2 of deforestation per 1 m3 of non-certifiable wood. Such an analysis can be further refined, considering for example regionalization. As an example, using such allocation of deforestation, the carbon footprint from non-certifiable softwood is about 10x higher than from certified softwood and ecosystem quality impacts about 2.5x higher. For paper the differences are smaller due to the contribution of other activities. Using such allocation, paper coming from non-certifiable wood is between 5% and 25% more impacting than full certified paper for carbon footprint and ecosystem quality. These preliminary results show that it is important to evaluate whether deforestation may be present in the supply chain of fiber-based products, and if so, account for its impacts.

606

Defining and implementing a sustainability strategy in industry: LCA and C2C® certification

M. Guiton, CRP Henri Tudor / Resource Centre for Environmental Technologies (CRTE); E. Benetto, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; A. Beloussova, CRP Henri Tudor

Life-Cycle Thinking is usually identified as the central approach of manufacturing industries sustainable strategy, since the products are at the core of their activities. The implementation of Life Cycle Assessment (LCA) as a fact based practice for process and product environmental improvement is therefore essential. Many of the manufacturing industries using LCA as an eco-design driver and a strategic tool are

aware that LCA is not sufficient at its current level of development to address some specific issues for their products and processes, such as product life-cycle waste management, or specific toxicity risk assessment and limitation. Therefore, we observe a growing interest from industries for other Life-Cycle Thinking approaches, like Cradle to Cradle (C2C®), striving to propose an integrated perspective for industrial products and processes design. By using the case study of a linoleum floor covering from Tarkett producer, the aim of this presentation is to demonstrate existing complementarities between LCA and C2C® that could lead to extend the boundaries of industries' sustainability strategy by the development of consistent benchmarks (reference values or thresholds). Whereas LCA measures quantitative life cycle potential environmental impacts with the final aim of reducing them, C2C® provides qualitative technical guidance for improving materials and energy flows management along products' or processes' life cycle by maximising the benefits they provide to humans and ecosystems. The latter can be used as global design strategy guidelines and can also lead to products' certification. Therefore, based on C2C® certification criteria and considering the company's economic constraints, the C2C® approach can potentially lead decision makers to set both qualitative and quantitative benchmarks, such as restrictions on certain ingredients because of their toxicity, substitution of components or chemical compounds, redesign of the product assembly to improve product recyclability, development of end of life recovery chain, etc. A proposal on how LCA could bear C2C® shortages and vice versa is built from the identified limitations of both approaches. From a scientific point of view, the analysis and positioning of the two methodologies has proceeded thought the investigation of the different assessment directionalities (eco-efficiency vs. eco-effectiveness).

607

Is Carbon Footprinting an appropriate method to combine with Data Envelopment Analysis for environmental benchmarking? The CFP+DEA method

D. Iribarren, Instituto IMDEA Energía / Systems Analysis Unit; I. Vazquez-Rowe, CRP Henri Tudor / Department of Engineering

Life-cycle (LC) approaches are currently used to provide sustainability benchmarks through combination with Data Envelopment Analysis (DEA), a linear programming methodology that measures the relative efficiency of multiple homogeneous entities (named decision-making units, DMUs). These joint applications, named LC+DEA methods, have already been applied to several production sectors, mainly agriculture and fishing. In particular, environmental benchmarks are of special relevance in the energy sector, as it is a key source of environmental impacts worldwide, e.g. in terms of climate change. Hence, we argue that the combination of Carbon Footprinting (CFP) with DEA may be an appropriate approach to evaluate and benchmark the performance of energy entities. A five-stage method is proposed to jointly implement CFP and DEA with the aim of providing benchmarks that can be of relevance for policy making in the energy sector. The stages of the method include (i) data collection for energy and material flows of each DMU, (ii) carbon footprint computation for each individual entity, (iii) calculation of operational efficiency and target operating points through DEA, (iv) CFP re-evaluation of inefficient units, incorporating the operational benchmarks obtained in the previous stage, and (v) interpretation of the results to facilitate decision making at political and company levels. Advantages of the CFP+DEA method include the consistent and quantitative minimisation of resources to attain efficient operational levels, while providing a useful mechanism to quantify and report environmental targets for industries and governments according to eco-efficiency criteria. On the contrary, the method presents certain constraints, some of which are common to those discussed in the available literature regarding the two tools (i.e., CFP and DEA) independently. It should also be noted that economic aspects are not thoroughly addressed through this method. Overall, the CFP+DEA method is presented as a robust approach to aid policy makers in the energy sector to avoid future potential bottlenecks, by tackling directly the issue of mitigating greenhouse gas emissions. The method profits from the advantages of the two independent methods, while avoiding some of their constraints thanks to their integrative application.

Developments in Environmental Quality Standards: bridging the gap between science and practical regulatory implementation (II)

608

Criteria for Evaluating and Reporting Ecotoxicity data (CRED) – Report from a ring test

M. Agerstrand, Stockholm University / Department of applied environmental science; R. Kase, Swiss Centre for Applied Ecotoxicology EAWAG EPF; M. Korkaric, Eawag Swiss Federal Institute of Aquatic Science and Technology / Department of Environmental Toxicology; C. Moermond, RIVM / Centre for Safety of Substances and Products

This presentation reports from the CRED-project, short for Criteria for Evaluating and Reporting Ecotoxicity data, aiming at strengthening the transparency, efficiency and robustness of risk and hazard assessments. This has been done by increasing the usability of peer-reviewed ecotoxicity studies in regulatory risk assessment of chemicals by providing guidance on how to report and evaluate ecotoxicity studies. Within the CRED-project we have performed a two-phased ring test with over 80 risk assessors from Europe, Asia and North America, representing academia, regulatory agencies, consultant firms and industry. In phase I the risk assessors were asked to evaluate ecotoxicity studies according the Klimisch method. In phase II the risk assessors was asked to evaluate the same ecotoxicity studies but now according to the newly developed CRED-evaluation method. The consistency of the reliability evaluation increased when using the CRED-evaluating method and the risk assessors evaluated the method to be more accurate, applicable, consistent and transparent in comparison to the Klimisch method. The results from the comparison were used to improve the CRED-evaluating method and to develop the CRED-reporting recommendations. The CRED-evaluating method include a set of reliability criteria as well as a set of relevance criteria, since both being equally important in the evaluating process of ecotoxicity studies for regulatory use. Both sets are accompanied by extra guidance material which includes examples of how the specific criterion should be used. The CRED-reporting recommendations are a guideline for peer-review publication of ecotoxicity studies. The guide instructs researchers how to produce studies with high reliability and high reproducibility, and thereby increasing the likelihood for inclusion in regulatory environmental hazard and risk assessments of chemicals. Moreover, a stringent reporting of studies allows editors, reviewers and regulators to evaluate the available information in a more structured and transparent way.

609

Deriving Environmental Quality Standards (EQS) for fungicides: the lack of biotests for aquatic fungi adds to uncertainty in EQS derivation.

M. Junghans, Swiss Centre for Applied Ecotoxicology EAWAG EPF / Ecotox Centre; L.D. Ittner, Swiss Centre for Applied Ecotoxicology EawagEPFL; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology

Classical aquatic risk assessment is based on toxicity to organisms representing a simple food chain from primary producers (e.g. algae) via primary consumers (e.g. waterflea) and secondary consumers (fish) to end consumers (birds, mammals). However, in creeks and small rivers the main energy input from primary production is not derived from algae and aquatic plants but from allochthonous material (e.g. leafs) that has been processed by detrivores like aquatic fungi. Hence, fungi play an important role for the functioning of those ecosystems. However, toxicity tests with aquatic fungi are scarce at best and data are missing for the majority of fungicides. This poses a problem for the derivation of environmental quality standards (EQS) for fungicides. Toxicity data for fungi seem to be mandatory for lowering the standard assessment factor (AF) from 100 to 10 when deriving a MAC-EQS (the EQS for short-term exposure). The EU TGD for deriving EQS states: "For substances with a specific mode of action the most sensitive taxa can be predicted with confidence. Where representatives of the most sensitive taxa are present in the acute dataset, an AF < 100 may again be justified". Fungicides have a specific mode of action and are designed for controlling fungi, thus these organisms may well be the most sensitive group and the lack of toxicity data for fungi represents a significant uncertainty in EQS derivation. It is apparent that toxicity tests and data for aquatic fungi are needed for a meaningful risk assessment for fungicides. This information gap was recently acknowledged in the new aquatic guidance document under the authorisation of plant protection products published by EFSA in July 2013. For the development of new bioassays it is essential to know the biodiversity of aquatic fungi as well as their functions in aquatic ecosystems. A second important need is answering the question which level of protection should be achieved. If they are treated the same as the currently considered taxonomic groups, aquatic fungi should be protected at the level of their structure (biodiversity) and their ecological function (ecological processes). EFSA however, proposes to protect aquatic fungi solely based on their function in ecosystems. Here we present a review of available information on the function and ecology of aquatic fungi. Consequences of setting different protection goals for biotesting and hazard assessment will be illustrated.

610

Deriving a Water Quality Standard for Iron from Field Evidence

A. Peters, WCA Environment Ltd; B.J. Adams, Rio Tinto / Product Stewardship; P. Simpson, WCA Environment Ltd; P. Whitehouse, Environment Agency / Evidence

The derivation of a Environmental Quality Standard (EQS) for iron in UK freshwaters is complicated considerably by its behaviour in solution, which tends to result in precipitation. The use of total, rather than dissolved, iron as a measure of exposure concentrations in ecotoxicity tests provides a reasonable surrogate for the toxic component of solutions which have been aged for three hours. Laboratory studies in which adverse effects are observed due to precipitate formation may be of relevance to EQS derivation although they are not relevant for classification. Field data can be an important line of evidence in setting quality standards alongside conventional laboratory ecotoxicity data. Information from field monitoring is rarely used directly for EQS derivation, although it is used in some cases as supporting information, for example in the selection of the appropriate assessment factor used to derive the standard. There have been several analyses of field evidence aimed at deriving an ecologically acceptable concentration of iron reported in the literature, although these studies have not taken account of the effect of water chemistry on the ecotoxicity of iron. Recent studies on the ecotoxicity of iron to fish, invertebrates and algae have shown a clear effect of water chemistry on iron toxicity. As such, water chemistry should ideally be taken into account when establishing quality standards for iron. This study aims to take account of water chemistry conditions on the ecotoxicity of iron in assessing whether or not impacts are observed on ecological communities in real field conditions. Previous analyses of the effects of iron on aquatic communities have not taken account of the effect of water chemistry on the ecotoxicity of iron. Various sources of information indicate that some invertebrate families are amongst the most sensitive aquatic organisms to iron toxicity. The derivation of an EQS for iron in UK freshwaters follows a weight of evidence approach, and incorporates several distinct lines of evidence to draw conclusions about an ecologically acceptable level of iron exposure.

611

The minimal model community as a comprehensive ecological risk assessment framework

Y. Tanaka, National Institute for Environmental Studies / Research Center of Environmental Risk

There is a gap between the ecological modelling for risk assessment of chemicals and the risk assessment framework demanded for regulation as regards precision and ecological relevance of estimation, the quality and quantity of required data, and the generality of application. Most ecological models used in ecotoxicology need acute or chronic toxicity data for various endpoints and organisms. On the other hand, the testing framework at the screening level produces toxicity data from very limited test organisms (e.g. algae, daphnia and fish), and the conventional method of ecological risk assessment, e.g., the hazard quotient method, does not include any ecological factors (e.g. life history of species, interspecific interaction) which potentially affect the interpretation for the derived ecotoxicity data. Here I present a simple aquatic ecosystem model (Tri-trophic Ecological Risk Assessment Model: TERAM), which, consisting of three trophic levels, can interpret the ecological significance and evaluate ecological risks based on the restricted ecotoxicity data. The presented model includes essential ecological factors (interspecific interaction, age-and-stage structure, size dynamics, and life history scenario of growth and reproduction) and toxicokinetics-toxicodynamics elements, whereas it can work with the minimual three-species screening-level ecotoxicity data (the fish acute mortality, the daphnia immobility, and the algal growth inhibition). The benchmark of ecological risk in the presented method is the annual population growth rate of the top predator (the fish), which summarizes the direct effect to the fish population and the indirect effect through interspecific interaction. As case studies I conducted the community-level simulations for 4 agrochemicals (fenitrothion, pyridaphenthion, pretilachlor, butachlor), using ecotoxicity data from AQUIRE (US EPA). The stochastic simulations based on uncertainties of toxicity data and acute-chronic extrapolations revealed the risk induced by such uncertainties. TERAM was able to estimate ecological risks of chemicals that had contrasting toxicities between the different trophic levels (e.g. daphnia and algae) by a common standard (the population growth rate of the top predator), because TERAM took into account the indirect effect of toxicants which directly affected the lower trophic levels by converting the indirect effect through interspecific interaction into the population-level effect at the top predator.

612

Closing the gap between setting standards and taking regulatory decisions

T. Warn; P. Whitehouse, Environment Agency / Evidence

This paper builds on experience in using standards to take decisions. Such actions have involved costs of tens of billions of Euros. Some work on devising standards pays little attention to the processes and discipline by which standards must be used to decide action. This can lead to targets that are ineffective or too complicated, and this can promote bad decisions. Work on a new standard may yield a concentration that is declared "safe". If this is to be used as a serious standard, it needs to be coupled with a clear statement on how often the concentration can be exceeded. It should be the job of the creator of the standard to provide this. It this is not done, the responsibility is shunted on to the users of the standard.\n Standards should reflect the discplines that will apply to how they are to be used. A serious standard cannot be an absolute limit; it must be something like an annual mean or an annual percentile. This allows an unbiased estimate of compliance and classification, a correct process for deciding controls on potential polluters, and a capacity to know the true statistical uncertainties in all of these processes. A review of such calculations should be part of the process by which a new standard is devised. This will advise the extent to which it is worth going into details of chemistry or toxicology, and will help ensure that a new standard does its job.

Molluscs, though the second largest clade next to the arthropods, have widely been neglected in environmental risk assessment schemes for chemicals, mainly due to the lack of standardised and broadly accepted test guidelines for molluscs. However, they are known to be uniquely sensitive to a number of endocrine disrupting chemicals (EDCs, e.g. organotins) and other substances (e.g. copper). Therefore the German Federal Environment Agency and the Department for Environment, Food and Rural Affairs of the United Kingdom supported the preparation of a *Detailed Review Paper* (DRP) *on Molluscs Life-cycle Toxicity Testing*[11].The DRP proposed *inter alia* the parthenogenetic mud snail *Potamopyrgus antipodarum* as standard test organism. In the *P. antipodarum* reproduction test the number of embryos in the brood pouch, reflecting the individual reproduction effort in snails, and adult mortality serve as main endpoints. The present study aims to develop and validate the partial life-cycle test on the reproduction of *P. antipodarum*. Here, results from two pre-validation studies of the reproduction test with the chemicals tributyltin (TBT) with nominal concentrations of 10 - 400 ng TBT-Sn/L and cadmium with concentrations of 3.13 - 25 μg/L at eleven laboratories are presented. The mean embryo number in snails exposed to TBT decreased with increasing concentrations. First results show comparable NOEC (65 to 160 ng TBT-Sn/L) and LOEC (160 to 400 ng TBT-Sn/L) values for TBT. The EC_{10} was between 109 (95%-CI: 44.6 - 268) and 132 ng TBT-Sn/L (95%-CI: 58.8 - 329) indicating a good inter-laboratory reproducibility with a coefficient of variation between 8.4% (EC_{10}) and 35.3% (LOEC). The good reproducibility is also reflected in the reproduction test with cadmium. EC_{50}-values varied between 5.55 (95%-CI: 3.14 - 8.35) and 19.9 μg/L (95%-CI: 16.4 - 24.0) with a coefficient of variation of 35.1%. The effect concentrations for TBT and cadmium are in good accordance with already published data. Both pre-validation studies show that the reproduction test with *P. antipodarum* is a well suited tool to assess effects of EDCs and other chemicals. [1] OECD. 2010. Chronic exposure to two components of tritanTM copolyester on Daphnia magna and Moina macrocopa

S. Jang, Dept Occupational and Environmental Health; B. Kwon, Dept Occupational and Environmental Health / Department of Occupational and Evironmental Health; K. Ji, Seoul National University

Tritan^{TM} copolyester, a novel plastic form manufactured by Eastman company, has been widely applied for packaging of beverages and food contact films as an alternative of bisphenol A. However, very limited information has been reported on the toxicity of tritan^{TM} copolyester among aquatic organisms. We investigated chronic toxicities of terephthalic acid (TPA) and 1,4-cyclohexanedimethanol (CHDM), two important co-monomers of tritan^{TM}, using freshwater crustacean including *Daphnia magna* and *Moina macrocopa*. Ten replicates with one neonate each were exposed to various concentrations of TPA (control, 0.1, 0.3, 1.1, 3.3, 10 mg/L) and CHDM (control, 1.2, 3.7, 11, 33, 100 mg/L). After 21 d of chronic exposure, the number of young per female and the number of young per brood of *D. magna* were significantly reduced as increased TPA concentrations. The number of young per female in *D. magna* exhibited slight decrease after exposure to CHDM.

In *M. macrocopa*, no significant change of survival and reproduction endpoints was observed by TPA and CHDM exposure. Since concentrations of TPA and CHDM that have been reported to occur in ambient waters are much less than the thresholds for effects on the endpoints studied here, direct impact due to tritan^{TM} exposure is not expected in ambient water. However, given the importance of reproduction, the consequences of endocrine disruption at environmentally relevant concentrations deserved further investigation.

616
Effects of benzophenone-3 exposure on endocrine disruption and reproduction in Japanese medaka (Oryzias latipes)
S. Kim, K. Choi, Seoul National University / School of Public Health
Benzophenone-3 (BP-3) has been widely used in sunscreens and other cosmetic products to protect human skin and materials from the harmful effects of UV irradiation. While BP-3 has been frequently detected in surface waters, sediments and biota, only limited information is available on its *in vivo* toxicity, particularly on fish. In the present study the endocrine disrupting potentials of BP-3 and its underlying mechanisms were investigated. Adult Japanese medaka pairs (F0) were exposed to 4.7, 8.4, 26, or 90 μg/L of BP-3 for 28 days. Effects on reproduction, sex steroid hormones, and transcription of various associated genes were determined. Additionally, the adverse effects on F1 fish were further examined with subsequent exposure to 5.4, 12, or 30 μg/L of BP-3 for 30 d exposure after hatching. Chemical analysis of water confirmed transformation of BP-3 to BP-1, more potent estrogen agonist. After 14 days, plasma concentrations of testosterone (T) were significantly decreased in male fish. The 17β-estradiol (E2) to T ratio (E2/T) showed significant decreasing trends in both males and females. Overall down-regulation of steroidogenic genes in gonads such as *star*, *cyp11a*, *cyp17*, *hsd3b*, *hsd17b3*, and *cyp19a* was also observed. In the liver of the male fish, vitellogenin induction was significant following exposure to 90 μg/L of BP-3 at both transcriptional and protein level. After 28 days of exposure, the daily number of eggs produced per female was significantly reduced at 26 μg/L of BP-3. However, continuous BP-3 exposure of F1 eggs did not affect the hatchability. This study clearly showed that low level of BP-3 could alter endocrine balance or affect reproduction performance. Effects of longer term exposure of F1 fish warrant further studies.

617
Development of in-vitro tests for the assessment of reprotoxicity in fish
D. Fernandes; C. Porte, CSIC IIQAB / Environmental Chemistry
There is now clear evidence that numerous xenobiotic compounds act as endocrine disrupters (EDs) in fish by affecting reproductive functions. Some of these compounds exert their action by binding to steroid receptors, and several well established in-vitro methods can assess this mode of action. However, few methods are available to detect non-genomic mechanisms of action. The developed in-vitro tests targeted specific enzymatic pathways that play a key physiological role in fish reproduction; such are testicular synthesis of oxyandrogens, ovarian synthesis of estradiol and maturation inducing hormones, and phase II metabolism of active steroids. This work proposes the use of gonad –different stages of sexual maturation- and liver subcellular fractions from different fish species, viz. carp –*Cyprinus carpio*– and sea bass –*Dicentrarchus labrax*– to carry out a first screening of compounds that act as EDs by inhibiting the synthesis and metabolism of active androgens and estrogens. A wide range of environmental pollutants, including pharmaceuticals, synthetic musks, organotin compounds, alkylphenols and polycyclic aromatic hydrocarbons (PAHs) have been investigated. Among the tested xenobiotics, the synthetic progestagens, drospirenone and norethindrone, had the strongest inhibitory effect on the synthesis of oxyandrogens (IC50s: 0.4-3.8 µM for CYP17 and CYP11b) followed by the PAH metabolite, 9-hydroxyphenanthrene (IC50s: 10-31 µM), nonylphenol, the polycyclic musks, galaxolide and tonalide, and the pharmaceuticals, fluvoxamine and fluoxetine. Interestingly, 9-hydroxyphenanthrene also inhibited ovarian P450 aromatase (CYP19) activity (IC50: 4.3 µM). Triphenyltin, tributyltin and nonylphenol inhibited the sulfation of estradiol (IC50s: 17, 18 and 41 µM) and the glucuronidation of testosterone and estradiol. The use of gonad subcellular fractions allow the detection of selected chemicals that by interfering with key enzymatic pathways might finally affect physiological processes, such as gamete growth and maturation in fish. These assays can be used to assess the effect of mixtures of individual compounds and environmental samples, and they may become useful tools for a more rational design of chemicals with reduced aquatic reprotoxicity.

618
A calibrated ecosystem model to assess the ecotoxicological risk of endocrine disrupters in aquatic environments
L. Clouzot, Universite Laval / Département de génie civil et de génie des eaux; M. Paterson, Fisheries and Oceans Canada; A. Dupuis, Department of Fisheries & Oceans-Canada; P. Blanchfield, M. Rennie, Fisheries and Oceans Canada; K.A. Kidd, University of New Brunswick; P.A. Vanrolleghem, modelEAU Université Laval / Département de génie civil et de génie des eaux
Ecological risk assessment of chemicals entering aquatic environments primarily focuses on impacts to individual organisms, although the overarching goal of risk assessment is the protection of ecosystem services. Experimental approaches to characterize the ecological impact of chemicals are costly and time-consuming and thus, the consequences on whole ecosystems remain unclear. This is especially true for endocrine disrupters released to natural waterways through the effluent of wastewater treatment plants (WWTPs). This study takes up the challenge to develop an ecosystem model that can predict the effects of endocrine disrupters discharged in WWTP effluents on aquatic populations, as well as ecosystem responses occurring through ecological interactions. The data used to develop and calibrate the model come from a multi-year whole-ecosystem study performed at the Experimental Lakes Area (ON, Canada) where the synthetic hormone 17α-ethinylestradiol (EE2), a potent endocrine disrupter, was added to an experimental lake for 3 years at environmentally relevant concentrations. Physico-chemical and biological data were collected before, during and after EE2 additions. Endocrine disruption was observed in all fish species, including the collapse of fathead minnowafter the second year of EE2 additions. The ecosystem model that was developed and calibrated is an object-oriented model based on simplified AQUATOX equations for the species naturally present in the experimental lake (benthic invertebrates, phyto- and zooplankton, fish). For each fish species considered, two classes are used in the model: juveniles and adults. The model has been successfully calibrated with the experimental data obtained before EE2 addition and a sensitivity analysis revealed great consistency between the simulation results and current knowledge on such ecosystems. The developed model can simulate endocrine disruption based on (i) a decrease of gamete viability, (ii) a decrease of gamete production or (iii) an increase of fish mortality. The model results show that an increase in adult mortality of fathead minnows affected its population dynamics but also populations of other fish species. In addition, changes in direct and indirect competitive interactions can be an important ecosystem-level effect of endocrine disrupters and compensatory mechanisms are important in food-webs. The model is being used to understand and predict the risk associated with endocrine disrupters.

Assessment of endocrine disruption in Australian rivers using chemical, in vitro, in vivo and in situ techniques
P.D. Scott, Griffith University / School of Environment and Smart Water Research Centre; M.E. Bartkow, Seqwater; S.J. Blockwell, Northern Ireland Water / Asset Management; H.M. Coleman, S. Khan, University of New South Wales / School of Civil and Environmental Engineering; R.P. Lim, University of Technology Sydney / School of Environment; J.A. McDonald, University of New South Wales / School of Civil and Environmental Engineering; H. Nice, Department of Water Government of Western Australia; D. Nugegoda, RMIT University / School of Applied Sciences; V.J. Pettigrove, The University of Melbourne / Zoology; L.A. Tremblay, Cawthron Institute; M.S. Warne, DSITIA; F.D. Leusch, Griffith University Smart Water Research Centre / School of Environment and Smart Water Research Centre
This study used an integrated approach combining chemical analysis of endocrine disrupting compounds (EDCs) and trace organic contaminants (TrOCs), multiple *in vitro* and *in vivo* bioassays, and *in situ* sampling to determine the level of endocrine activity in Australian rivers. A monitoring stage spanning 1-year, 73 sites and 285 water samples from various land-use scenarios (wastewater, industrial, residential, agricultural and undeveloped) provided data on the prevalence and concentrations of 57 unique chemicals. The endocrine disrupting potential was also quantified by utilizing 3 reproductive endpoints using the estrogen receptor (ER-), androgen receptor (AR-), and progesterone receptor (PR-) CALUX assays. Estrogenic activity was the main activity detected by *in vitro* assays, and was measurable in 19% of samples (>0.1 ng/L 17β-estradiol equivalents, EEQ). In many cases low concentrations of the synthetic estrogenic ethinylestradiol was a significant contributor to the estrogenic activity. *In vivo* lab experiments were then carried out using a native species (rainbowfish; *Melanotaenia fluviatilis*) and a prevalent exotic species (mosquitofish; *Gambusia holbrooki*) exposed to pure compounds (atrazine, bisphenol A, ethinylestradiol, estrone, propylparaban, pyrimethanil) at 10x environmental concentration as well as different mixtures (hormones and personal care products, industrial compounds, pesticides) at environmental concentrations. Vitellogenin protein and mRNA were quantified to measure the estrogenic response of exposed fish. Only the high concentration of estrone (750 ng/L) induced a significant increase in vitellogenin protein and mRNA expression. Exposure data generated using chemical and *in vitro* results along with effects data from the *in vivo* experiments were combined to generate a simple risk assessment. Mosquitofish were then sampled at 4 hot-spot locations and 2 undeveloped (reference) sites, as predicted by the risk assessment. Analysis of physiological and gonopodium morphology, histology, vitellogenin protein and body burden of priority chemicals are currently underway. This is the most comprehensive Australian study on endocrine disruption to date.

Sustainability of Swiss Chocolate Production

Ecosystem services, payment for ecosystem services, biodiversity: Securing future supplies and preserving biodiversity by paying cocoa farmers for Ecosystem Services
A. Felperlaan , CREM
Cocoa farmers that grow cocoa under the shade of indigenous trees, can make an important contribution to the preservation of biodiversity. This is optimal with a shade cover between 40% and 60%, thereby maintaining both biodiversity and decent production levels. In order to maintain this optimum, farmers must be trained in *best agroforestry practices* such as pruning, planting and soil fertility management. In addition to biodiversity conservation, ecosystem services (ES) from cocoa agroforestry include provision of a buffer for – or corridor between – nature reserves, natural control of pests, carbon storage and sequestration, food security and income diversification, water quality and quantity, and soil protection and soil quality. Some of these services are of direct local or regional benefit (improved soil fertility, clean and sufficient drinking water), others are more of global interest (biodiversity conservation and carbon sequestration). Up to now, cocoa farmers are not rewarded for their ES. This is a missed opportunity. Financial compensation for their services could possibly guarantee a better supply of cocoa and at the same time contribute to preserving biodiversity. One way of rewarding cocoa farmers for their delivered services could be to integrate Payments for Ecosystem Services (PES) as an optional (add-on) or independent module into existing certification schemes, the advantage being that it can benefit from existing infrastructures and a wide support from the supply chain. Alternatively, tradable 'biodiversity' credits could be developed (similar to carbon credits), however, this is very costly and time-consuming. Thirdly, a fund could be created for financing biodiversity friendly projects. Advantages of a fund include a more secure base for funding (also others than supply chain actors can donate) and the fact that it is inclusive to all farmers: it is open to certified and non-certified farmers as well as farmers that currently produce other crops. An important bottleneck of PES is to find buyers that are willing to pay for ES. In contrast to, for example, local drinking water companies that have a direct economic interest in clean and sufficient ground and surface water, external parties generally have no or little direct interest in ES. The value of ES can then be related to an improved corporate image or be part of the overall CSR strategy (for example, stop deforestation, increase productivity, improve farmer's income and preserve biodiversity).

622
Overview of scientific evidence for chocolate health benefits
J. Van Wensem, TCB
The potential health benefits of consuming chocolate have only recently been discovered. Laboratory studies and observational and small scale experimental studies on humans have found that chocolate consumption not only lowers blood pressure, but that it may also have positive effects on serum cholesterol, platelet activity, endothelial function, and glucose tolerance. There are several bioactive compounds in chocolate that may promote alertness. Chocolate may affect stress levels by prompting serotonin production, which is a calming neurotransmitter. The number of publications concerning cocoa and chocolate is increasing steadily. More than 1,300 publications regarding "cocoa" or "chocolate" have been added to the PubMed database between 2005-2010; this was an increase of about 60% on the previous 5 years. Of such publications, an increasing proportion concerns the effects of polyphenols and, in particular, flavonoids on human biology and health. The biological mechanisms of flavonoids are still unknown. They have been related to, among other things, their antioxidant properties and to the fact that they increase the bioavailability of nitric oxide, which has vasodilatory and other beneficial effects on the cardiovascular system, but no scientific consensus exists. Studies that link chocolate consumption with health outcomes (instead of intermediate outcomes like blood pressure) are less common. There appears to be some scientific evidence to justify eating a moderate amount (approximately 2 oz) of dark chocolate daily.

Ecological risk assessment of agro-pesticides used in the Nha Trang area, Vietnam using the PRIMET model
J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; H. Tran Thi Minh, Institute of Oceanography Nha Trang; V. Le, Stockholm University / Ecology Environment and Plant Sciences; M. Olstedt, Department of Ecology Envionment and Plant Sciences DEEP; H. Le Van Lan, Institute of Oceanography Nha Trang; C. Amid, DEEP; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra; M. Tedengren, Department of Ecology Envionment and Plant Sciences DEEP
Vietnam with a population of 80 million is highly dependent on its agriculture and on its coastal marine resources. The country has seen a steadily increase of agro-chemicals to enhance the production of rice and other crops. Pesticide use has reached over 40 000 tons per year and is rapidly increasing. Only little research has been done to assess the risks that these pesticide pose to the Vietnamese people and to their environment. In this study pesticide data was gathered from 2007-2012 in the villages of Vinh Phuong, Vinh Ngok, Vin Than in the watershed of the Cai River, Nha Trang, Vietnam. Total surface area of the fields, pesticides in rice, vegetables, coffee and cashew and their application patterns were gathered along with hydrological data of water streams that drain the fields into the Cai River. Predicted environmental concentrations (PECs) of the pesticides and their risk to aquatic organisms was then calculated using the 1st Tier Ecological Risk Assessment PRIMET (a Decision Support System for assessing Pesticide RIsks in the tropics to Man, Environment and Trade). The PRIMET model is designed to yield a relatively worst-case risk assessment with interviewed data supplied from local farmers, pesticide characteristics, application scheme and physical senario of the assessed environment. PRIMET generated risk values, i.e Exposure Toxicity Ratio's (ETRs), the quotient between the environmental concentration (PEC) and the estimated safe concentration (PNEC) were calculated for all the pesticides in use and ecological risks were compared between crops and villages. Results are discussed in relation to ecological risks from pesticide applications to aquatic organisms of the local streams and the Cai River.

MO002
EVALUATION OF TOXIC AND GENOTOXIC EFFECTS IN SEDIMENTS OF COASTAL SYSTEMS LOCATED IN THE GULF OF MEXICO
A.S. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; A. Vazquez Botello, G. Ponce Velez, S. Villanueva Fragozo, Lab Contaminacion Marina ICMyL UNAM
In our country studies on the occurrence and effect of pollutants in aquatic systems are scarce, despite the fact that the degree of pollution has increased on par with the development of human settlements and tourism, industrial, agricultural and oil activities. The aim of this study was to detect the presence of compounds with toxic and genotoxic effects in sediments of 5 coastal lagoons located in the Gulf of Mexico: 4 in Veracruz State (Pueblo Viejo, Tamiahua, Tampamachoco, Mandinga y Alvarado) and 1 in Tabasco State (El Yucateco) in order to delimit potential areas of risk and evaluate the effects of contaminants in species of economic importance. (*Crassostrea virginica y Mugil cephalus*). For the evaluation of the sediment toxicity, bioassays were performed with *Artemia franciscana* nauplii and for the detection of genotoxicity Chromotest microassay was applied and the degree of DNA damage in tissue samples *de A. franciscana, C. virginica,* and blood samples of *M. Cephalus,* was determined by the technique of single-cell electrophoresis (Comet Assay). The results show clear differences ($p < 0.01$) in the degree of deleterious effect on the DNA in the cells of organisms from each lagoon system, and the seasons examined. In the lagoons in the Gulf of Mexico, the degree of genetic damage was (High to low damage): El Yucateco >Tampamachoco > Mandinga > Alvarado > Pueblo Viejo > Tamiahua, being the rainy season where most deleterious effect was detected. The above results are consistent with pollutants levels recorded in the collecting sites. Also, with tests to assess the toxic and genotoxic effect of sediments have been detected potential risk areas in three locations in Pueblo Viejo Lagoon (mono verde, Barranco amarillo y Tamacuil), 3 in Tamiahua (La Loza, Cucharas y B. Corazones), 3 in Mandinga (Laguna Redonda, B. Kokina y B. Salazar), 4 in Yucateco lagoon (río Chicozapote, Boca río Zapote, Boca laguna y La Cuchupeta). In these places the implementation of activities such as cultivation of organisms, fishing or recreation may pose a risk to human health.

MO003
EVALUATION OF THE EFFECTS OF DETERGENT IN Lemna gibba L. Y Egeria densa Planch. MACROPHYTES
A.S. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; J. Morales Torres, Universidad Autonoma Metropolitana Iztapalapa / Ciencias de la Salud Lab Nutricion vegetal
Synthetic detergents are compounds used in large quantities in industrial and domestic activities. its formula is secret but generally contain surfactants (LAS, ABS) and additives that constitute persistent pollutants and are toxic to aquatic organisms. Because in our country there are few studies with detergents, and wastewater from Mexico city have a considerable contribution of these compounds, in this study an evaluation of the effects of detergents on biomass production, concentration chlorophyll, carotenoid production, levels of phenols and lipid peroxidation was performed in aquatic macrophytes: *Lemna gibba* and *Egeria densa*. Bioassays were carried out for 10 days in which the macrophytes were exposed to five concentrations of the surfactants, LAS and Triton X and 5 trademarks (Ariel, Ace, Foca, Rome and Salvo). In the results obtained significant differences between the responses of the control group and exposed to detergents were observed. The most toxic surfactant were: LAS and detergents containing enzymes (Salvo). A decrease in biomass and the level of chlorophyll and an increase in concentration of carotenoids, phenols and the degree of lipid peroxidation in all cases was observed. Because Mexico only 14% of the wastewater generated receive some type of treatment, it is important to conduct evaluations of sublethal effects of detergents in order to propose appropriate management measures to reduce the risk for the presence of these compounds in aquatic systems.

MO004
EVALUATING THE RESPONSE OF MICROALGAE Monoraphidium SP (CHLOROPHYTA) TO DETERGENTS
A.S. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia Laboratorio Alejandro Villalobos; J. Morales Torres, Universidad Autonoma Metropolitana Iztapalapa / Ciencias de la Salud Lab Nutricion vegetal
The detergents are synthetic products used in large quantities for domestic and industrial cleaning, these compounds are formed by a surfactant and additives such as water softeners, preservatives, pigments, enzymes, foam stabilizers, dyes and perfumes. Since the studies performed to evaluate the effect of these compounds on aquatic organisms are scarce, the aim of this study was to determine the toxic effects of three surfactants LAS (lauryl alkyl sulphonate), lauryl dimethil (hidroxyetil) ammonium chloride and Triton X in the microalgae *Monoraphidium* sp. Bioassays were carried out with duration of 72 hours to assess the toxicity of detergents, determining the EC_{50} (effective concentration 50) which is the concentration that inhibits population growth by 50%, lipoperoxidation and pigments production. The results obtained a significant differences between the responses of the control group and algae exposed to detergents was observed. The toxicity of surfactants based in the calculated EC_{50} was (from greatest to least toxicity): Lauryl dimethil> LAS> Triton X. The decrease in chlorophyll levels was of 68%, 33% and 20% in the test with Hidroxyetil, LAS and Triton X, respectively was observed. The surfactant with greater oxidative effect was LAS. Because in Mexico only in 14% of the wastewater generated receive any treatment is important to continue conducting assessments of sublethal effects of detergents in order to propose appropriate management measures to reduce the risk by the presence of these compounds in aquatic systems

MO005
Assessing the ecological impact of banana farms on water quality using aquatic macroinvertebrate community composition
O. Svensson, A. Sanderson Bellamy, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra; M. Tedengren, Department of Ecology Envionment and Plant Sciences DEEP; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP
In Costa Rica considerable effort goes to conservation and protection of biodiversity, while at the same time agricultural pesticide use is among the highest in the world. Several protected areas, some being wetlands or marine reserves, are situated downstream agricultural areas where large-scale banana farms constitute a major land use, with an average of 57 pesticide applications per year. The banana industry is increasingly aware of the need to reduce their negative environmental impact, but few ecological field studies have been made to evaluate the efficiency of proposed mitigation strategies. This study evaluated if benthic macroinvertebrate community structure is sensitive enough to detect environmental impact of banana farming, and thereby usable to assess improvements in management practices. Aquatic invertebrate samples were collected at 13 sites between March and April 2007, using kick-net sampling. Samples were taken both up- and downstream banana farms in fast flowing streams, with mostly cobbles for substrate in runs and riffles. The changes in community composition were visualized and tested on significance at the family level using ordination methods. Additionally, the

Biological Monitoring Working Party (BMWP) score system was applied along with a number of community composition descriptors. In total, 2890 specimens were collected, belonging to 14 orders and 49 families or taxa. The results indicates that surface waters immediately up- and downstream large-scale banana farms have different macroinvertebrate community compositions, with fewer sensitive taxa according to the BMWP-score values at the downstream sites. Rapid assessment using macroinvertebrate community composition thus appears to be a possible means to detect negative impact from chemical-intense agriculture. As the method is moderately time-consuming, low-cost and highly ecologically relevant it could become a useful complement to chemical analysis of pesticide residues in environmental risk assessment.

MO006
The application of the SPEARpesticides bioindicator in South Africa
W. Malherbe, North West University / Zoology Department
Chemical monitoring within aquatic ecosystems is often insufficient to determine quality as it does not take into account higher level effects on biota, instream speciation of chemicals, interactions with other physical impacts and variations due to longitude and time. To overcome this, instream biota are used as environmental indicators as they can integrate all of these higher level effects. However, many indices of biotic integrity are not sensitive enough to isolate community effects due to pesticide exposure as the communities also respond to other anthropogenic and natural stressors. A bioindicator system making use of macro-invertebrate traits, that is pesticide specific was therefore developed in Europe to overcome some of these challenges. The system, called SPEAR (SPEcies At Risk), has been applied as an indicator to link pesticide exposure and effects to insecticide toxicity. The aim was to apply the SPEAR system in South Africa to determine its applicability and effectiveness at linking pesticide exposure to changes in the macro-invertebrate community. For the purposes of this initial study, it was decided to use both the European and Australian $SPEAR_{pesticides}$ databases to determine if there are any differences between the results. This would in turn help to determine which database would be better suited for application within South Africa. The SPEAR systems indicated differing results when using the European and Australian databases with the Australian database indicating poorer ecological condition. These differences can possibly be attributed to the differing sensitivities between the two continents as studies have shown that there are differences between the sensitivities of tropical and temperate biota. The results indicated that all of the sites have either been exposed or not been exposed to pesticides; or that there was some interaction with other factors i.e. nutrients or salinity. It may also be that the Australian and European databases are not representative of the macro-invertebrate sensitivities to pesticides in this particular region. Further studies in different regions with more data points are needed to determine whether the SPEAR system is effective in South Africa.

MO007
Impact of the pesticide Vertimec® 18 EC on tropical freshwater plankton communities
J. Resende, Department of Hydraulic and Sanitary Engineering; A. Vasconcelos, M. Pereira, University of São Paulo; E.G. Espindola, University / Hydraulics and Sanitation
In recent years pesticides have been detected in many tropical freshwater ecosystems. However, little research has been done regarding their effects in surface water in tropical regions. In order to evaluate the effects of insecticide Vertimec® 18 EC over the tropical freshwater plankton communities we performed an outdoor mesocosm experiment with the presence of tadpoles species *Lithobates catesbeianus* (bullfrog). Six treatments were analyzed: two cases of no contamination (control and control + tadpoles) and two cases of pesticide contamination considered both with absence and presence of tadpoles: 0.002 $mL.L^{-1}$ (the concentration expected to reach the water body after application of the pesticide) and 0.008 $mL.L^{-1}$ (the LC_{50} for tadpoles of bullfrogs). Phytoplankton and zooplankton community and some environmental variables (pH, conductivity, dissolved oxygen, temperature, turbidity, chlorophyll *a* and nutrients) were monitored during 20 days. It was observed a total of 33 zooplankton species distributed between Rotifera (21), Cladocera (8) and Copepoda (4). Regarding phytoplankton, a total number of 94 taxa were identified. Chlorophyceae was the most diverse algae class with 43 taxa, followed by Cyanophyceae (18), Euglenophyceae (10), Bacillariophyceae (8), Zygnemaphyceae (6), Chlamydophyceae (4), Cryptophyceae (4) and Chrysophyceae (1). Treatments with the presence of the pesticide led to the mortality of all species of cladocerans and copepods. As an indirect effect of these and of the increase of nutrients, the density of phytoplankton tended to increase (decreased chlorophytes, whereas cyanophytes, cryptophytes and euglenophytes increased in abundance). In the treatment with 0.008 $mL.L^{-1}$ of the pesticide, all the tadpoles died 24 hours after the beginning of the experiment, suggesting that Vertimec® may be more harmful to tadpoles in natural conditions. As a result of the death of the tadpoles, the cladocerans and the copepods, there was an even more significant increase in the phytoplankton and rotiferans density. Therefore, due to the toxic mode of action of insecticides, cladocerans and copepods were more sensitive to Vertimec. Furthermore, indirect effects also occurred to phytoplankton and to rotifers. These results highlight the importance of experiments in semi-natural systems for assessing the direct and indirect effects of contaminants on water ecosystems.

MO008
Macromelanophage Centers (MMCs) and PAHs in Ariopsis felis from the southern Gulf of Mexico
N. Ramirez, Marine Resources; L. Aguirre-Macedo, Cinvestav Merida / Marine Resources; G. Gold-Bouchot, Cinvestav Unidad Merida / Marine Resources
Five individual fish (*Ariopsis felis*) were collected in each of 16 sampling stations in the southern Gulf of Mexico, on the coast of the Mexican states of Tabasco and Veracruz in June, 2011. Fish were dissected, livers and bile extracted, and frozen in liquid nitrogen until analysis. A portion of the liver, the kidney and spleen were preserved for histology. Macromelanophage centers (MMCs) in liver, kidney and spleen were assessed by number and area. 10 sections of each organ and fish were analyzed microscopically using image analysis software (ImageJ). Fluorescent aromatic compounds (FACs) were measured in bile by fixed-wavelength fluorescence, and the concentrations of hydrocarbons (Total PAHs, low molecular weight [LMW-PAHs] and high molecular weight [HMW-PAHs] PAHs) were measured in liver by gas chromatography. Prevalence of MMCs was higher in the spleen (70% of all fish), then in the liver (42.5%), and the lowest in the kidney (16%). Total PAHs in the liver were in the range from 324.3 to 4,980.8 µg/g; Low molecular weight PAHs were in the range from 236.1 to 1632.8 µg/g, and high molecular weight PAHs in the range 68.8 to 4422.0 µg/g. In the case of fluorescent aromatic compounds, the concentration ranges were, for Benzo(a)Pyrene from 0.07 to 0.47 µg/mL; Pyrene was found from 0.13 to 0.66 µg/mL; Nafthalene from 13.2 to 53.6 µg/mL, and Fenanthrene from 16.1 to 95.4 µg/mL. The concentrations of low molecular PAHs in the liver, and the metabolites of PAHs in bile (FACs) were higher than those of high molecular weigth., indicating a petroleum source for this hydrocarbons. This is confirmed by the higher concentrations of methyl-naphthalenes compared to naphthalene. There was no relation between MMCs and PAHs, but there is a relation with some organochlorine pesticides. The concentrations of PAHs in the liver, PAHs metabolites and MMCs were higher in the catfish in this work, than the fish from the same species in the oil producing zone in the southern Gulf of Mexico. This work gives useful information to understand biomarker responses in relation to pollutant concentrations for these two species in the Gulf of Mexico, and their use in environmental monitoring and assessment.

MO009
Pesticide contamination of surface water in Guadeloupe and Martinique (French West Indies): co-occurrence of compounds related to past and current agricultural uses
F. Caupos, Agence Caraïbes; F. Rateau, G. Hielard, S. Kanor, P. Loricourt, Office de lEau; C. Verges, ASCONIT Consultants; L.L. Lagadic, INRA / UMR INRAAgrocampus Ouest Ecology and Ecosystem Health
In the French Lesser Antilles (Guadeloupe and Martinique), in application of the Water Framework Directive, local water agencies have implemented chemical monitoring in a large number of rivers. A total of 25 and 28 sites in Guadeloupe and Martinique, respectively, are sampled every month in order to follow water concentration of more than 40 molecules identified as "priority substances"; "priority hazardous substances" and "hazardous substances". Both historical and insular tropical contexts confer to Guadeloupe and Martiniquespecificities in regard to the nature of the pollutants that are found in freshwaters. In the past, many organochlorines, in particular chlordecone and technical HCH, were used in bananas' plantations. Nowadays, pesticides, such as glyphosate, AMPA and asulam, used as herbicides, and azoxystrobin, imazalil or thiabendazol, used as fungicides, can be found in freshwaters of Martinique and Guadeloupe. The aim of this study was to assess water chemical quality in these two islands considering both the European Regulatory requirements and local specificities in terms of pesticide uses. Data collected from 2008-2012 and 2009-2011 inMartinique and Guadeloupe, respectively, were provided by the local water agencies. Annual average concentrations of pollutants most commonly found in freshwater were calculated and analyzed using Principal Component Analysis. The results showed that organochlorines are the most frequently detected pesticides in surface waters of Martinique and Guadeloupe. These compounds were found mainly in rivers of the North Atlantic Coast of Martinique and the South of Basse-Terre in Guadeloupe. In these areas, chlordecone was found at the highest concentrations (*e.g.* 2.73 µg/L in theRougeRiver, Martinique in 2011; 2.9 µg/L downstream of theGrandeAnseRiver inGuadeloupe in 2010). In the same areas, high concentrations in fungicides were found in some sites (e.g. 1.72 µg/L thiabendazole in The Pocquet River,Martinique, in 2012). Moreover, in the central and southern parts ofMartinique, multi-contamination has been observed which includes organochlorines (at lower concentrations than in the North), glyphosate, AMPA, monuron, and diuron. In addition to pesticides, hydrocarbons (e.g. benzo[a]pyrene and fluoranthrene) were present. In Guadeloupe, these compounds were also detected but at lower

concentrations than in Martinique.

MO010
Pollutants and Biomarkers in Fish from the Southern Gulf of Mexico
G. Gold-Bouchot, Cinvestav Unidad Merida / Marine Resources; L. Aguirre-Macedo, Cinvestav Merida / Marine Resources; V.M. Vidal-Martinez, Marine Resources; O. Zapata-Perez, CINVESTAVIPN Unidad Merida / Marine Resources
Five individual fish were collected in each of 86 sampling stations in the southern Gulf of Mexico in June, 2012. The fish were of two species: a catfish *Ariopsis felis* and a flatfish *Scyacium gunteri*. Fish were dissected, livers and bile extracted, and frozen in liquid nitrogen until analysis. A portion of the liver, the kidney and gills were preserved for histology. The expression of five genes (Citochrome P-450-1A, Glutathion-*s*-Transferase, catalase, methallothionein and vitellogenin) was measured in liver. Hyperthophia in gills, granuloma in liver and kidney, and macromelanophage centers (MMCs) in liver were assessed. Fluorescent aromatic compounds (FACs) were measured in bile, and the concentrations of six metals (Cr, Cd, Pb, Hg, Ni and V) and hydrocarbons (low molecular weight [LMW-PAHs] and high molecular weight [HMW-PAHs] PAHs and total hydrocarbons) were measured in liver. Additionally, fish length and weight we recorded. Three research questions were investigated: 1) Are there differences in biomarker responses in the two fish species?; 2) Do fish size and weight affect biomarker response? If so, use as covariates; and 3) Is there a relationship between pollutant concentrations and biomarkers after removing the effect of covariates? Multivariate methods were used to answer the questions, RDA for gene expression and CCA for histology. There were significant differences in gene expression for the two species, with catfish having higher expressions, and for histology, with flatfish having more lessions. Weight was related to both gene expression and lesions, and was used as covariate. Only metals were related with gene expression (6.1% variance, and weight 0.6%) in flatfish, and with FACs in catfish (27% variance, and 0.2% for weight). There was no relationship between pollutants and histological lesions in flatfish, and with hydrocarbons (22.2% variance) in catfish. Particularly there was a strong relationship between HMW-PAHs and granuloma in the kidneys. This work gives useful information to understand biomarker responses in relation to pollutant concentrations for these two species in the Gulf of Mexico, and their use in environmental monitoring and assessment.

MO011
Comparison of Vertimec ® 18 EC effects to Ceridaphnia silvestrii for culture contaminated water and samples of contaminated artificial mesocosms.
M. Pomaro Casali Pereira, Sao Paulo University / Departament of hidraulic and sanitary engineering; J. Resende, Department of Hydraulic and Sanitary Engineering; A. Vasconcelos, University of São Paulo / Hydraulics and Sanitation; E.G. Espindola, University / Hydraulics and Sanitation; C. Botta, University / CRHEA
Vertimec ® 18 EC is a powerful pesticide that even at low concentrations causes toxicity to aquatic organisms. *In situ* uncontrolled factors can influence the contaminant effect, differentiating the commercial product toxicity from contaminated samples *in situ* toxicity. This study evaluated and compared the direct effects of Vertimec ® 18 EC for the cladoceran *Ceriodaphnia silvestrii* using contaminated mesocosms samples and culture contaminated water with the pesticide. The mesocosms was divided in three cases of contamination: without contamination (control), 0.002 (case 1) and 0.008 mL L^{-1} (case 2) and this concentrations correspond to the pesticide concentration in runoff water of strawberry crops and EC_{50} for tadpoles *Lithobates catesbeianus* respectively. Each case was carried out with (a) and without (b) tadpoles presence, used to simulated complex biological relationships. Samples were taken in 3, 96 and 192 hours after contamination in addition the sample before contamination. Nutrients, chlorophyll *a*, pH, dissolved oxygen, temperature and conductivity were monitored during the experiment. As the concentrations used in the *in situ* experiment are highly toxic to cladocerans, in order to find the EC_{50}, 48h, the mesocosms samples were diluted in 6 concentrations (100%, 50%, 25%, 12.5%, 6, 25% and 3.12%). For the toxicity tests with pesticide application in the culture water, the concentrations used were 62.5, 125, 250, 500 and 1000 nL L^{-1}. For the first mesocosms samples (3h) the EC_{50}, 48h, were 18.41% (368.2 nL L^{-1}, case 1a) and 10.38% (207.6 nL L^{-1}, case 1b) and less than 3.12% (62.5 nL L^{-1}, 2a and 2b). In both cases 1a and 1b toxicity values decreased over time, being 29.73% (594.6 nL L^{-1}) and 46.65% (933 nL L^{-1}) in samples of 192h, respectively. However, to cases 2a and 2b, the toxicity values remained lower than 3.12% (62.5 nL L^{-1}). The control without tadpoles showed no toxicity, whereas with tadpoles showed toxicity after 192 hours due the increased ammonia concentration excreted by tadpoles, considered toxic to cladocerans. The EC_{50}, 48h, for culture contaminated water was 81,64 nL L^{-1}. These results indicate high toxicity of Vertimec ® 18 CE to *C. silvestrii*, and highlighted the importance of use ecosystem models to understand the real effects of pesticides, since the toxicity values for mesocosms samples were lower than in culture contaminated water. \n

MO012
Metal pollution in eutrophic environments. Is the toxic effect of cadmium on Danio rerio embryos modified by the presence of cyanotoxins?
L. Luna-Martinez, Instituto Politécnico Nacional Escuela Nacional de Ciencias Biológicas; F. Martínez-Jerónimo, Escuela Nacional de Ciencias BiológicasIPN / Laboratory of Experimental Hydrobiology
Aquatic environments are exposed to different hazards that affect their biota. Eutrophication is observed in lakes and ponds enriched with nitrogen and phosphorus from agricultural fertilizer discharges and secondary wastewater treatment plant effluents; blooms of noxious, toxin-producer cyanobacteria are frequently observed in these conditions. On the other hand, the discharge of toxic metals and pesticides adds stress conditions to hydrobionts. Usually, aquatic organisms in polluted environments are exposed to multiple and different types of stressors, and it is important to determine the combined effects produced by them. In this study, the single and joint effect of cadmium (Cd) and aqueous crude extracts (ACE) of one toxigenic strain of *Microcystis sp.* (VU-5) were evaluated in early life stages of *Danio rerio*; the methodology used was that indicated in the OECD guideline 236 (Fish Embryo Acute Toxicity Test). *Microcystis* biomass was grown under laboratory conditions in autoclaved Z-8 medium, and microcystin content was determined with a commercial ELISA kit; a controlled stock of *D. rerio* reproducers were used to obtain fertilized eggs. Embryos of 2 hours post fertilization (hpf) were exposed to selected Cd and *Microcystis* extract concentrations during 96 h; in addition to the effects indicated in the guideline (coagulated embryos, no somite formation, tail not detached, and no heart beat), teratogenic effects and hatching percentage were recorded. Once the acute effects were determined, 2 hpf embryos were exposed to the LC_{50} value of the *Microcystis* ACE in combination with the same Cd concentrations tested previously (2.5, 5, 10, 20, and 40 mgL^{-1}). LC_{50} were 335 mg L^{-1} and 12.33 mg L^{-1} for Cd and ACE, respectively. The LC_{50} for the Cd+ACE mixture was significantly lower (2.85 mg L^{-1}) than for the single exposure to Cd, indicating increased toxicity when both stressors act jointly. Reduction in pigmentation, delay in development, and teratogenic effects (edema, body deformities, and no eye formation) were mainly observed in embryos exposed to *Microcystis* extracts, and increased in frequency with the Cd+ACE mixture. The toxic effect of Cd increased when microcystins acted at the same time; teratogenic effects of ACE exposure were also documented. It is important to take into account the effects of in situ produced stressors (e. g. cyanotoxins), because they can increase the toxic response of aquatic biota to chemical pollutants.

MO013
Brain cholinesterase response in the climbing perch fish (Anabas testudineus) after exposed to Vitashield 40EC.
T.T. Nguyen Thanh, Nong Lam University / fisheries; H. Berg, Orebro University; C. Hguyen, Can Tho University / College of Env Natural Resources; T. Phan Thi Bich, Can Tho University / College of Environment and Natural Resources
Abstract High use of pesticides in intensive rice farming in the Mekong Delta in Vietnam pose a hazard to the environment and people's health. Chlorpyrifos ethyl is a commonly used insecticide, but little research on the negative impacts of this organophosphate exists on the aquatic environment on tropical conditions. Both acute and sub-acute toxicity tests were carried out in a static and non-renewable system to investigate the effects of chlorpyrifos ethyl on brain cholinesterase (ChE) of native climbing perch fingerling (*Anabas testudineus*). Environmental parameters, such as dissolved oxygen, water temperature, and pH, fluctuated similarly to field conditions. In LC_{50}- 96h test, fingerlings of climbing perch were randomly exposed to five levels of chlorpyrifos, from 0.8, to 4.5 ppm and one control treatment with three replicates. Five levels of chlorpyrifos, 1, 5, 10, 15 and 20% of the LC_{50}- 96 h value, were tested to assess the sensitivity and recovery of brain cholinesterase activity in climbing perch fingerling exposed to chlorpyrifos. The results showed that chlorpyrifos was highly toxic to climbing perch, with a 96-h median lethal concentration (LC_{50}) of 1.73 ppm**.** Chlorpyrifos also caused long-term ChE inhibition, with 30% inhibition remaining after 96h forthe four highest concentrations. Recovery of brain ChE activity was very slow, and at termination of the experiment after seven days, the recovery of brain ChE activity was still significant lower in fish from the four highest concentrations as compared to the control. The finding form this study suggest that insecticides, such as organophosphates, can have long lasting sub-lethal effects on aquatic species in the Mekong Delta. Keywords: *Anabas testudineus, Chlorpyrifos ethyl, Acetylcholinesterase, pesticide impact, rice farming, Mekong Delta*

MO014
Pesticide run-off during rain events in Caribbean lowland agricultural area of Costa Rica
S. Vargas Villalobos, Universidad Nacional; A. Saravia Arguedas, Universidad Nacional / Laboratorio de Química Marina; L. Castillo Martinez, Universidad Nacional / Instituto Regional de Estudios en Sustancias Toxicas IRET; A. Rico Artero, Wageningen University and Research Centre / Department of Aquatic Ecology and Water Quality Management; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; C. Ruepert, Universidad Nacional / IRET
The Caribbean lowland of Costa Rica is characterized by intensive agricultural activities like banana and pineapple plantations but also by its coastal canal and lagoon system with a rich biodiversity and important ecological value. Agrochemical use is normally high and can lead to the pollution of the aquatic environment by run-off following the heavy rains. To evaluate the potential environmental impact of pesticides in the lagoon system the understanding of the factors that contribute to pesticide runoff in the tropics is important. In this study pesticide runoff was followed in a stream that receives water from a banana and a pineapple plantation during rain events and a simple run-off model was applied to estimate the amount of the pesticides contained in the surface runoff (1). Water samples were collected before, during and at the end of rain events in the stream 500 m from the banana and pineapple plantation with an estimating drainage area of 260 and 400 ha respectively. Pesticides commonly used in these agricultural activities were analyzed in the water samples. Discharge of the stream was measured during the sampling and compared with precipitation data. The herbicides ametryn, diuron and hexazinone, commonly used in pineapple, were detected most frequently, with the highest concentrations found for hexazinone of up to 35 μg/L. Other frequently found pesticides were the insecticides carbaryl, chlorpyrifos, diazinon and ethoprofos with a maximum of 2.3 μg/L. The fungicides chlorothalonil, epoxiconazole, metalaxil and triadimenol were detected less frequently, in concentrations of up to 1.3 μg/L. During a rain event of more than 100 mm the highest runoff was found for the herbicides with a total estimated runoff of almost 15 kg/day and for the insecticides and fungicides, for which loads of 0.56 and 0.79 kg/day were estimated respectively. With the model the highest runoff potential can be expected for the pesticide applications in the pineapple plantation, characterized by higher field slopes, lack of buffer zones and the high use of herbicides which seems consistent with the observed loads found in the stream. This study discusses how the run-off model can be used to derive maximum predicted environmental concentrations (PEC) of pesticides and to assess the environmental risk of these pesticides on native aquatic organisms and the implementation for risk reduction strategies. 1) Berenzen N, et al. Chemosphere. 2005,58, 683-691.

Assessing exposure risk of agrochemicals on tropical aquatic species using Species Sensitivity Distributions (SSDs) in Nha Trang, Vietnam
M. Olstedt, Department of Ecology Envionment and Plant Sciences DEEP; M. Tran Thi, Institute of Oceonography; C. Amid, DEEP; H. Le Hoai, H. Le Lan, Institute of Oceanography; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra; M. Tedengren, Department of Ecology Envionment and Plant Sciences DEEP; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP
Abstract Run-off transport of pesticides from agricultural fields to adjacent land and watersheds is posing a growing threat to non-target species. The aim of this study was to assess the toxicity of two pesticides, the insecticide Furadan (Carbofuran) and the organophosphate herbicide Glyphosate on native Vietnamese fish, arthropods, coral and algae species in the Nha Trang area. The species sensitivity distribution method (SSD) was used to compare relative sensitivities to the pesticides. Since most ecotoxicological studies of pesticides have been carried out with freshwater species in temperate regions, geographical differences in sensitivity and the possibility of extrapolating temperate toxicity data on tropical species were evaluated. LC_{50}/EC_{50}-96h and 7 day standard toxicity tests were analyzed for mortality and immobility for vertebrates and growth inhibition for invertebrates. Additional aquatic single-species LC50 or EC50 values fromfish, crustaceans and algae were collected from the open literature and existing toxicity databases e.g. US Environmental Protection Agency (US-EPA) ECOTOX database www.epa.gov/ecotox. The E_TX 2.0 Program was used for estimating HC5 and HC50 values, fitting a log-normal model to the data assessed by Anderson-Darling goodness-of-fit test at $\alpha = 0.05$. Carbofuran was more toxic to crustaceans and fish than to the herbicide Glyphosate (96h L(E)C50 (μg/L); fish *Lates calcarifer* = 139, shrimp *Litopenaeus vannamei* = 78, lobster *Panulirus homarus* = 13,9) whereas Glyphosate was more toxic to the algal species (96h L(E)C50 (μg/L); *Chaetoceros muelleri* = 10652, *Skeletonema costatum* = 29837 and *Acropora formosa* = 6000 (NOEC value). When comparing tropical and temperate fish exposed to Carbofuran and Glyphosate, results indicate no statistically significant difference in species sensitivity. Example from fish (*L. calcarifer*); T-test assuming equal variance, t = -0.3, p = 0.8 (Carbofuran) and t = 0.7, p = 0.5 (Glyphosate). Results show no statistical differences between tropical and temperate regions (fish and crustaceans data) suggesting that the SSD method can be used for ecological risk management in tropical regions.

MO016
Effect of pesticides used in banana and pineapple plantations on aquatic ecosystems in Costa Rica
N. Diepens, Wageningen University / Department of Aquatic Ecology and Water Quality Management; S. Pfennig, Universidad Nacional / Central American Institute for Studies on Toxic Substances IRET; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; C. Ruepert, Universidad Nacional / IRET; L.E. Castillo, Universidad Nacional Costa Rica / IRET
Current knowledge on fate and effects of agricultural pesticides comes mainly from temperate ecosystems. More studies are needed in tropical systems in order to assess contamination risks to non-target endemic tropical species from the extensive use of pesticides e.g. in banana and pineapple plantations. In this study, acute laboratory toxicity tests with the organophosphate pesticides ethoprophos and chlorpyrifos were conducted on two Costa Rican species, the cladoceran *Daphnia ambigua* and the fish *Parachromis dovii*. Tests showed that chlorpyrifos was more toxic than ethoprophos to *D. ambigua* and *P. dovii* and that *D. ambigua* was also more sensitive than P. dovii to both pesticides. Additionally, bioassays were performed by exposing *Daphnia magna* and *P. dovii* to contaminated water collected from the field. Chemical analyses of field water revealed that fungicides were generally the most frequent pesticide group found, followed by insecticides/nematicides and herbicides. The bioassays and values obtained from the literature confirmed that *D. magna* was more sensitive to pesticide contamination than *P. dovii* and that *D. ambigua* was more sensitive than *D. magna*, suggesting that the native cladoceran is a more suitable test species than its temperate counterpart. Species sensitivity distributions for both fish and arthropods showed no significant difference in sensitivity between tropical and temperate fish and between the tropical and temperate species exposed to chlorpyrifos in this study. Cholinesterase activity (ChE) was also measured in *P. dovii* in laboratory tests in order to assess the applicability of this biomarker. ChE inhibition in *P. dovii* was observed in the lab at levels below the LC_{10} of both ethoprophos and chlorpyrifos, confirming that ChE is an efficient biomarker of exposure. Both indigenous Costa Rican species used in this study were found to be suitable standard tropical test species. Further studies are needed to investigate how protective the safe environmental concentrations, derived from LC_{50} of native tropical species, are for protecting tropical aquatic natural communities.

MO017
Insect diversity on high-input, low-input and organic banana farms
A. Sanderson Bellamy, O. Svensson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; M. Tedengren, Department of Ecology Envionment and Plant Sciences DEEP; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP
High intensity of pesticide use in banana production is problematic not only for human health and the surrounding environment, but can threaten the provision of ecosystem services on which farm productivity depends. This research investigates the effects of varying pesticide-use intensities on on- farm insect diversity, using three different types of farm management systems: high pesticide input conventional system, reduced pesticide input conventional system and organic system. Insect sampling was done using pitfall and yellow bowl traps, left for a 24-hour period at 2 locations inside the banana farm, at the edge of the farm, and in adjacent forest. Species were classified to family level and then morphospecies. Insect species community composition and diversity were compared using multivariate statistics with ordination analysis and Monte Carlo permutation testing, and revealed that each of the management systems were significantly different from each other for both trap types. Insect diversity decreased as production management increased its pesticide use. Reduced insect diversity resulted in fewer functional groups and fewer insect families assuming different functions essential to ecosystem health. Organic farms had similar species composition on the farm compared to adjacent forest sites, whereas species composition increasingly differed between farm and forest sites as pesticide-use intensity increased. We conclude that while organic production has minimal impact on insect biodiversity, even small reductions in pesticide-use intensity can have a significantly positive impact on on-farm insect biodiversity and functional roles supported.

MO018
Feasibility of different colored clays for the composition of formulated sediments regarding pH, dissolved oxygen and metal availability parameters for cultivation of Hyalella azteca
A.L. Arine, Unesp / Biology Laboratory and Environmental Chemestry Laboratory; C. Watanabe, V. Campos, R. Fracacio, Unesp
The clay fraction plays an important role in the sediment compartment of water bodies due to its high capacity of reaction and adsorption. This work evaluates the implementation of several colored smectite clays obtained commercially for the composition of formulated sediments. Stabilization capability of pH and dissolved oxygen under mild aeration and presence of organic matter (*Elodea* sp.), measured on a daily basis for 15 days, as well as the bioavailability of metals in the water

column (Al, Fe, Cd, Co, Cr, Cu, Fe, Mg, Mn, Ni, Pb, Zn) were analyzed. The analysis of metals in water was done with both surface and interstitial fraction. The methodology of Silverio (1999) was used to evaluate bioavailable metal concetration, and total metal concentration by acid digestion method suggested by EPA (1996). The metal content was determined by ICP-OES analysis. Results showed that dissolved oxygen remained above 4 mg L^{-1} throughout the experiment for all tested clays, in agreement with the minimum recommended value for cultivation of *H. azteca*. The values of pH became progressively more alcaline along the experiment for all the clays. The sample containing green clay had more stable responses and closer to the recommended value for the cultivation of epibenthonic organisms (between 7.2 and 7.7). There was greater availability of free metals in intersticial water than in the water column, which may cause greater toxicity for bentonic organisms compared to creatures present in the water column. The clays used in the present work showed high level of said metals as result of impurities responsible for its colors. Process FAPESP 2012/14583-5

MO019

Effects of Triclosan on the transcription expression of CYP1A, CYP3A and their enzymes activity in the Yellow Catfish (Pelteobagrus fulvidraco)

P. Ku, Department of EcologyHydrobiology Research Institute Jinan University; X. Wu, Jinan University; R. Ou, Department of EcologyHydrobiology Research Institute Jinan Univercity; L. Wang, Department of Ecology Jinan University China; X. Nie, Department of Ecology Jinan University

Triclosan (5-chloro-2-(2, 4-dichlorophenoxy) phenol, TCS) is widely used in personal care products, industrial, veterinary and household products as a spectrum antibacterial agent. TCS can be universally detected in aquatic ecosystem due to its partial removation by the wastewater treatment process. However, limited information is provided about its potential adverse impacts on aquatic organisms, especially upon the expression of genes related to detoxification system and their enzymes activity of fish. We first cloned CYP1A, CYP3A and Alpha-GST of Yellow catfish (Pelteobagrus fulvidraco), an indigenous fish species in Pearl River Delta, South China. The gene expression of CYP1A and CYP3A and GST and their changes of enzymes activity of Phase I (EROD, APND and ERND), Phase II enzymes (GST, CAT) and MDA in the liver of Yellow catfish exposed to TCS (0.5, 5, 50 and 500 μgL-1 TCS, respectively) for 24h, 72h and 168h were determined by Real-PCR and a spectrofluorometer approach. The results showed that CYP1A mRNA expressions was significantly induced after TCS exposure for 24h and then significantly inhibited after 72h and 168h.Expressions of CYP3A were significantly inhibited for 24h and 72h but significantly induced for 168h at relatively low concentrations(0.5 and 5 μgL-1 TCS) while CYP3A was always induced at the highest concentration (500 μgL-1 TCS). GST mRNA expressions were significantly induced after 24h, slightly inhibited for 72h and remarkablely induced at the lowest concentration(0.5 μgL-1 TCS) while inhibited at the highest concentration. EROD, GST and MDA activities were significantly inhibited at 24h. ERND and EROD activities were significantly induced at the lowest concentration and inhibited at the higher concentration for 72h. Similar trends were observed for GST activity at 72h. CAT and MDA activities were induced at 72h while slightly inhibited at 168h at low concentrations. In general, ERND, EROD, CAT and MDA activities displayed stronger induction at the lower concentration (0.5μgL-1) than the ones at the higher concentrations at 72h, while APND, ERND, CAT and MDA activities showed more significant change at the concentration of 50μgL-1 at 168h. All enzymes tested in this study exhibited dose-effect relationships to some extent. EROD and GST were more sensitive in response to TCS exposure compared to other enzymes.

MO020

Erythrocyte oxidative damage and antioxidant defense system of traíra, Hoplias malabaricus, injected with crude extract of cyanobacteria, Radiocystis fernandoi.

M.M. Sakuragui, Federal University of Sao Carlos / Department of Physiological Ciencies; T. Peixoto, N.d. Souza, M.G. Paulino, D. Tavares, Federal University of Sao Carlos / Department of Physiological Sciences; A.P. Terezan, J.B. Fernandes, Universidade Federal de São Carlos / Quimica; A. Giani, Federal University of Minas Gerais / Department of Botanical; M.N. Fernandes, Univeridade Federal de Sao Carlos / Ciencias Fisiologicas

The erythrocytes have vital functions in the oxygen and carbon dioxide transport and hydrogen ion buffering. The microcystins (MCs) are toxins produced by cyanobacteria that may increase the free radicals and induce oxidative stress. In this context, this study evaluated the toxicity of MCs present in the crude extract of *Radiocystis fernandoi* on the blood cells of traíra, *Hoplias malabaricus*. Fish were separated in control group (VC-injection with saline 0.9%) and two groups injected intraperitonial with MCs (100 μg g^{-1} body mass): MC12h and MC96h. Twelve and ninety-six hours after injection the blood was sampled and the activity of superoxide dismutase (SOD), catalase (CAT), glutathione-s-transferase (GST), glutathione peroxidase (GPx) as well as the levels of glutathione (GSH) and lipid peroxidation (LPO) were determined. No significant changes occurred in the activities of SOD and CAT. However, the activities of GST and GPx increased in the MC12h group. GSH levels increased in the erythrocyte in the group MC96h. LPO levels increased in erythrocytes of both groups: MC12h and MC96h. GST catalyzes the conjugation of xenobiotics withGSH, thereby facilitating their elimination from cell organelles. The elevated level of GSH suggests a protective role in the MC96h group. The results suggest that after 12 h of MCs injection induced GPx and GST activity and after 96 h the GSH system was activated. However, the antioxidant defenses was not efficient to avoid oxidative stress in the red blood cells as the LPO levels increased in both groups: MC12h and MC96h injected with crude extract of *R. fernandoi*. GSH system and LPO are good biomarkers of acute MCs contamination. Financial support: CAPES Proc. 2276/2011, CNPq/INCT-TA Proc. 573949/2008-5 and CEMIG Proc. GT346.

Anatomical alterations in rice leaf during senescence and aluminum toxicity

M. KUMARAN, Pondicherry University / Department of Ecology and Environmental Sciences; A. Vijaya Bhaskara Rao, Dept o Ecology and nvironmental Sciences / Deptof Ecology and Environmental Sciences

Aluminum limits the growth and productivity in crop plants. In our present study, we studied the anatomical alterations in aluminum treated rice leaves. The anatomical studies were carried out using Nikon labphoto 2 microscopic Unit. Alittle is known about the anatomical aspects in senescing rice leaf on exposure to Al toxicity. In the present study, two rice varieties i.e., ADT-43, and Pro Agro 6129 were selected to compare and to evaluate histological changes in rice leaves anatomy. The leaf bits were placed in petri dishes of 20 cm diameter and treated with aluminium solution at a concentration of 300μM and distilled water was used as a control. The treatment was exposed for 8 days. We observed that the structures of the leaf ADT 43 when control there was no significant alterations were observed on exposure to 300μm of aluminum, the vascular bundles, Bulliform cells vessel elements and mesophyll tissues are intact. In the control plant the air chambers are reduced in number and the vascular bundles are also much smaller. The bulliform cells are also larger in the control plants. The midrib of Pro Agro 6129 control plant remain intact with wide air chambers, well preserved partition filaments and large and prominent vascular bundles and distinct mesophyll tissue. The bulliform cells are distinct. In the Pro agro 6129 variety there is a general deformity of the midrib as well as lamina on exposure to aluminum. The air chambers in the midrib are reduced too. The vascular bundles of the midrib are slightly modified both in structure and measurements. The lamina is very much affected having lost the structure and organization of the mesophyll tissue, bulliform cell of vascular bundle on exposure to 300 μm aluminum, in Pro Agro 6129. On the whole, the results indicate that ADT-43 is resistant for aluminum toxicity and Pro Agro is sensitive rice variety. **Keywords**: Aluminum, Rice, Mesophylls, leaf epidermal, Stomata.

TIER II. In situ toxicity and ecological assessment of pesticide run-off in the Madre de Dios River and Lagoon, Costa Rica.

F. Mena, Universidad Nacional / Instituto Regional de Estudios en Sustancias Toxicas; S. Echeverria Saenz, Universidad Nacional / Instituto Regional de Estudios en Sustancias Toxicas IRET; M. Arias, Universidad Nacional; P.J. van den Brink, Alterra and Wageningen University; C. Ruepert, Universidad Nacional / IRET; L. Castillo, Universidad Nacional; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP

The Madre de Dios river and lagoon (RMD) is a biodiversity rich watershed formed by a system of streams, rivers, chanels and a coastal lagoon communicating with the Caribbean Sea. This area also sustains an important agricultural activity (mostly banana, rice and pinneapple) with intensive use of pesticides which may pose a contamination risk to this ecosystem. We investigated toxicological and ecological effects caused by pesticide run-off from agriculture. The evaluation was carried out from october 2011 to november 2012 at five sites, four along Madre de Dios river and affluents (sites 1 to 4) and one reference site (5) in a stream outside RMD, that receives less pesticides. Acute toxicity to *D. magna* was evaluated in water samples collected from all sites. Fish biomarkers (Cholinesterase, Glutathione S-transferase and Catalase activities and Lipid peroxidation) were measured in juveniles of *Parachromis dovii*, exposed in cages during 48 hr at each site. An Integrated Biomarker Response (IBR) was calculated. Macroinvertebrate community (MC) structure was investigated by placing four artificial substrates (clay bricks) for colonization over one month, per site. After that, organisms were recovered, sorted in the laboratory and identified. Toxicity to *D. magna* was observed only in site 4 in nov-2011. Responses of fish biomarkers were more frequent and consistent at sites 2, 3 and 4 and this pattern was confirmed by the IBR. Sites with higher IBR were also the ones where higher amounts of pesticide residues were detected. Variations in the structure and diversity of MC related to diminished dissolved oxygen and increasing concentrations of NO_3, total Phosphorus and pesticides. Macroinvertebrates structure was clearly different from site 5, which had the highest diversity and the lowest pesticide concentrations. Amongst the other four sites, the MC was most impacted in site 1, with the lowest diversity and the lowest dissolved oxygen of all. Sites 2 and 3 had very similar community compositions while site 4 shared species with all the other sites. Evidences of effects at different biological organization levels (sub-individual, individual and community) were observed during this evaluation. Early responses in fish biomarkers, acute toxicity and changes on MC were asociated with sites impacted by intensive agriculture, habitat degradation and presence of pesticides.

PREDICTED TOXICITY RISKS OF PESTICIDES USED IN PADDY RICE FIELDS IN THE MEKONG DELTA, VIETNAM, AND COMPARISON BETWEEN DIFFERENT AGRO-MANAGEMENT REGIMES

N. Stadlinger, Stockholm University / Ecology Environment and Plant Sciences; H. Berg, Orebro University; T.T. Nguyen Thanh, Nong Lam University / fisheries; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; P. van den Brink, AlterraWageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra

Vietnam is one of the leading rice producing countries in the world with the Mekong Delta being one of its most important regions. The intensive pesticide use in rice cultivation has led to a severe pollution that presents a potential toxicity threat to the environment and public health. There have been several attempts of reducing farmers' pesticide use, such as Integrated Pest Management (IPM) programs. Rice-fish culture is also practiced among many farmers in the Delta and comes with many benefits; besides reducing the economic risks of the farmer it can provide a number of ecosystem services. Integrated rice-fish farming is, however, likely to be more vulnerable to chemical pollution as fish are stocked directly in the trenches of the rice fields. In this study the pesticide use of rice and rice-fish farmers of two provinces, with and without previous IPM training obtained from interview studies was compared using the first-tier risk assessment model. In combination with higher-tier models, worst case application scenarios obtained from PRIMET and risks to aquatic organisms could be identified, in this case with a particular focus on cultivated fish. The results show that there were major differences in risks between the two provinces Can Tho and Tien Giang. The pesticide management of Can Tho farmers had significantly higher acute toxicity risks, mainly due to the use of pyrethroids and organophosphates. Tien Giang farmers were generally using less toxic pesticides such as neonicotinoids. The highest risks were found among conventional rice farmers in Can Tho, indicating that they are able to use more pesticides, as they do not have to consider negative effects on fish. This study shows that the PRIMET model was a useful tool to perform risk assessments on rice farmers' pesticide use in order to understand risks for the surrounding aquatic environment. Many farmers in the area have abandoned integrated rice-fish farming and replaced it with two seasons of rice farming and one season with only fish. This is likely to be a result of pesticides' negative effects on fish in the integrated system. A comparison between the ecological risks following different management regimes and current pesticide compounds used is discussed in order to provide best possible protection of fish and other non-target aquatic organisms.

MO024

Assessment of ecological risks of pesticide use in banana and pineapple cultivation on aquatic ecosystems in Costa Rica using the PERPEST model.

P.J. van den Brink, Alterra and Wageningen University; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; L. Castillo, Universidad Nacional; C. Ruepert, Universidad Nacional / IRET

Costa Rica is a major agro-economy and one of the largest producer of banana and pineapple. These crops are among the world's most pesticide intensive with a total pesticide charge of ca. 45 kg and 30 kg active ingredient per hectare and year for bananas and pineapple respectively. The pesticides may pose a severe contamination risk for Costa Ricas' rich wildlife, particularly in streams and watersheds located downstream from the plantations. In a project called TROPICA (Tiered Ecological Risk Assessment in Costa Rican Agriculture) we gathered data on land use (GIS), pesticide applications (interviews), and pesticide residue concentrations in water and biota samples (GC-MS) in streams of the Limon Province, in the Caribbean Lowlands of Costa Rica in order to assess the toxicity risks from these pesticides on native wildlife. Here we present the results of a risk assessment made using a model called PERPEST. PERPEST is based on a case-based reasoning (CBR) approach, built on data extracted from freshwater mesocosm and microcosm experiments in order to predict the toxic effects of a particular concentration of a pesticide on different taxonomic groups, i.e. crustaceans, fish, and algae. When the effect of a particular concentration of a pesticide has to be predicted, the PERPEST model searches for analogous situations in the database based on relevant toxicity characteristics of the compound, exposure concentration and type of ecosystem to be evaluated. This allows the model to use information on other pesticides for predicting effects of a particular pesticide. In this study, the latest version of the PERPEST model was used, which also allows to evaluate mixtures of pesticides. Hence for each sample taken at each site an overall estimate of the ecological risks was obtained. Results are presented in terms of ecological risk values to various native taxonomic groups and discussed in relation to the pesticide use in the production of bananas and pineapple in the region.

MO025

Additive effects of herbicide and elevated temperature in the branched coral Acropora formosa - Nha Trang, Vietnam.

C. Amid, DEEP; M. Olstedt, Department of Ecology Envionment and Plant Sciences DEEP; J. Gunnarsson, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; H. Le Lan, H. Nguyen, Institute of Oceanography; H. Tran Thi Minh, Institute of Oceanography Nha Trang; H. Doan Nhu, Institute of Oceanography; P.J. van den Brink, Alterra and Wageningen University; M. Hellstrom, Stockholm University / Department of Ecology Envionment and Plant Sciences DEEP; M. Tedengren, Department of Ecology Envionment and Plant Sciences DEEP

Coral communities are currently experiencing global declines in abundance, distribution and diversity. Despite vast interdisciplinary work, few studies have attempted to describe combined effects of environmental stressors (i.e. marine pollutants) and increased temperature on circumtropical reefs. An experimental study was designed to investigate effects of the herbicide Glyphosate and elevated temperature on the tropical staghorn coral *Acropora formosa*, collected in the bay of Nha Trang in November 2012. Combined effects were investigated by means of physiological measurements describing fluctuations in photosynthetic capacity, i.e. gross primary production, dark respiration, chlorophyll *a* content, zooxanthellae densities and coral bleaching using a customized colorimetric method. Fragments of the staghorn coral *A. formosa* were adversely effected by the combination of elevated temperature (+3°C), compared to *in situ* water temperature of 28°C and high Glyphosate exposure (12.0mg·L^{-1}). Significant additive effects of temperature and herbicide were observed both for chlorophyll *a* and for two photometric variables (MIG_E and MIG_{RE}) developed to describe changes in coral physiology through alterations in color by means of digital imagery. The results of this study add further weight to the notion that combined stressors poses a greater threat than earlier recognized. Coral communities within tropical and sub-tropical 'latitude belts' are currently already in close proximity of their upper thermal limits and are additionally exposed to land-use malpractices through increased riverine discharges of suspended particles and pollutants. Conservational policies need to be devised to counteract this course of events. The decrease of chlorophyll *a* and the increase of color loss suggest that coral bleaching is related to the concentration of photo pigments and quantifiable by colorimetric methods. The significant effects of bleaching described by MIG_E and MIG_{RE} respectively show that (1) deleterious effects on coral physiology occur during combined exposure of temperature and herbicide and (2) that there is a relationship between color, zooxanthellae densities and chlorophyll *a*. Measurement of non-intrusive nature, such as the digital image processing method used in this study, should be encouraged and developed further in order to quantify important physiological variables, e.g. chlorophyll *a* content and zooxanthellae densities.

MO026

Oceanic transport of Perfluorinated compounds into Antarctic waters, and the influence of the Antarctic Circumpolar Current

S.J. Wild, Griffith University; R. Bossi; D. Hawker, Griffith University / School of Environment; R. Cropp, Griffith University; S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program SOPOPP

Despite the apparent pristine conditions and remoteness of Antarctica, persistent organic pollutants have been detected in the region since the 1960s. Today a large variety of organic pollutants can be found in the Antarctic environment and its subsisting species. Unlike the more traditional persistent organic pollutants, perfluorinated compounds (PFCs) such as perfluorooctane sulfonate (PFOS) and other poly- and perfluorinated alkyl substances (PFAS) tend to have very low volatility so are less prone to long-range atmospheric transportation. These types of compounds however readily dissolve in water when in ionic form and appear to accumulate in the world's oceans. As a result of this, one of the primary transport mechanisms for PFCs is believed to be through the oceanic currents. These oceanic currents, similarly to atmospheric currents, are believed to transport these towards compounds the poles where they may accumulate. In the Southern Ocean, the Antarctic Circumpolar Current is major physical feature presenting a barrier for direct north-south transport of surface waters. It is assumed that this barrier is also currently serving to inhibit bulk transfer of hydrophilic pollutants such as PFCs from higher latitude into the water surrounding the Antarctic continent. This hypothesis was supported by recent evidence indicating that Antarctic species, that cross the polar front zone to forage have detectable PFC burdens, whilst those who are restricted to south of the Antarctic Circumpolar Current do not. The barrier however is not impervious, with continuous exchange of older upwelling water bodies and some surface water exchange occurring, presenting the possibility of long term bulk input via this pathway. In order to investigate levels of PFCs in Southern Ocean surface waters and ascertain the role of the Antarctic circumpolar current in mechanistic transfer of pollutants south of the polar front zone, water samples were collected along longitudinal sampling transects from Hobart to the Antarctic Continent in 2011 and 2012. Two litre samples were collected every half to one degree of change in latitude. The preliminary results from this investigation indicate levels of PFOS as well as other PFAS within the southern ocean are currently at levels in the parts per thousand. The trends and patterns of detection are

further interpreted within this presentation.

Trace element bioaccumulation in rope-grown Mytilus galloprovincialis: knowledge update

J. Richir, University of Portsmouth / Institute of Marine Sciences; S. Gobert, University of Liege / Laboratory of oceanology

Numerous trace elements (TEs) can be considered as potential pollutants of the environment, their mining productions and industrial uses increasing worldwide. Their monitoring can be achieved through the use of bioindicator species, such as the Mediterranean mussel Mytilus galloprovincialis (Lamarck, 1819). That species has been widely used to monitor the chemical pollution of coastal ecosystems by Cr, Ni, Cu, Zn, Cd, Pb, As, Ag and V. Conversely, environmental levels of Be, Al, Fe, Mn, Co, Se, Mo, Sn, Sb and Bi have been little or not monitored so far in mussel watch programs. Bioaccumulation processes of these 19 TEs in rope-grown M. galloprovincialis purchased from a salt pond with good chemical water quality were thus investigated in the present study.\nMussels efficiently accumulated the 19 studied TEs. Bioaccumulation processes were driven by numerous mutually dependent biological parameters such as the mussel size and flesh weight, the sex and the reproductive status and the body compartment considered. TE bioaccumulation was a power function of the mussel soft body dry weight; total contents linearly increased with the shell length. Small-size mussels overall concentrated more TEs, with a high inteindividual variability, consequently influencing the modelling of their bioaccumulation in the whole rope population. Although a large range of rope-grown M. galloprovincialis sizes can be used for monitoring purposes, one will thus take care not to use extreme size individuals. The influence of gametogenesis in determining female body higher TE concentrations prior to spawning could not be neglected and varied depending on the element. TEs were preferentially accumulated in the hepatopancreas, except for Zn, Se, Cd and Mo, more concentrated in gills. Gametogenesis did not influence TE distribution between body compartments, but likely diluted their concentrations as a direct consequence of massive reproductive tissue production.\nSo, results from the present study underline the potential use of M. galloprovincialis in the biomonitoring of numerous little studied TEs and give some insights into the decisive role played by some relevant biological parameters in bioaccumulation processes of the 19 investigated TEs in rope-grown mussels.

MO028

Accumulation of organotins and perfluorooctane sulfonate in wharf roach (Ligia exotica Roux) and its ability to serve as a biomonitoring species for coastal pollution

Y. Oshima, Faculty of Agricutlure Kyushu University / Faculty of Agriculture; M. Honda, S. Matsunaga, Faculty of Agriculture Kyushu University; S.L. Undap, Sam Ratulangi University; T. Sekiguchi, N. Suzuki, Institute of Nature and Environmental Technology Kanazawa University; Y. Shimasaki, Kyushu University / Faculty of Agriculture

In this study, we measured the accumulation of tributyltin (TBT) and perfluorooctane sulfonate (PFOS) in wharf roach (*Ligia exotica* Roux) and examined the species' ability to be used for TBT and PFOS biomonitoring in coastal environments. In an exposure tests, wharf roach were exposed to TBT or PFOS via diet for 2 d. TBT and PFOS were accumulated in wharf roach. The concentrations of these compounds gradually decreased during the depuration period, but they were still detected 12 d after exposure ceased. The biological half-lifes of TBT and PFOS in wharf roach were estimated to be about 4 d and 11.9 d. In a field study conducted in 2011–2012, wharf roach were collected from 15 coastal sites in Japan and 3 sites in Manado, Indonesia. TBT was detected in both Japanese and Indonesian samples. The highest concentration of TBT was found in wharf roach collected at Bitung ferry port, Manado (57.9 ± 16.5 ng/g), which is close to a shipyard, and the highest concentration at a Japanese site was 12.3 ± 6.2 ng/g. However, PFOS was detected only in Hakata and Tarami ports. Thus, we were able to detect organotins and PFOS in the coastal environments by testing wharf roach, suggesting that *L. exotica* might serve as a good bioindicator for monitoring organotin pollution.

MO029

Metal interaction between the mussel Bathymodiolus azoricus and the polychaete Branchipolynoe seepensis from the hydrothermal vents: endosymbiosis or parasitism?

C. Cardoso, University of Azores / DOP; T. Gomes, University of Algarve / CIMA; A. Colaco, University of Azores / IMARDOP; R.L. Santos, Universidade Federal do Maranhão; M.J. Bebianno, University of Algarve / CIMA

Hydrothermal vents are deep-sea environments characterized by high pressure and temperature, as well as high concentrations of heavy metals, sulphides and methane. The vent mussel *Bathymodiolus azoricus* is the dominant species at most sites along the Mid-Atlantic-Ridge, with the capacity to accumulate high levels of metals in its tissues. The commensal polychaete *Branchipolynoe seepensis* is commonly found in the palleal cavity of these mussels, where the polychaete is known to clean the gills surface from particles in excess. Nevertheless, their biological interaction is not yet clear, especially considering metal uptake and bioavailability. So, the main goal of the present work was to understand the association between both species, in a metal bioaccumulation perspective. Mussels *B. azoricus* were collected in August 2013, during the mission BIOBaz, in two sites from the hydrothermal vent Lucky Strike (Eiffel Tower and Monteségur) and one site from the hydrothermal vent Rainbow (PL07). Mussels were dissected and tissues (gills, digestive gland and mantle) and polychaetes (whenever present) were separated, frozen in liquid nitrogen and stored at -80ºC. Metal concentrations (Cd, Cu, Zn, Ni, Fe, Mn, Ag and Co) were determined in total and subcellular fractions of mussel tissues, as well as in whole soft tissue of polychaetes by atomic absorption spectrophotometry. Additionally, a biomarker of metal exposure, (metallothionein-MT) and a biomarker of oxidative damage (lipid peroxidation-LPO) were determined in mussels and polychaetes tissues. The results show different metal concentrations in mussels and polychaetes between sites and subcellular fractions (higher in Rainbow), reflecting inter and intra variation of water chemistry between hydrothermal sites, as well as the ability of these species to regulate their intracellular metal levels (as also shown by MT levels). LPO was higher in mussel gills followed by the digestive gland and mantle, especially in mussels from Rainbow. As for polychaetes, the same tendency was observed, with higher LPO in organisms collected in Rainbow compared to Lucky Strike, while in Menez-Gwen no polychaetes were found. Overall, the presence of the commensal polychaete in gills of *B. azoricus* seems to be an adaptation to the high metal concentrations in the water column near vent sites.

MO030

Acute and subacute responses of Crangon crangon (Crustacea) to ocean acidification due to CO2 injection

A. Gerhardt, LimCo International GmbH

Carbon Capture and Storage (CCS) business is expanding worldwide. During CO2 injection into subsea rocks the surrounding water is threatened by acidification. Moreover, leackage from rocks might contribute to uncontrolled pulses of acidification of seawater. The aim of the project is to identify sensitive marine indicator species and study their behavioural responses to acute and subacute exposure to low pH by CO2 injection. *Crangon crangon*, brown shrimp, is an edible widely spread species. Two different scenarios were tested: (1) stepwise small pH downshifts (0.2 units) from pH 8 to pH 6, (2) continuous exposure to low pH (pH 6.5, 3 days). The experiments were performed in a flow-through system placed in a climate room, the behaviour of the shrimp being recorded quantitatively and continuously with the Multispecies Freshwater Biomonitor (MFB). Shrimp responded rapidly (within 20 Min.) and sensitively to small pH-downshifts in both a stepwise and a continuous regulation with significantly increasing locomotory activity (avoidance). Shrimp also responded to constant low pH with (1) increased avoidance, (2) increased nocturnal activity, (3) post-exposure increased search time for food (optimal foraging theory) and (4) subsequent acclimation to generally low activity towards the end of exposure. In conclusion, *C. crangon* is a suitable indicator species for ocean acidification with rapid, sensitive behavioural responses, which can appropriately be recorded in the MFB in marine monitoring programs. The project is funded by the Research Council of Norway CLIMIT program (project No. 215637). Research work is carried out at the International Research Institute of Stavanger (IRIS), Stavanger, Norway.

MO031

Long term toxicity studies with marine species

L. Manfra, A. Tornambe, ISPRA; f. savorelli, ARPA EMR; S. Canepa, F. Oteri, ISPRA; A. Rotini, Tor Vergata University; M. Mannozzi, ISPRA / ISPRA; A. Cicero, ISPRA

A long term toxicity evaluation was conducted on marine species: algae (*Phaeodactylum tricornutum*), mollusks (*Tapes philippinarum*), crustaceans (*Artemia franciscana*) and fish (*Dicentrarchus labrax*), exposing them to Diethylene glycol (DEG). This is an additive used during oil and gas exploitation process to prevent hydrate formation and corrosion events. It may be released into the sea by the main discharge (Produced Formation Water, PFW) of oil/gas platforms. A full DEG ecotoxicological characterization is required according to Italian law. In literature are reported acute toxicity studies with marine species (bacteria, rotifers, crustaceans, mollusks and fish) but not long term exposure results. The aim of this study is to determine the long term effects of DEG for marine organisms and then to integrate these results with previous acute toxicity studies, to verify if the current DEG threshold value (3.5 g/l) is safe for the marine PFW discharge.

MO032

Combined effects of microplastics and adsorbed contaminants on marine microalgal photosynthesis and growth

S. Sjollema, P. Redondo-Hasselerharm, University of Amsterdam; M. van der Meulen, DELTARES; M. Kraak, University of Amsterdam; D. Vethaak, DELTARES

Microalgae play a key role in aquatic ecosystems due to their position at the base of the food chain and contamination at this level could therefore result in unfavourable effects on higher trophic levels. Hence, there is an increasing concern about the potential effects of microplastics on microalgae. These microplastics, synthetic polymers with a diameter smaller than 5 mm to the nanoscale range, have a widespread occurrence and negative effects on different trophic levels have been described. The effect on microalgae can be direct, as adhesion of the plastics to the algal cell walls might block the light needed for photosynthesis, as well as indirect as additives and adsorbed contaminants may leach from the polymers, causing toxic effects. It has been demonstrated that nanoplastics (20nm) can adsorb to microalgae, thereby hindering photosynthesis, but the effect of the larger microplastics on microalgae is still unknown. Therefore, the aim of this study was to determine the effect of microplastics on microalgal photosynthesis and growth. To this purpose a range of marine microalgal species were exposed to different sizes of microplastics (polystyrene) to determine if the effect is species and/or size specific. As microplastics have the ability to both sorb and leach POPs and other contaminants, thereby potentially affecting their bioavailability, the interaction between microplastics and a model herbicide was studied. To this purpose the water was spiked with the photosynthetic inhibitor and microplastics and their joint effect on algal photosynthesis and growth was assessed. This work was funded by the European Union Seventh Framework Programme under grant agreement No 308370 (CLEANSEA project).

MO034

Metals and other elements in tissues of wild fish from fish farms and comparison with farmed species in sites with oxic and anoxic sediments

I. Kalantzi, Hellenic Centre for Marine Science / Institute of Oceanography; K. Black, Scottish Association for Marine Science; S.A. Pergantis, University of Crete / Chemistry; T.M. Shimmield, Scottish Marine Institute / Scottish Association for Marine Science; N. Papageorgiou, University of Crete / Department of Biology; K. Sevastou, Hellenic Centre for Marine Research / Institute of Oceanography; M. Tsapakis, Institute of Oceanography; I. Karakassis, University of Crete / Department of Biology

The behavior of some metals in the marine environment changes when redox is altered, occasionally resulting in changes in bioavailability. Around organically enriched, highly reducing fish farms, the bioavailability of metals is likely to be low due to the presence of metal-binding phases in sediments, such as organic material and sulphides. However, metals bound to the sediment might pose a threat to aquatic biota either through leaching into the water-column by direct contact or through consumption of contaminated benthic organisms. Wild fish assemblages around fish farms are often exposed to conditions that are unusual for the Mediterranean, such as the hypoxia in farms established at shallow, poorly flushed sites with reducing sediments. The biology and physiology of wild fish may be affected as they become farm effluent feeders, feeding on commercial pellets and subsequently altering their fat deposition and fatty acid composition. Furthermore, recreational and commercial fishing in the vicinity of fish farms is a common phenomenon in Greece. Therefore, it seems that metal and other element determination in farmed and wild fish around fish farms is important in human health risk assessment. Metal accumulation in different fish species may be affected by many factors such as size, sexual maturity, seasonal changes, feeding habits, trophic level, water quality and environmental contamination. In the present study, farmed fish and wild fish aggregating in the vicinity of four Mediterranean fish farms with different environmental conditions were sampled. Levels of metals (including As and Se) were measured in the muscle, liver, gills, bone and intestine. The wild fish from sites with anoxic substrata accumulate metals (including As and Se) from the ambient habitat in their gills whereas those from sites with oxic substrata concentrate these elements through their diet in their intestine. Tissues of wild fish aggregating around farm cages accumulate a greater number of these elements and with higher concentrations than farmed fish. Habitat, diet, ecological needs, fat content of fish, and protein expression may play an important role in these element differences between fish species. Fe in flathead grey mullet, As in surmullet, rainbow wrasse, grey gurnard and picarel and Hg in bogue may pose a risk for human health. Farmed and wild fish are good sources of P, K, Cr and Se while flathead grey mullet, picarel and comber are excellent sources of Ca and Se.

MO035

Metals in benthic macrofauna and biogeochemical factors affecting their trophic transfer to wild fish around fish farm cages

I. Kalantzi, Hellenic Centre for Marine Science / Institute of Oceanography; N. Papageorgiou, University of Crete / Department of Biology; K. Sevastou, Hellenic Centre for Marine Research / Institute of Oceanography; K. Black, Scottish Association for Marine Science; S.A. Pergantis, University of Crete / Chemistry; M. Tsapakis, Institute of Oceanography; I. Karakassis, University of Crete / Department of Biology

Macroinvertebrates may accumulate metals from their environment through various pathways, including water, diet and/or sediment, through respiratory and digestive surfaces. However, the effectiveness of metal uptake from these sources may vary according to ecological needs and metabolism of animals and also contamination gradients in water, food and sediment as well as other factors such as salinity, temperature and interacting agents as well as species-specific physiological attributes. Furthermore, metal accumulation may differ according to the ability of macrofaunal taxa to tolerate environmental disturbance. Benthic macrofauna behavior can also influence the pathways, rates and relative balance of sedimentary biogeochemical cycles, mainly through their bioturbation activities. It is known that sediments beneath and close to fish farms are enriched with metals and other elements because of either sedimentation of metals contained in fish feed and fish faeces or due to changes in metal behavior related to modification of environmental conditions. Wild fish are often attracted by fish farms feeding on unused feed pellets but also on benthic invertebrates. In the present study, benthic macroinvertebrates and wild fish aggregating in the vicinity of four Mediterranean fish farms were sampled. Concentrations of metals and other elements were measured in macrofaunal taxa and in fish tissues (muscle, liver, gills, bone, gonad, stomach, intestine, stomach content). Biological and geochemical characteristics play an important role in metal accumulation in benthic invertebrates, and consequently in metal transfer to higher trophic levels. Macroinvertebrates accumulated lower concentrations of most metals and elements than their respective sediment, except As, P, Na, Zn and Cd. Elemental concentrations of benthic organisms increased with increasing sediment metal content, except Cd, and with % silt, refractory organic matter and chlorophyll-*a* of sediment due to the influence of sediment geochemistry on metal bioavailability. Tolerant species were found to accumulate higher concentrations of most metals and elements, except for Cd, than equilibrium species. The ecological and morphological characteristics of the benthic invertebrates can affect the bioaccumulation of metals and elements in macrobenthos. Hg and P were found to increase their concentrations from zoobenthos to of wild fish aggregating around fish cages feeding on macrofauna.

MO036

Contaminants from boatyards - a risk to the coastal ecosystem

B. Eklund, D. Eklund, Stockholm University

The contamination in pleasure boat yards has been investigated. Measured concentrations of copper, zinc, lead, mercury, cadmium, tributyltin (TBT), the 16 most common polycyclic aromatic hydrocarbons (∑16 PAHs) and the seven most common polychlorinated biphenyls (∑7 PCBs) from investigations at 34 boat yards along the Swedish coast have been compiled. The maximum concentrations were 7 700 for Cu, 10 200, for Zn, 40 100 for Pb, 188 for Hg, 18 for Cd, 107 for TBT, 630 for carcinogenic PAHs, 1 480 for ∑16 PAHs and 3.8 mg/kg DW for ∑7 PCB; all 10-2000 higher than the Swedish environmental qualitative guidelines. In addition, the mean of the median values found at the 34 places shows that the lower guidance value for sensitive use of land was exceeded for the ∑7 PCBs, carcinogenic PAHs, TBT, Pb, Hg, and Cu by a factor of and 380, 6.8, 3.6, 2.9, 2.2 and 1.7, respectively. The even higher guideline value for industrial use was exceeded for the ∑7 PCBs and TBT by a factor of 15 and 1.8, respectively. TBT, PAHs, Pb, Cd and Hg are prioritized substances in the European Water Framework Directive (WFD) and should be phased out as quickly as possible. Because of the risk of leakage from boatyards, precautions should be taken. The high concentrations measured are considered to be dangerous for the environment and human health and highlight the urgent need for developing and enforcing pleasure boat maintenance guidelines to minimize further soil and nearby water contamination.

MO037

Impact of boat maintenance on biofouling

M. Bighiu, Applied Environmental Science; A. Eriksson Wiklund, B. Eklund, Stockholm University

Biofouling of boat hulls is a natural process that can have detrimental economic and environmental effects because it leads to increased fuel consumption and CO_2 emissions and facilitates the transport of invasive species to new habitats. The extent of biofouling (expressed as dry biomass) on 102 leisure boats in Stockholm, Sweden was assessed in relation to different boat maintenance methods such as the use of copper, zinc or biocide-free paints and the use of boat washers. The influence of other factors such as sailing time, boat age or boat position in the harbor was also investigated. No significant difference was found in the amount of fouling on boats using copper, zinc or other biocide-free paints. This result is rather surprising because it is not in accordance with the common knowledge that copper paints are the most efficient antifouling paints currently available. Moreover, the common belief that sailing often reduces the amount of biofouling does not apply in our study, because there was no relationship between the sailing time and the degree of fouling. As regards the different areas of the boat hull, the stern was affected by biofouling to a significantly higher extent than the port or the starboard side. In addition, boats which have been positioned with the stern towards East have significantly higher fouling than those positioned towards North or West. Since the

light conditions affect the growth of photosynthetic organisms (which were the predominant fouling organisms in our study), we recommend considering the boats' position in harbors for minimizing fouling. Moreover, boats that have used boat washers had significantly lower fouling at the end of the season so we encourage the use of this environmentally-friendly maintenance method. These results suggest that the maintenance habits ought to be reconsidered and that the use of toxic compounds in antifouling paints may be unnecessary for leisure boats in the northern part of the Baltic Sea.

MO038

Lethal and sub-lethal effects of aniline to the copepod Tisbe battagliai: simulation of Hazardous and Noxious Substances (HNS) spill profiles

M. vannoni, Cefas; T. McGowan, Cefas Lowestoft Laboratory; D. Sheahan, J. Aldridge, Cefas; M. Kirby,

Hazardous and Noxious Substances (HNS) are chemicals, other than oil, which have potential hazards to human health or to other organisms. Over the last decades transportation of HNS by sea has increased significantly so emphasizing the need to be prepared to respond to incidents involving HNS. The European project ARCOPOLplus recently identified 23 HNS as having high likelihood of being present in martime transport incidents suggesting these be the focus of efforts to fill data gaps. This study therefore considered aniline, one of the 23 chemicals listed as priority for improving existing data. The volume of chemical spilt at sea and its behaviour (e.g. whether it dissolves or evaporates) and location (e.g. open sea or nearshore) are major factors influencing extent of any impact. Chemical modelling can predict the dispersion and fate of a chemical during a spill and this can be linked to toxicity data to predict likely impact. However toxicity data is usually derived from constant exposure studies and under natural conditions this rarely occurs. This work investigates the acute and chronic toxicity of aniline using representative spill profiles. The copepod *Tisbe battagliai* was chosen as test species because of its sensitivity and importance in the marine food webs. Tests included short exposures (1 and 2 hours), simulated varying concentration spill profiles (based on modelling data) and constant exposures. Different life stages of Tisbe were used to obtain acute and sub-lethal effects data. Results indicate that aniline does not have prolonged effects even after exposure to relatively high peak concentrations providing exposure duration is short e.g. 1-2 hours. Preliminary data indicate realistic spill profiles may have negligible impact for chemicals that do not accumulate or persist due to the relatively rapid dilution that occurs at offshore locations. At near shore locations more significant effects are predicted. This study indicates that use of standard toxicity data could lead to an overestimate of the potential harm caused by a spill. Whilst such a precautionary approach is recommended where there are significant threats to marine resources, more realistic assessments may be of value in predicting actual levels of impact and potential for recovery. *This work has been carried out with support from Defra, Project MERR C5905 and in the frame of ARCOPOLplus project, co-funded with ERDF through the Atlantic Area Transnational Programme*

MO039

Integrated assessment of the chemical environmental state of Cartagena Bay (NW Mediterranean) in relation to marine chemical contamination

C. Martinez-Gomez, B. Fernandez, J. Valdes, C. Navarro, M. Albentosa, J.A. Campillo, V. Leon, J.M. Benedicto, Instituto Español de Oceanografia; T. Burgeot, IFREMER / BIOGEOCHIMIE ECOTOXICOLOGIE; D. Vethaak, DELTARES

Cartagena bay (SE Spain) was chosen as study case of the NW Mediterranean region to demonstrated the suitability of the integrated marine environmental monitoring of chemicals and their effects proposed by European experts (ICON Project) for the North Sea. Coordinated sampling of key environmental matrices (surface sediment, fish and mussels) was performed in Autumn 2008, considering biogeographical characteristics. The benthic fish red mullet (*Mullus barbatus*) and mussels (*Mytilus galloprovincialis*) were used as target species. Due to scarcity of mussel populations on natural substrates, mussels were transplanted for a period of six weeks in a coastal site located in the bay. Contaminant related-biomarkers of exposure and effects were measured in both target species. Contaminant concentrations were analyzed in sediments and biota but also and sediment-passive samplers. *In vivo* embryotoxicity bioassays were performed using sediment elutriates. Additionally, a battery of *in vitro* gen reporter bioassays covering different mode of action of toxicants were also investigated using extracts of the sediment-passive samplers. Chemical and biological data were assessed against its corresponding assessment criteria, and then integrated over levels of matrix. Assessment was expressed with varying levels of aggregation (contaminants, bioassays, biomarkers of exposure and biomarkers of effects) to graphically represent the proportion of different types of determinants exceeding either level of assessment criteria. Subsequently, data were aggregated further into a single schematic showing the proportion all determinants that exceed assessment criteria in Cartagena bay, using a threshold of 95%

MO040

Hepatic histopathological findings in Ariidae Cathorops spixii submitted to anthropogenic metal exposure in two Brazilian estuaries

J.d. Azevedo, Federal University of Sao Paulo / Biological Sciences; H.N. Silbiger, University of São Paulo USP / Biological Oceanographyc; J.E. Sarkis, IPEN - Nuclear and Energy Research Institute / Center for Chemical and Environmental Technology; J.F. Dias, University of São Paulo USP

Histopathological lesions are used as biomarkers of contamination by organic and inorganic chemical compounds in the aquatic systems and can reflect chronic effects in sentinel species. Previous work demonstrated the ability of the catfish *Cathorops spixii* to be an efficient bioindicator species for metals contamination. Cananéia estuary is considered an area of environmental protection, and UNESCO World Heritage Site (WHS), and as such, several biomonitoring studies in the São Paulo State, Brazil, use this estuary as a reference environment due to the fact that it shows very little human influence. However, in recent years, several studies have been indicating the presence of some toxic metals, for instance mercury (Hg) and lead (Pb). Santos-São Vicente estuary has a long history of contamination and release of pollutants, for instance metals such as Pb, Cd, Ni, Mn, Cu and Hg as a consequence of different anthropogenic activities such as petrochemical, metallurgical and harbor. In the present work, histopathological lesions in liver were investigated in the Ariidae *Cathorops spixii* from Cananéia estuary and in two sites affected by industrial and domestic sewage disposal, in order to verify the possible impact of the introduction of metals to the local fish species. Fish were collected in Cananéia and in two sites of the Santos São-Vicente estuary subjected to different anthropogenic influence (industrial and domestic sewage disposal). Biometric data (total length –TL- and total weight -TW- of each fish) was obtained and the fish dissected by collection of the hepatic liver to histopathological and metals analysis. Analyses of Hg was performed by FIA-CV AAS and Pb, Cd, Cu, Mn and Ni concentrations were determined by ICP MS. Fish from Cananéia showed higher levels of Mn (80%) and Cu (66%). The most important injuries observed in individuals from the impacted areas (industrial and domestic sewage) were the presence of necrotic areas, hepatitis focal, vacuolization and rupture of blood vessels. The occurrences of lesions were significantly higher in individuals from domestic and industrial area than in fish from Cananéia estuary ($p>0.05$).

MO041

Influence anthropogenic pollution on starfish's Asterias rubens at different level of biological organisation

A. Poromov, Lomonosov Moscow State University / Translational Science Laboratory

There is growing concern that the invertebrate test organisms commonly employed in the field of aquatic ecotoxicology may not be sufficient to accurately screen for the possible deleterious effects of contaminants discharged into the marine environment. The use of echinoderms has been proposed to redress this problem, due to their ecological importance and their evolutionary closeness to the chordates. A suite of biomarkers which operated at different levels of biological organization (sub-cellular, cellular, individual and community level) were identified for use with the common starfish *Asterias rubens* L. *and copepods Scottomyzon gibberum* Scott. Adult females of *S. gibberum* live on starfish body surface of and can induce galls formation. Specimens of the *Asterias rubens* were collected near the Biological station of Lomonosov MSU at Kandalaksha Bay of the White Sea during the summers of 2012-2013 years from 10 points which characterized by different anthropogenic pollution level and ecosystem type. Indexes which widely used in parasitological studies were calculated to characterize population: prevalence, intensity, abundance, aggregations indexes and also copepods location on host body. The population increases from mid-June to late September. Population heterogeneity is shown, which can be attributed to anthropogenic load and ecosystem type. Population of copepods on starfishes increases with depth. Ecotoxicity bioassay was made with 4 different heavy metals composite concentration in salinity 21 and 25.7 ‰ (normal). Micronuclei induction was estimated in coelomic fluid phagocytic cells, which are caused by both chromosome breakages and spindle apparatus dysfunction. Low salinity level case of decrease proliferation of phagocytic cells and bacterial infection. In normal salinity heavy metals cause a dose-dependent increase the number of micronuclei. Habitat reaction (righting behaviour) shows adaptation for influence heavy metals and salinity after 10 days of experiments.

MO042

Early maternal exposure to estrogens cause malformations in eelpout fry

J.E. Morthorst, University of Southern Denmark / Department of Biology; N. Brande-Lavridsen, B. Korsgaard, University of Southern Denmark; P. Bjerregaard, University of Southern Denmark / Biology

Recently malformations among eelpout (*Zoarces viviparous*) fry living in North European coastal areas with high anthropogenic input have been observed. The specific chemicals or group of chemicals causing the observed malformations are unknown. In oviparous fish species fry malformations can be induced by exposure to chemicals including endocrine disrupters. The eelpout is a viviparous and stationary fish and maternal exposure to chemicals including endocrine disrupters might explain the fry malformations observed in nature. The aims of the present experiments were to investigate mother-offspring interactions e.g. teratogenic effects upon maternal exposure to 17β-estradiol (E2) and environmental chemicals with known endocrine disrupting effects; the PAH pyrene, the synthetic hormone 17α-ethinylestradiol and 4-*t*-octylphenol and to investigate if a teratogenic window for E2 could be established. Wild pregnant eelpout with newly fertilized eggs were either (1) exposed continuously to 17β-estradiol (E2) (5.7-133 ng/L), 17α-ethinylestradiol (≈20 ng/L), 4-t-octylphenol (≈6.25-50 ng/L) or pyrene (≈ 500 ng/L) for six weeks or (2) exposed to E2 during different weeks of pregnancy to investigate if a teratogenic window for E2 could be established. None of the chemicals influenced the survival of the females. Plasma levels of E2 and the yolk protein precursor vitellogenin were increased in mothers exposed continously to E2 and an increased abundance of fry malformations was observed at the highest E2 concentration. If exposure takes place within the first two weeks of pregnancy ovarian function and fry development is severely affected. As eelpout are fairly stationary during their pregnancy individual populations could be differentially influenced as the local exposure scenarios are different and most likely vary from year to year.

MO043

Effects of 107Ag and 63Cu stable isotope sublethal exposure in oysters Crassostrea gigas using cell and tissue level biomarkers

A. Rementeria, UPVEHU; M. Mikolaczyk, L. Lanceleur, G. Blanc, Université Bordeaux / UMR EPOC; M. Soto, University of Basque Country / Zoology and Animal Cell Biology Research Centre for Experimental Marine Biology and Biotechnology PIEUPVEHU; B. Zaldibar, University of the Basque country UPVEHU / oology and Animal Cell Biology; J. Schafer, Université Bordeaux / UMR EPOC

Marine bivalves such as oysters are known to be good sentinel organisms. Their sedentary way of life and their ability to accumulate pollutants with little metabolic transformation make them ideal organisms for this purpose. Many marine pollution monitoring programs have used oysters to obtain chemical and biological data. Previous studies have demonstrated that cell and tissue level biomarkers are reliable and sensitive tools to assess organisms and environmental health status. Silver and copper are both elements present in the environment that in high concentrations impair biological processes and affect environmental health status and even human health. In order to study the biological effects produced by these metals and their accumulation kinetics and pathways, a 28 d laboratory experiment was carried out. Oysters were exposed directly to a range of environmentally relevant concentrations of silver and copper stable isotopes (^{107}Ag and ^{63}Cu). The use of stable isotopes allowed precise and rapid tracing metal accumulation in five different tissues. Different endpoints were measured in oysters at different levels of biological complexity including induction of metallothioneins, alterations in lipofuscin and lipid contents, metal accumulation and distribution in tissues and target cells, histopathological alterations at tissue level, and changes in organism condition and mortality rates. Results indicated higher mortality in oysters exposed to high concentrations of Ag and the combination of Ag and Cu together with a general decrease in the condition index after 20 days of exposure. Histological examination and quantification of alterations in the digestive gland indicated a higher digestive gland atrophy and over time tissue degeneration in animals exposed to high Ag and Cu concentrations. A similar pattern was observed for histopathological lesions. Moreover, in the more affected oysters a progressive arrest of the gamete development occurred. Autometallographical screening for metal ions indicated the presence of metals mainly in the gill epithelium, the digestive cell lysosomes and in the basal layer of the digestive tubule epithelium of oysters exposed to Ag and Cu. In general, obtained results indicate a close relationship between metal exposure at environmentally relevant concentration levels and physical degradation of oysters. MO044

Intertidal biota and the rock shell populations after accidents of Fukushima Dai-ichi Nuclear Power Plants

T. Horiguchi, National Institute for Environ Studies / Center for Environmental Risk Research; H. Yoshii, National Institute of Radiological Sciences; S. Mizuno, Fukushima Prefectural Government; T. Ohara, National Insittute for Environmental Studies; H. Shiraishi, National Institute for Environmental Studies / Research Center for Environmental Risk

To investigate possible adverse ecological effects caused by accidents of the Fukushima Dai-ichi Nuclear Power Plants (1F) accompanied with big earthquakes and Tsunami in March 2011, we conducted field surveys at intertidal zones of 43 sites along the coastal line of eastern Japan from April to August 2012. The number of species of intertidal biota seemed to get smaller as the site was close to 1F. No rock shell (*Thais clavigera*) specimens were collected at 8 sites of Fukushima prefecture, which were located around 1F. Because the rock shell specimens were collected at many sites in Miyagi and Iwate prefectures, where enormous Tsunami attacked, it is unlikely that smaller number of intertidal species and no rock shell specimens around 1F were caused by Tsunami. Contaminated cooling water leached from the nuclear reactors to the sea may have given any impacts to intertidal biota including the rock shell populations around 1F.

MO045

Application of European C14 method (OECD 215) on early life stage fish growth response to marine species Dicentrarchus labrax

A. Tornambe, L. Manfra, S. Canepa, ISPRA; A. Rotini, Tor Vergata University; F. Oteri, G. Martuccio, ISPRA; M. Mannozzi, ISPRA / ISPRA; A. Cicero, ISPRA

C14 Method as described in the EU Regulation 440/2008 on juvenile fish growth toxicity test is designed to assess the chronic effects of chemicals on freshwater species. However, the use of a marine species widely distributed and well known as the sea bass can be considered more appropriate to assess the impact of dispersed chemical substances in the sea. The purpose of this study is to analyze the adaptation of the C14 Method to the marine species *D. labrax*. Toxicity tests were carried out exposing *D. labrax* to sodium dodecyl sulfate (SDS). This is an anionic surfactant widely employed in industry, agriculture, and domestic use and therefore it is found in abundance in the environment, particularly in the sea. Adaptations of the method are reported and results of growth response of *D. labrax* to the SDS are showed.

MO046

Evaluation of the detoxification mechanisms of metals in aquatic organisms by characterization of hepatic metallothionein (MT)

J.d. Azevedo, Federal University of Sao Paulo / Biological Sciences; J.E. Sarkis, IPEN - Nuclear and Energy Research Institute / Center for Chemical and Environmental Technology; S.O. Rogero, J.R. Rogero, IPENCNENSP

Metallothionein (MT) has been thoroughly used as a biomarker of metals exposure. MT is a low-molecular-weight protein which has many sulfhydryl groups due to the large amount of cysteine in the molecule. These sulfhydryl groups bind a variety of metals and therefore, presumably, make them less toxic to other cellular constituents. However, biochemistry aspects of the protein as isoforms identification and quantification and their specific mechanisms of detoxification in sentinel species are, as yet, weak. Previous data showed that fish, such as the catfish *Cathrorops spixil*, are efficient bioindicator species to metals contamination in coastal aquatic areas under anthropogenic influence, for instance inputs of Pb, Cd, Hg, Ni, Fe, Zn, Cu and Mn. *C. spixil* is the most common catfish in the Brazilian coast and has a feeding habit mainly of materials and organisms upon the sediment, where the availability of contaminants is high. In order to understand intrinsic aspects of the detoxification process of toxic metals in sentinel species in natural and anthropogenic conditions, hepatic samples of *C. spixii* were collected in a non-polluted (Cananeia), as well as one polluted, estuary (Santos-São Vicente) and tested under different assays in order to establish an effective bioanalytical technique to purify the protein like-MT, identify and quantify the specific isoforms and the metal contents in the cell. Therefore, hepatic samples were submitted to ultracentrifugation, thermocoagulation and a chromatographic purification and identification of MT isoforms by size-exclusion-HPLC and anion-exchange-HPLC, respectively. The elution of the protein was made with online UV/Vis detection. Metals in hepatic cytosols were also quantified by HR-ICP-MS. Obtained results showed that the established protocol of bioanalytical technique was effective to purify MT-like protein by SE-HPLC and to identify its isoforms by AE-HPLC. With these analytical strategies, it was possible to identify two kinds of MT isoforms (MT-1 and MT-2) in the *C. spixil*. Fish MT-1 from polluted areas showed a strong linkage with the levels of Cu, Hg, Pb, Fe and Ni suggesting that the MT-1 is an effective biomarker of metal contamination.

MO047

Assessment of the environmental impact of the dumped chemical warfare agents at the Baltic Sea using caged blue mussels (Mytilus trossulus)

R. Turja, Finnish Environment Institute SYKE / Marine Research Centre; M. Brenner, Alfred Wegener Institute / Biosciences; J. Barsiene, University of Vilnius; K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre

Chemical weapons dumped into the sea after World War II possess growing concern for the marine environment; metal shells of different chemical munitions lying on the bottom are severely corroded and dangerous contents pollute the sediments. Chemical warfare agents (CWAs), such as mustard gas and various arsenic-based compounds (e.g., Clark I and Adamsite) and their degradation products have been detected in noticeable concentrations in sediments at the major dumping sites at the Baltic Sea. Blue mussel caging approach was applied to assess environmental impact of thousands of tons of CWAs at the main dumping site at the Bornholm Basin. Due to the patchy occurrence of the CWAs in the sediments mussel caging method was chosen to deploy the organisms exactly at sites where high CWA concentrations were detected in sediments and to one reference site. Biomarkers representing different biological functions including antioxidant defence, biotransformation, neurotoxicity, lysosomal membrane stability, geno- and cytotoxicity, cellular energy allocation and condition index were investigated. Moreover, tissue concentrations of different CWAs and the possible metabolic

derivatives of these compounds were analysed in mussels together with “classical” contaminants, such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs) and trace metals. Further, mussel cages were equipped with salinity, temperature and oxygen sensors to follow the fluctuations in the environmental parameters during the two and half month caging time. Environmental parameters indicated mixing of the near bottom water in the lower water layer where the cages were deployed (at 60 meters). Significant biomarker responses were observed at the two contaminated sites compared to the reference site indicating CWA induced effect on molecular and cellular level; however the possible anaerobic conditions and lower food availability in deep waters led to decreased bioenergetic status of the caged mussels. Results of the still on-going chemical analysis will be employed together with the biomarker responses and environmental data in the multi-level integrated impact assessment of the area.

MO048

Tracking Munitions in Two Coastal Marine Ecosystems Using Stable Nitrogen Isotopes

M. Ballentine, R.W. Smith, University of Connecticut / Department of Marine Sciences; T.S. Ariyarathna, University of Connecticut / Dept of Marine Sciences; P. Vlahos, University of Connecticut / Departments of Marine Sciences and Chemistry; c. tobias, University of Connecticut / Department of Marine Sciences

2,4,6 – trinitrotoluene (TNT) and hexahydro – 1,3,5 – trinitro – 1,3,5 – triazine (RDX) are munitions compounds used widely at U.S. Department of Defense facilities, including coastal military installations. TNT and RDX are introduced in many countries into coastal marine ecosystem through manufacturing, detonation, and legacy munitions. TNT and RDX and their derivatives are U.S Environmental Protection Agency priority pollutants and have known toxicity for terrestrial and aquatic species. While both TNT and RDX have been shown to persist in freshwater environments and soils less is known of the fate and transport in marine systems. As part of a multi-scale marine ecosystem fate and transport study, a time series of large mesocosms that includes sediments and varying trophic levels of biota were spiked with nitrogen isotope labeled TNT and RDX separately. TNT and RDX bulk concentrations (and associated breakdown products) in seawater and biomass were measured using extraction methods in acetonitrile and GC/ECD. Nitrogen isotope values were obtained using EA/IRMS methods. TNT was found along with 2 primary derivatives 4 amino-dinitrotoluene (4-ADNT) and 2 amino-dinitrotoluene (2-ADNT). The derivatives were measured often 2 times higher than the total TNT in all biota. The ratio of 4-ADNT to 2-ADNT measured in the biota was often found to be 3:1 respectively. In the majority of the biota, the ^{15}N attributed to the munitions continued to rise through the time series. Only 2 to 3 percent of the total ^{15}N in the biota can be attributed to munitions measured in the tissue. When normalized to mass, the macro algae contained 50 percent or more of the total ^{15}N in the system. This large percentage is most likely due to the uptake of ammonium measured in the system. RDX and four main derivatives were measured with MNX the only derivative that was measured with any consistency. The ^{15}N attributed to the RDX was taken up quickly but did not continue to rise over the time series. Approximately only 3 percent of the ^{15}N can be attributed to RDX. The total μmol of ^{15}N normalized to mass was typically equal in each species in the system. In both ecosystem experiments, the TNT and RDX were shown to enter into unknown pathways within the biota. Further studies with amino acids and single organ system analysis are in progress to better understand the fate of the munitions.

MO049

Using stable nitrogen isotope tracer to investigate ecosystem distribution and fate of munitions compounds in marine environments

c. tobias, R.W. Smith, M. Ballentine, University of Connecticut / Department of Marine Sciences; T.S. Ariyarathna, University of Connecticut / Dept of Marine Sciences; P. Vlahos, University of Connecticut / Departments of Marine Sciences and Chemistry

The explosives 2,4,6-trinitrotoluene (TNT) and hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) are common munitions constituents. Within the contiguous 48 United States, there are approximately 41 active military installations located within the coastal zone. Munitions operations on active facilities consist of storage, loading, packing, and live fire exercises. Several active installations maintain live fire ranges in intertidal and subtidal marine habitats. The number of active bases, combined with decommissioned facilities with historical TNT /RDX contamination, and offshore munitions dump sites indicate the probable likelihood that multiple marine habitats at multiple locations receive exposure to TNT and RDX. Currently there is little ecosystem-level understanding of how munitions compounds behave in marine environments. How fast are these compounds assimilated into various organisms or trophic levels, under natural conditions? How fast are they transferred between trophic levels, mineralized, cycled, or stored? What ecosystem characteristics control the partitioning of these compounds between pathways that remove them, and pathways that store / recycle them? Here we present an approach using ^{15}N isotope labeled munitions compounds that may provide resolution to some of these ecosystem-scale questions. Theory and application is presented as well as results of multi-trophic level experiments that demonstrate the efficacy of using this approach to resolve magnitudes of compound breakdown vs accumulation in biomass. Additional keywords: Stable isotope, nitrogen, munitions, ecosystem, marine

MO050

Tracing the cycling and fate of the explosive 2,4,6-trinitrotoluene in a simulated sandy coastal habitat with a stable isotopic tracer, 15N – [TNT]

R.W. Smith, University of Connecticut / Department of Marine Sciences; T.S. Ariyarathna, University of Connecticut / Dept of Marine Sciences; M. Ballentine, University of Connecticut / Department of Marine Sciences; C. Cooper, Wilfrid Laurier University / Department of Marine Sciences; c. tobias, University of Connecticut / Department of Marine Sciences; P. Vlahos, University of Connecticut / Departments of Marine Sciences and Chemistry

TNT is produced and used in massive quantities worldwide. In the United States, TNT contamination has been observed in ground and surface water, as well as in soils. Even more alarming is the quantity of unexploded ordnance (UXO) dumped directly into the ocean over the last 100 years. Despite the extensive studies that exist on the behavior of TNT in the environment, including solubility, transport, transformation, remineralization, and biological uptake, several factors limit our understanding of the ultimate toxic potential of this compound in marine systems. Specifically, it is difficult to predict how these individually defined controlling factors will interplay in an environment as physically, biologically and chemically complex as the coastal ocean. Here, we introduce both single pulse and steady-state additions of isotopically labeled ^{15}N-[TNT] into a previously constrained aquaria-scale simulated coastal marine habitat and perform extensive enrichment analysis of both dissolved and particulate organic and inorganic N fractions in order to provide the most complete view to date of the partitioning and the ultimate fate of TNT in seawater. ^{15}N enrichment was observed in all measured fractions, including NO_x, NH_3, N_2, bulk sediment N, suspended particulate N (PN), and N present in biological tissue. The production of reduced derivatives, 2amino-dinitrotoluene (2a-DNT), and 4amino-dinitrotoluene (4a-DNT), was also observed. Principal components analysis (PCA) indicates two distinct reaction pathways, the first proceeding through reduction to reduced derivatives, stripping off of ammonia functional groups, and subsequent denitrification. The second, as yet undefined, is initialized through surface sorption to suspended particulate matter (SPM). In fact, the concentration of SPM is shown to control the overall breakdown rate of TNT in the system. A mass balance of measured ^{15}N fractions accounts initially for 80% of all introduced ^{15}N, but only 20% at the end of the experiment. We provide evidence through PCA and correlations with reduced derivatives that the “missing” ^{15}N represents the buildup of an unmeasured derivative.

MO051

Toxicity of PAHs in Mytilus galloprovincialis at different stages of gametogenesis measured by physiological biomarkers

C. González-Fernández, Spanish Institute of Oceanography / Marine ecosystems; M. Albentosa, J. Campillo, Instituto Español de Oceanografia; L. Vinas, Spanish Institute of Oceanography; A. Franco, Instituto Español de Oceanografia; J. Bellas, Centro Oceanografico de Vigo / IEO (Instituto Espa?ol de Oceanografia)

Large scale marine monitoring programs have some difficulties in the assessment of the effect of pollution in the biological responses of the organisms, mainly due to the high temporal and spatial variability of marine ecosystems. In this context, gametogenic cycle has to be considered due to its influence on the biomarkers normally used as indicators of pollution. The gonadal development of the wild mussel (*Mytilus galloprovincialis*) used as a sentinel species in the N-NW Spanish marine pollution monitoring Program, takes place between late autumn and winter and spring where main spawning occurs. During late summer and early autumn, there is a storage of reserves that will be used for the next gametogenesis. The aim of this study was to evaluate the effect of the reproductive status of the mussels on their response to the polycyclic aromatic hydrocarbon (PAH) fluoranthene (FLU), measured by several physiological biomarkers as clearance rates, absorption efficiency and respiration rates which can be integrated in the scope for growth SFG index. Exposure of mussels to FLU was carried out twice: when the mussels are in resting time (September-October) and when the gonads are completely full (March). Mussels were exposed to two nominal FLU concentrations (3 and 60 $\mu g\ L^{-1}$) for 3 weeks. Then, mussel physiological rates were measured under the same standardized laboratory conditions (temperature and food concentration) for both reproductive stages. Biological characterization of mussels from a biochemical, histological and anatomical point of view was performed.

MO052

Comparative study on PAH metabolites in cod (Gadus morhua) from the Baltic Sea to Greenland

U. Kammann, Thünen Institute / Institute of Fisheries Ecology

Polycyclic aromatic hydrocarbons (PAH) are important environmental contaminants which may lead to reproductive effects or formation of liver tumours and associated lesions in fish. Therefore PAH and their metabolites are part of international monitoring programmes and recommendations. In the light of the

European Marine Strategy Framework Directive monitoring data and assessment criteria are brought together for evaluating the environmental status in marine and coastal regions. Low contaminated reference areas are needed to calculate background assessment criteria. Cod (*Gadus morhua*) is a fish species widely distributed in northern European waters and therefore a suitable object for environmental assessments on a big regional scale. Cod samples collected between 2006 and 2012 in the western Baltic Sea, North Sea, Barents Sea, Norway and Greenland were included in the present study. To assess the PAH exposure of fish, the concentration of the main metabolite 1-hydroxypyrene was determined in bile by HPLC with fluorescence detection. The results show that PAH metabolites can be used to create a spatial overview on PAH contamination in northern European marine fish such as cod. Concentrations of PAH metabolites differed according to sampling region. Lowest concentrations were found in cod caught close to Greenland suggesting this area as reference region to develop new background assessment criteria.

Pacheco, University of Aveiro / Dept of Biology; C. Vale, IPMA Instituto Portugues do Mar e da Atmosfera

Coastal lagoons with symptoms of eutrophication often present low oxygenated waters, particularly during the night. Under such conditions, sediment could release metals to the overlying water. Thus, inhabitant organisms may accumulate metals that were provided from the sediment, which could be on the basis of physiological responses. In summer 2007, a field transplantation experiment was performed with *Carcinus maenas* in three short-term exposures (8 h) along 24 hours, namely: (i) period 1 - between 15:30-23:30, corresponding to a day-night exposure; (ii) period 2 – between 23:30-07:30, corresponding to a night exposure entirely; (iii) period 3 – between 07:30-15:30, corresponding to an exclusively day exposure. The study was carried out in a coastal lagoon with eutrophication symptoms and moderate contamination by metals (Óbidos lagoon, Portugal), addressing particularly a confined area (Barrosa branch – BB) where metals could be released from the sediment at night. Crabs werecaptured at a reference site (Lower lagoon - LL) and transplanted to BB and caged, in order to evaluate the accumulation of metals (Fe, Zn, Mn, Pb, Ni) and oxidative stress responses (CAT, SOD, GR, GST, GSH_t, LPO) in hepatopancreas. Selenium levels were also determined in hepatopancreas due to its antioxidant role as cofactor. The results were compared with a group caged at LL. Crabs transplanted to BB exhibited higher levels of metals in hepatopancreas, particularly Zn (after period 1), as well as Ni and Se (after period 3), reflecting the higher metal availability at this site. The enhancement of Se levels at BB could be regarded as a protective mechanism against a pro-oxidant pressure. Moreover, as a sign of toxicity, a CAT activity reduction and increased LPO levels were recorded in hepatopancreas of crabs transplanted to BB site (after period 3), matching with the higher accumulation of Ni. Overall, it was demonstrated that the intermittence on metals bioavailability can be detected. Metals accumulation was not completely synchronised with physiological changes or with the peak of metals in water, revealing the complexity of biological responses. Nevertheless, oxidative stress endpoints measured in crab hepatopancreas showed their efficacy as early warning markers and, due to the nature of the biochemical phenomena involved, appear as particularly adequate to detect fluctuations on water quality in a hour time scale.

MO054

Baseline of oxidative stress biomarkers in natural populations of sea anemones in three ecoclimatic marine environments

J.R. Gadelha, University of Aveiro / Biology department; A.O. Arana, Universidad Autónoma de Campeche EPOMEX; P.B. Gomes, Universidade Federal Rural de Pernambuco / Biology; J.R. Von Osten, Universidad Autónoma de Campeche EPOMEX; F. Morgado, CESAM Universidade de Aveiro / Biology; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies

Biomarkers have been widely used for the assessment of exposure and/or effects to environmental contaminants. The oxidative stress biomarkers is common used on marine organism to assess the stress levels and effects and damages caused by natural, chemical and/or physical stressors. The sea anemones target species has a wide distribution in the Atlantic and coastal areas where it may be found in both contaminated and pristine areas. It is abundant and plays a key role in coastal ecosystems. Therefore, this species seems to be a good candidate to be used as a sentinel species. It may then be assumed that six co-generic species *Anemonia sargassensis, Anemonia sulcata, Actinia bermudensis, Actinia equina, Bunodossoma canjicum* and *Bunodossoma caissarum* could be a valid tool for evaluation studies of environmental contamination. The main aim of this study is to detect significant basal levels activity GST, GR, CAT, LPO and SOD measurable as a biomarker environment, on natural populations of sea anemones, under environmental stress and sources of pollution in three different climatic scenarios. In order to detect different levels of contamination in the sampling locations, validating the combination of the activity levels of these enzymes with different pollutants sources and verify the spatial and interspecific variations.

MO055

Effect of nutritive condition on antioxidant biomarkers: Consequences for large-scale monitoring programs

J. Campillo, Instituto Español de Oceanografia; C. González-Fernández, Spanish Institute of Oceanography / Marine ecosystems; J. Bellas, Centro Oceanografico de Vigo / IEO (Instituto Espa?ol de Oceanografia); M. Albentosa, Instituto Español de Oceanografia

The monitoring of the chemical pollution and their biological effects carried out by the Spanish Oceanographic Institute along the N-NW coast of Spain is based on the study of both the accumulation and biomarker responses in mussel (*Mytilus sp*). This program covers more than 2,500 km of coastline, and is characterized by a great variability of environmental conditions such as food availability and quality, temperature or salinity. In previous works we have found that environmental conditions variability produce spatial differences in mussel nutritional status which seems to mask the biomarker responses to pollution. A laboratory study was designed in order to establish the levels of antioxidant biomarkers in mussels within a gradient of energetic status. Several experimental trophic conditions were simulated by regulating daily food ration from very negative to highly positive energy balances. Levels of catalase (CAT), glutathione transferase (GST), glutathione reductase (GR), and lipid peroxidation (LPO) in the digestive gland were used as biomarkers of oxidative stress. Relationships between mussel body reserves (lipids, proteins and carbohydrates) and levels of those biomarkers have been established. Comparisons between biomarkers levels found in the field study at N-NW coast of Spain with those from laboratory simulations were used to assess the effect of the mussel nutritive condition on these biomarkers. In general, nutritive condition is clearly affecting the level of the antioxidant biomarker.

MO056

The effect of pharmaceutical compounds on the larval development of the estuarine shrimp Palaemon longirostris

E. GONZALEZ-ORTEGON, INSTITUTE OF MARINE SCIENCE OF ANDALUSIA / ECOLOGY AND COASTAL MANAGEMENT; L. Gimenez, L. LeVay, School of Ocean Sciences Bangor University; E. NIETO, INSTITUTE FOR MARINE SCIENCE OF ANDALUSIA ICMANCSIC / ECOLOGY AND COASTAL MANAGEMENT; M. Hampel, Instituto de Ciencias Marinas de Andalucía CSIC / Consejo Superior de Investigaciones Cientificas; J. Blasco, Inst Ciencias Marinas de Andalucia / ECOLOGY AND COASTAL MANAGEMENT

The most frequently detected pharmaceuticals compounds (PhCs) in coastal waters comprise the anti-inflammatory and analgesic diclofenac sodium (DS), the lipid regulator clofibric acid (CA) and the fungicide clotrimazole (CLZ). These compounds are on the priority lists of the UK Environment Agency and the Oslo and Paris Commission (OSPAR). We studied mixture effects of CA and DS, and individual effects of CLZ on growth, development and body mass of larval stages of the estuarine shrimp *Palaemon longirostris*. Drug residues found in the aquatic environment usually occur as mixtures. Thus, an accurate prediction of the mixture toxicity of DS and CA could be indispensable for environmental risk assessment. In previous studies on marine larvae of *P. serratus* identified toxic effects of CLZ on larval survival and larval growth, and these effects depended on osmotic and food stress. Not all species should respond to environmental change in the same form; thus, we must also consider the inter-specific life histories to test the potential toxicity effects of CLZ in the estuarine shrimp *P. longirostris*. The larvae were exposed to environmental relevant concentrations (DS: 36-70, CA: 9.6-40 and CLZ: 0.07-0.14 $\mu g\ L^{-1}$) and concentrations that are higher than those measured in nature in order to explore thresholds that lead to sublethal effect (DS: 700 ; CA: 400 μg and CLZ: 4 $\mu g\ L^{-1}$). Larvae were reared at two temperatures (18°C and 24°C) and two salinities (20 and 32 PSU). At environmental concentrations, these PhCs had no effect on larval survival and development of *P. longirostris*.The effects of these PhCs on larvae appeared at high doses. At both experimental temperatures, CA increased duration of development in *P. longirostris* larvae. Toxicity of the mixture DS and CA, increased duration of development at the lowest experimental temperature and reduced number of stages and growth rate. These effects were similar to CLZ effects, but in this case the number of stages had a significative reduction. DS, at high doses and warmer waters, decreased growth rate and larval body mass. In particular, CLZ, CA and the mixture of CA and DS increased intermoult duration required to reach the first juvenile stage. Acknowledgements This work was carried out while E. González-Ortegón was MC Pstdoctoral Fellowship from the EC.Furhter financial support was provided by SCARCE (Consolider-Ingenio 2010 CSD2009-00065).

MO057

Effects of tralopyril, triphenylborane pyridine and capsaicin on zebrafish

embryos (Danio rerio)

I.B. de Carvalho Benta Santos Oliveira, University of Aveiro CESAM / Biology department; K.J. Groh, Eawag / UTOX Environmental Toxicology; C.M. Barroso, CESAM & Department of Biology, Aveiro University; K. Thomas, NIVA / Product Metabolism; M.J. Suter, Eawag Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology

Biofouling is associated with problems such as the deterioration of diverse aquatic equipment and installations, the dissemination of invasive species or increased fuel consumption by ships due to frictional drag. Antifouling (AF) biocides are added to paints to boost their efficacy for biofouling prevention. These antifouling paints (AFP) are economically highly relevant. However, often they were found to harm the environment. This obvious conflict is far from being solved. Restrictions in the use of AF biocides imposed by the Biocidal Product Regulation (BPR, Regulation EU No. 528/2012) are resulting in an increased need for environmentally safer alternatives. Such substitutes are expected to maintain a good AF performance, but at the same time to undergo a rapid transformation to less toxic products once released into the water. Moreover, they should have low toxicity to non-target organisms as well as low tendency to bioaccumulate. The current work investigates the toxicity of emergent AF biocides, tralopyril, triphenylborane pyridine (TPBT) and capsaicin, to the early life stages of the non-target model organism, zebrafish. The endpoints assessed were the mortality and the occurrence of sublethal effects. Based on preliminary data, tralopyril seems to be the most toxic among the three compounds as the LC_{50} ranged between 6 and 8 μg/L. For TPBP, LC_{50} is within 500 and 750 μg/L, while capsaicin seems not to induce mortality up to 1mg/L. Sublethal effects included slow heart rate, heart edema, deformations of the axis and non-inflation of the swim bladder. Tralopyril showed a clear dose-response in the inhibition of the swim bladder inflation at 120 hpf (EC_{50} around 2 and 4 μg/L) and seldomly was found to cause lordosis. TPBP also influenced the inflation of the swim bladder, but data are not as consistent as for tralopyril. Moreover, TPBP induced heart edema starting from 100 μg/L and diminished the heart rate at 250 μg/L and above. For capsaicin, the most relevant effect was the increase in the heart rate of embryos exposed to 100 μg/L and above. Since the mode of action of the investigated compounds is incompletely understood, the causes underlying the reported sublethal effects remain unclear. With the ongoing proteomic analysis we hope to reveal differentially expressed proteins that may provide first insights into the molecular mechanisms accountable for these toxic effects.

MO058

Pharmaceutical residues and occurrence of antibiotic-resistant bacteria in Hong Kong surface waters and sediments

M.B. Murphy, University of Hong Kong / Dept of Biology Chemistry; K. Wan, Hong Kong Polytechnic University / Department of Health Technology Informatics; M.M. Tsui, City University of Hong Kong and State Key Laboratory in Marine Pollution / Department of Biology Chemistry; J. LAM, The State Key Laboratory in Marine Pollution; M.V. Boost, Hong Kong Polytechnic University / Department of Health Technology and Informatics

The occurrence of pharmaceuticals in the natural environment due to extensive human use and release is well-documented. The widespread occurrence of these compounds in both abiotic and biotic samples has raised concern about their potential toxic effects with regard to both ecological and human health, especially regarding the increasing global prevalence of drug-resistant bacterial strains. We reported previously that wastewater treatment plants (WWTPs) in Hong Kong release high concentrations of some antibiotics into the local marine environment; likewise, clinical studies have shown that the rate of antibiotic resistance among some bacterial strains is very high in the city. This study measured pharmaceutical concentrations and bacterial counts/prevalence in seawater and sediment samples collected in Victoria Harbor, into which many WWTPs discharge their effluents, as well as more open marine waters and an aquaculture zone. Preliminary data show that 11 antibiotics were detected at the sampled locations, with azithromycin, cefuroxime and erythromycin-H_2O detected in all of the seawater samples at concentrations ranging from 5.6-181.6 ng/L. Lincomycin was only detected in Victoria Harbor samples, while clarithromycin was detected both in Victoria Harbor and the aquaculture zone, but not in more open marine waters. Preliminary bacterial analysis of the seawater samples indicated high total bacterial counts in the majority of the samples, while selective culture of Gram-negative rod-shaped bacteria isolated from the seawater samples indicated the presence of several resistant bacterial species, including potentially pathogenic *Vibrio* and *Aeromonas* species. Ampicillin-resistant species were found in all of the seawater samples, and species resistance to chloramphenicol and tetracycline were also present. Total bacterial counts in sediments were approximately 10-fold lower compared to those in seawater samples. Ampicillin- and tetracycline-resistant species were also identified in the sediments after selective culture was performed, though not all of the samples contained resistant bacteria, and resistant species were generally less prevalent in the sediment samples compared to the seawater samples. The results of these analyses will be used to carry out a probabilistic risk assessment of pharmaceuticals in the Hong Kong environment to determine their potential ecological risks.

MO059

Population level effects of embryo development disorders in the benthic key species Monoporeia affinis

R. Martin, Stockholm University / Department of Applied Environmental Science ITM; M. Breitholtz, Inst för tillämpad miljövetenskap / Department of Applied Environmental Science ITM

Embryo development in the Baltic Sea key species *Monoporeia affinis* has been used for decades as an indicator of environmental health in regional assessments and in the Swedish national monitoring program. Several laboratory and field studies have shown that this indicator can be successfully applied to monitor and assess effects of chemical substances as well as other environmental stressors, such as decreased oxygen levels and increased water temperature. Currently, embryo development in *M. affinis* is put forward as a potential core set indicator for chemical pollution assessment and monitoring in the Baltic Sea under the European Commission's Marine Strategy Framework Directive. Despite this indicator´s extensive use in environmental monitoring and assessments it is currently not known whether developmental effects translates in to effects at higher levels of biological organization. In this study we have developed matrix models that describe several populations of *M. affinis*, both in the Baltic Sea and in large lakes of Sweden. We use these models to estimate potential long-term effects on population densities due to increased rates of embryonic development disorders in *M. affinis*. Our results show that long term abundances could be drastically reduced at levels of disturbed embryonic development that have been observed at multiple sites along the Baltic Sea coast. Furthermore, we will present results, based on these models, which assess potential population effects of different future scenarios of increased chemical pollution, eutrophication and temperature.

MO060

Sediment associated-toxicity in the Mar Menor lagoon (SE Spain) under calm and stormy conditions: applicability of the sea-urchin embryotoxicity test

C. Martinez-Gomez, C. Navarro, E. Arques, V. Leon, Instituto Español de Oceanografia

Toxicity of surface sediments from the Mar Menor Lagoon (SE, Spain) was assessed by using the sea-urchin embryotoxicity test (SET). The bioassay was performed exposing fecundated eggs of *Paracentrotus lividus* to whole sediment and sediment elutriates, simulating calm and stormy conditions respectively. Results clearly indicated that storm/windy events may substantially increase the water toxicity associated with sediment resuspension through the water column in the Mar Menor Lagoon.

MO061

Baltic Sea sediments in a comprehensive ecotoxicological investigation using chemical analysis and a bioassay battery

N.C. Niehus, Hamburg University of Applied Sciences HAW / Department of Environmental Engineering; J. Loerks, RWTH Aachen University / Institute for Environmental Research Biology V; S. Lang, Hamburg University of Applied Sciences / Environmental Technology; T. Seiler, RWTH Aachen University / Institute for Environmental Research Biology V; H. Hollert, RWTH Aachen University / Institute for Environmental Research; G. Witt, HAW Hamburg / Department of Environmental Engineering

The Baltic Sea, one of the largest brackish water bodies, is considered to be an exceptionally sensitive and endangered marine ecosystem. The average residence time of Baltic Sea water ranges between 25 and 50 years, thus facilitating the accumulation of pollutants in sediment. From thirteen sites in the Baltic Sea sediment cores were collected and separated in different layers. For a ecotoxicological risk assessment chemical analysis and as set of bioassays were performed. Ecologically relevant processes such as bioconcentration and baseline toxicity of hydrophobic organic carbons (HOCs) are mostly controlled by the chemical activity (a) of the substance rather than by its total concentration in the sediment. To calculate chemical activity and thus to predict bioconcentration and baseline toxic potential of the contaminant mixture the freely dissolved concentrations (C_{free}) of PAHs and PCBs were measured in sediment pore water using solid phase microextraction, a passive sampling technique based on the principle of equilibrium partitioning. Sediment toxicity was assessed by comparing $\sum a$ to the range of a known to produce baseline toxicity. Extracts from PLE (pressurized liquid extration) and mild methanol/water extraction, were investigated for their dioxin-like potential (EROD-assay with the RTL-W1 cell line) and their embryotoxic impact on *Danio rerio* (Fish embryo toxicity test – *FET*). A sediment contact test (SCT) with *Danio rerio* using native sediments was performed for comparison. The mild methanol/water extracts revealed no effects in this study. In contrast the PLE extracts gave strong embryotoxic potential and indicated dioxin-like activity for all investigated sampling sites. Interestingly, PLE extracts in the FET showed similar results as the SCT using native sediments. Chemical analysis of PLE extracts was carried out to calculate ChemTEQ values. The results were compared to the BioTEQ values from the EROD-assay. ChemTEQ values up to 24 % of the RTL-W1 BioTEQ values were found. Results showed that despite elevated total PAH and PCB concentrations in Baltic Sea sediments, HOC bioavailability was limited since the estimated $\sum a$ was well below baseline toxicity levels. However, Baltic Sea sediments have a toxic potential as the bioassays showed. In addition to the baseline toxicity the bioassays reflect very specific toxicities. Furthermore the methanol/water extraction might not be useful for representing bioavailable HOCs.

MO062

Comparison of trace elements bioavailability and their bioaccumulation in Manila clam Venerupis philippinarum from Atlantic and Mediterranean estuarine environments.

A. Sfriso, Ca Foscari University of Venice / Department of Molecular Sciences and Nanosystems; F. Minello, L. Gobbo, Ca' Foscari University of Venice / Molecular Sciences and Nanosystems Department; S. Chiesa, University of Aveiro CESAM / Biology; R. Freitas, Biology; E. Figueira, CESAM University of Aveiro; S. Breda, Ca' Foscari University of Venice / Molecular Sciences and Nanosystems Department; C. Bettiol, Department of Molecular Sciences and Nanosystems; E. Argese, Ca' Foscari University of Venice

The concentrations of trace elements in aquatic environments may be enhanced in seafood, posing risks for human consumption. Among seafood products, marine bivalves play an important role in terms of exploitation and production. The Manila clam *Venerupis philippinarum* (Adams and Reeve, 1850) represents almost 20% of molluscs production worldwide, being Europe the second producer after China. In Europe, the species was introduced in many coastal systems, like Ria de Aveiro (Portugal) and Venice Lagoon (Italy), due to its high reproductive and growth rates and its tolerance to a wide range of environmental conditions. Health risks for human consumption can occur in these high harvested estuarine environments, since illegal fishing and collection of clams are occurring over regulated activities. In Venice Lagoon, the highly polluted industrial zone of Porto Marghera represents a dangerous site; in Aveiro Lagoon, the main toxicological concern is related to the Laranjo basin, an Hg highly polluted area prohibited to fisheries activities. Total metals and metalloids concentration is widely used as standard for food safety, although bioavailability of trace elements in the biota depends on the partition of elements into several geochemical phases of the sediments. The distribution in the different phases depends specifically on parameters such as pH, redox conditions, temperature, occurrence of organic matter and benthic activity. Thus, total element determination does not always yield sufficient information for an accurate risk assessment. As a consequence, speciation data are required to get knowledge about mobility, bioavailability and impact of elements on biological organisms. The aim of this study is to compare the data obtained for total metal content, bioavailability of trace elements in sediments of harvested areas, and bioaccumulation of trace elements in *V. philippinarum* in two different estuarine areas. In particular, the partitioning of trace elements by geochemical speciation was investigated to check for any similarity in behavior of trace elements depending on environmental conditions, and to understand the mechanisms of trace elements bioaccumulation in clams coming from two different harvesting regions. These data are fundamental to assess the risk for human consumption of clams, both for Aveiro and Venice coastal communities.

MO063

Monitoring toxicity of PAHs in intertidal sediments for five years after the Hebei Spirit oil spill in Taean, Korea

L. Chang-Hoon, NeoEnBiz Co; J. Lee, NeoEnBiz Co / Institute of Environmental Protection and Safety; C. Sung, NeoEnBiz Co; S. Moon, S. kang, Institute of Environmental Protection and Safety, NeoEnBiz Co; J. Lee, NeoEnBiz Co; U. Yim, Korea Institute of Ocean Science Technology / Oil & POPs Research Group; W. Shim, Korea Institute of Ocean Science and Technology / Oil and POPs research group; S. Ha, Korea Ocean Research and Development Institute

Ecotoxicological monitoring of intertidal sediments was performed for 5 years after the *Hebei Spirit* oil spill in Taean, Korea. Sediment toxicity was observed on most of the beaches 4 months after the spill and later decreased rapidly to nontoxic levels 8 months after the spill. The concentrations of total polycyclic aromatic hydrocarbons (TPAHs) in the sediments ranged from 2 to 530,000 ng/g during the monitoring. More than half of the samples containing residual oils within sediment layers exhibited significant toxicity 5 years after the *Hebei Spirit* oil spill. Using a logistic regression model, the median lethal concentration of TPAHs to amphipod *Monocorophium uenoi* was estimated to be 36,000 ng/g. From the 63 chemistry and toxicity data, the effect range low, effect range median, threshold effect level, and probable effect level were derived to be 3,190, 54,100, 2,480, and 29,000 ng/g, respectively. The relative compositions of the PAH groups indicated that the weathering process is still ongoing.

MO064

Organic priority substances and microbial processes in marine coastal sediments (Adriatic Sea, Italy)

n. ademollo, IRSACNR; L. Patrolecco, Water Research Institute Italian National Research Council; S. Amalfitano, IRSA CNR; W. Dellisanti, Water Research Institute IRSACNR; P. Mancino, Water Research Institute Italian National Research Council; L. Langone, S. Miserocchi, CNR Institute of Marine Science ISMAR; A. Zoppini, IRSA CNR

PERSEUS EU FP7 Project (Policy-oriented marine Environmental research in the Southern European Seas) aims to identify the interacting patterns of natural and human-derived pressures on the Mediterranean and Black Seas, to assess their impact on marine ecosystems and, using the objectives and principles of the Marine Strategy Framework Directive as a vehicle, to design an effective and innovative research governance framework based on sound scientific knowledge. In the frame of this Project (subtask 1.3.3 ADREX: Adriatic and Ionian Seas Experiment), a preliminary monitoring survey has been conducted in the Adriatic Sea (Italy) in order to verify the occurrence and the variation of selected classes of organic priority substances in sediments and to study the structural and functional characteristics of native bacterial communities. The study site represented a good natural laboratory sensitive to climate variability and human pressure, owing to the semi-enclosed nature of the Adriatic Sea and to the increasing trend of human activities in the coastal regions. During the cruise ADRI 13, (November 2013) three coastal areas sited in front of Ancona, Gargano Promontory and Bari were sampled. In every sites surface sediment was collected and in selected sites dated sediment cores were analysed. The compounds investigated are included in the list of organic prioritary substances: PAHs, bisphenol A (BPA), alkylphenols (Aps), selected on the basis of the anthropogenic pressure. The extraction-clean-up was performed by ultrasonic bath with the appropriate solvent followed by analytical determination with LC-MS and HPLC UV-fluorescence. The microbiological analysis of bacterial abundance was determined by epifluorescence microscopy and flow cytometry; the rate of bacterial carbon production was determined by measuring the ^{3}H-leucine uptake rate and the community respiration was estimated by the measurement of the *electron transport system* (ETS) activity. Microbes associated with marine sediments play an important role in the C-flux being responsible for the transformation of organic carbon (autochthonous and allochtonous) into biomass. The results of these studies will improve the knowledge on how the environmental factors and the human pressure influence the changes in the assimilation or mineralization rates, affect the C-flux in the trophic chain and potentially the fate of organic pollutants.

MO065

Toxicity tests to assess the possibility to use clam harvesting waste as gabions filler material in the Venice lagoon

g. cipolato, Molecular Sciences and Nanosystems Department; A. Zuin, Ca Foscari University of Venice / Molecular Sciences and Nanosystems Department; D. Minetto, Cà Foscari University; G. Libralato, Veneto Nanotech SCpA / Department of Environmental Sciences Informatics and Statistics; S.-. Manente, Ca Foscari University of Venice / Department of Molecular Sciences and Nanosystems; A. Volpi Ghirardini, University Ca Foscari of Venice; G. Ravagnan, Ca Foscari University of Venice

Since *Venerupis philippinarum* introduction in 1983, clams harvesting has spread enormously in the Venice lagoon. This kind of activity include an operational phase that consists in sieving all material previously collected, picking out clams of commercial interest. During this phase operators obtain a waste that they usually discard in lagoon. This kind of waste, that is mostly composed by shells, wood, sediment and different kind of inert materials, can accumulate in specific areas in the long term. The accumulation of this material on the seabed, particularly in Manila clam (*V. philippinarum*) fishing concessions, can interfere with fishing operations by reducing the collection efficiency. According to Institutions responsible of fisheries resources supervision in the Venice lagoon, the management of this waste has become an urgency. So we worked to define a strategy in order to collect this material and to avoid the need for its disposal; finally we took into account the possibility to use it as a filler, in total or partial replacement of the material currently used, for manufactured devices such as gabions and submerged barriers to be used for banks protection and consolidation in the Venice lagoon as well as for beaches protection from erosion. In order to deepen the knowledge of this kind of material, potentially usable for engineering works aimed at morphological and environmental protection and to establish if it can be considered safe and stable, we planned a series of ecotoxicological experiments. Toxicity tests were carried out on a matrix composed of environmental waste material mainly made by clams resulting from the sieving phase and collected during a sampling campaign in the Venice lagoon. It was necessary to investigate the presence of any toxic effects, due to release phenomena and synergies, through the implementation of three batteries of ecotoxicological tests with three different species (*Vibrio fisheri*, *Mytilus galloprovincialis* and *Phaeodactylum tricornutum*). We evaluated the toxicity of elutriates obtained from homogeneous matrix representing wastes obtained from *V. Philippinarum* fishing in different collection areas in the Venice lagoon. This work provided the opportunity to better define all characteristics of this material that can't be derived from simple multielemental chemical analysis: particularly we could predict his behavior once reinserted into the aquatic compartment inside gabions or submerged barriers.

MO066

Toxicity test method based on the inhibition of reproduction in Ulva: revision

M. Kim, H. Choi, Incheon National University; A. Park, J. Park, Incheon National University / Life Sciences; S. Jo, Incheon National University; E. Park, GreenPioneer; Y. Kim, Department of Marine Science College of Natural Sciences Incheon National University / Marine Science; T. Han, Incheon National University / Marine Science

During progression of reproduction the green macroalga, Ulva, shows a visible change in thallus colour from yellow green (vegetative stage) to dark olive (reproductive stage) and then to white at the terminal stage of reproduction. The extent of reproduction is determined by image analysis measurements, and/or visual inspection of the proportion of the reproductive area out of the total area. Based on the inhibition of reproduction in Ulva, a new bioassay method was developed. Setting up the *Ulva* bioassay is quite easy and the test is simple to follow. However, the visual quantitative scoring of the discoloration of the disks was not easy and was often subjective since the exact "vegetative" vs "reproductive" parts are sometimes hard to differentiate although a difference between the treatments and controls can be clearly seen. We have therefore conducted a wide range of experiments using various measurement techniques including:a) Spectrophotometric measurements of *in vivo* thallus and photosynthetic pigments (after solvent extractions), b) fluorometric measurements of *in vivo* thallus and photosynthetic pigments (after solvent extractions), c) Staining of reproduced thallus portions. d) Green color recognition image analysis. So far, we have found that the use of staining method using Evans blue and the use of image J programme is worth exploring further as it would complement the present methodology. by providing more objective criteria for discerning the color change due to reproduction.

MO067

Parhyale hawaiensis as an alternative organism in marine toxicity tests

A. Santos, FACULTY OF TECHNOLOGY UNICAMP / LEAL Laboratory of Ecotoxicology and Environmental Microbiology; M. Artal, University of Campinas UNICAMP; G.d. Umbuzeiro, FACULTY OF TECHNOLOGY UNICAMP / LEAL

With the increase of urbanization and pollution of coastal areas around the world, there is a concern with the preservation of marine environment. Therefore representative organisms of this environment, which will serve as a source of data for the regulatory field and protection of aquatic life are important. *P. hawaiensis* is an marine amphipod that occurs in the American coast and it is easy to grow in laboratory conditions. The aim of this study was to verify if *Parhyale hawaiensis* could be an alternative organism in toxicity testing. A basic protocol for culturing and testing was elaborated, testing was performed with a reference substance (Zinc Sulphate) and the developed protocol was applied to test two textile azo dyes CI Disperse Red 1 and CI Disperse Red 13. The average LC50 (96h) for zinc was 0.60 mg $Zn.L^{-1}$ (±0.30, n=9). Tests showed good repeatability and sensitivity to Zn was similar to the response with other amphipods. Disperse Red 13 presented an average LC50 (96h) of 1.94 $mg.L^{-1}$ (±0.94, n=3). LC50 (96h) for Disperse Red 1 varied from 3.1 to 37.4 $mg.L^{-1}$ (n=4). Precipitation of the Disperse Red 1 was the probable cause of the highly variable LC50. The results of this study suggest that *Parhyale hawaiensis* is a promising organism for ecotoxicological studies. More experiments are being conducted for optimization of culturing and testing conditions. **Acknowledgments:** FAPESP Thematic Project 2008/10449-7, Scientific Innitiation fellowship 2012/09512-1 for AS; Master fellowship 2010/14033-0 for MCA.

MO068

Optical detection of low concentrations of toxic nano particles in saline solutions; approximating a pseudo-estuary environment

n. hma salah, University of Plymouth; D. Jenkins, L. Panina, Plymouth University; R. Handy, University of Plymouth / School of Biomedical and Biological Sciences

One of the holy grails of environmental toxicology is the detection of very low concentrations of toxic nanoparticles in the aquatic environment. In the laboratory there are established methods that enable these measurements to be made. SEM can be used with a sample where the liquid has been evaporated and this can reveal size, shape and chemical composition. Dynamic light scattering or laser diffraction are also established methods of particle characterisation;providing both size and shape information. SPR is label free detection, but particles can be identified as the SPR angle is directlty determined by the particles refractive index. In this paper we explore the detection of Ag nanoparticles and silver nitrate in de-ionised water and saline solution. The detection of the SPR phase response is also measured, to explore extended detection sensititivty.

MO069

Physical stressor (temperature tolerance) test exposition with temperate sea anemone Actinia equina, a climatic and environmental changes simulation

J.R. Gadelha, University of Aveiro / Biology department; P.B. Gomes, Universidade Federal Rural de Pernambuco / Biology; F. Morgado, CESAM Universidade de Aveiro / Biology; J.R. Von Osten, Universidad Autónoma de Campeche EPOMEX; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies

Atlantic and Mediterranean warming-related diseases outbreaks and species shifts have recently been documented. Biomarkers of short-term effects on the health or resistance of organisms are necessary to assess and understand mechanisms affecting marine biodiversity. Until now, climate warming has been studied at population or community level. Here we offer a better understanding of such phenomena at the organism level, using anatomic-morphological approaches to interpret effects of natural physical stressors, according to behavioral patterns. Elevated temperature and solar radiation, are now recognized as the primary environmental stresses that lead to mass benthonic organisms, mainly cnidarian bleaching. Intertidal organisms are subject to a variety of stresses such as desiccation, water temperature, acidification, increase salinity, nutrient limitation, space competition and predation. The thermal stress is a knower such a mainly environmental factor responsible for climatic and environmental changes. This study takes a behavioral (morphological and anatomic parameters) to identifying changes soon after exposure to physical stressors in the temperate sea anemone *Actinia equina*. Sea anemones were subjected to variation temperature range over a 96 h period. Behavior endpoints were divided to be differentially showed as a function of temperature stress. Behavioral patterns analysis placed the differentially ecological functions in a wide range of categories including tentacle flexion, tentacle retraction, column cavitation, peristome depression and oral disc flexion. This suggests that the early stress response to elevated temperature involve essentially all aspects of same chemical reactions, in this case we observed an receptors functioning and the frequency of open-close oral sea anemones, tentacles and columns anatomic alterations to detect earlier the effects of physical stress induction.

MO070

Characterization of an ecdysone receptor and a vitellogenin-like cDNA in the estuarine copepod eurytemora affinis

c. Boulange-Lecomte, Laboratory of Ecotoxicology; B. Xuereb, University of Le Havre; E. LEGRAND, Laboratory of Ecotoxicology; A. Duflot, University of Le Havre / Laboratory of Ecotoxicology; J. Forget-Leray, Univesity of Le Havre / Laboratory of Ecotoxicology

Aquatic ecosystems constitute the chemicals' final destination. Since 2000, European Union acts to protect them through the Water Framework Directive. One of the chemicals' families targeted by this directive is pesticide. Their endocrine disruption (ED) potential is well documented in vertebrates. However, few data are available on invertebrates whereas they represent 95% of the wild fauna. The development of specific tools to diagnose ED exposure and/or effects in invertebrates is then required. Among candidate biomarkers, the induction of the female-specific vitellogenin (VTG) protein in males is standardly used, in particular in fish. Moreover, in arthropods, sexual maturation and molting are controlled by the hormone ecdysone which acts through its cognate receptor, the ecdysone receptor (EcR). In this context, the present study consists in developing Vtg and EcR assays in the sentinel crustacean *Eurytemora affinis*. This widespread calanoid copepod is considered as a key species in the food-web of temperate estuaries. We isolated both Vtg and EcR cDNAs in *E. affinis* using degenerated and RACE-PCRs. Phylogenetic analysis of Vtg revealed that the identified gene is an ortholog of the *vtg2* gene. The VTG shares a low amino acid sequence identity with copepods (20%) and eumalacostracans (< 10%) whereas the EcR was moderately conserved in both subclasses (40%). The mRNA basal levels and fluctuations associated with life cycle were assessed by quantitative PCR in both males and females. Finally, in order to evaluate the relevance of the use of Vtg and EcR transcript quantifications as ED biomarkers, mRNA variations will be evaluated after exposure to model endocrine disruptors.

MO071

Development of a humpback whale cell line as a versatile tool for in-vitro toxicity assessment

M. Burkard, Griffith University / Southern Ocean Persistent Organoic Pollution Program; K. Schirmer, Eawag / Environmental Toxicology; D. Whitworth, The University of Queensland / School of Veterinary Science; S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program SOPOPP

Persistent Organic Pollutants (POPs) are widely produced chemicals characterized by their persistence, bioaccumulation, toxicity and long-range environmental transport. Semi-volatile POPs are transported by air over long distances and are detectable in Antarctic biota. Polar foraging humpback whales *(Megaptera novaeangliae)* are dependent on a lipid-rich diet and accumulated lipid stores to undertake the longest migration and associated period of voluntary fasting, known in any mammal. This extreme life-history leads to an elevated sensitivity to the effects of POP toxicity. Measuring the toxicological impact of POPs on wild populations of humpbacks is a greater challenge in chemical risk assessment. Herein, we report for the first time the successful derivation of humpback whale cell cultures gained from integument tissue. Whales were biopsied late in their migration with flotation darts fired from an air rifle. Biopsies were collected from the dorsal area and measured 0.8 cm x 3.5 cm. Separated tissue was processed and maintained at 37°C, 5% CO_2 and in sterile growth medium. After 10 days the first cells grew out of tissue explants and high proliferation was observed after 20-25 days. The interface tissue lying between the epidermis and blubber section has shown to be most suitable. Obtained primary cells showed fibroblastic morphology with the typical fibrous and long-spindled form. Infinite long-term cell cultures will be obtained by mechanically induced mutations delivered by using a plasmid encoding the simian virus (SV 40) large T antigen. Early passaged and immortal cell cultures will be characterized according to morphology, growth, cryogenic preservation, metabolic activity, karyotype variations and fibroblast specific markers. This project aims to assess the toxicological impact of identified priority POPs in whale blubber by multiple- endpoint cytotoxicity assays. Humpback whale blubber and Antarctic krill extracts will serve as a novel exposure medium mimicking environmentally relevant mixtures representative of the main diet of adult and nursing young. The derived cell line will contribute a unique tool to study the effect of organic pollutants and provide more accurate and reproducible approaches for integrated toxicity risk assessment of humpback whales.

MO072

Biochemical responses induced by sucralose in Daphnia magna

A.E. Wiklund, Stocholm University / Department of Applied Environmental Science ITM; B. Liewenborg, Stockholm University / Department of applied environmental science; M. Adolfsson-Erici, E. Gorokhova, Stockholm University / Department of Applied Environmental Science ITM

Sucralose is an intensively sweet food additive derived from sucrose in a process where three hydroxyl groups are substituted for three chlorine atoms, producing a very stable substance and has become a popular substitute for sugar. Its exceptional stability in combination with high water solubility and popularity has resulted in measurable concentrations not only in recipient waters but also further out in the oceans. Animal and human studies have concluded that sucralose is safe for human use and earlier studies in aquatic organisms indicate low bioaccumulation potential and negligible acute/chronic toxicity. However, in non-standardized surveys, significant feeding and behavioural alterations have been reported in crustaceans, indicating possible sublethal behavioural effects. We hypothesized that these effects are related to alterations in acetylcholinesterase (AChE) and oxidative status and investigated changes in AChE and oxidative biomarkers (oxygen radical absorbing capacity, ORAC, and lipid peroxidation as thiobarbituric acid reactive substances, TBARS) in the crustacean *Daphnia magna* exposed to sucralose (0.0001-5 mg L^{-1} of). The results showed that the sucralose concentration was a significant positive predictor for ORAC, TBARS and AChE activities in the daphnids, although the biomarker responses followed non-monotonic concentration-dependent relationships. These responses support our hypothesis and suggest that exposure to sucralose may induce neurological and oxidative mechanisms that might have consequences for animal behaviour and physiology.

MO073

Filling the gaps in our knowledge of the effects of priority Hazardous and Noxious Substances on marine biota.

T. McGowan, Cefas Lowestoft Laboratory; D. Sheahan, Cefas; M. Kirby,

Hazardous and Noxious Substance (HNS) can be defined as any substance other than oil, which if introduced into the marine environment is likely to harm living resources and other marine life. There is a current paucity of knowledge about the effects of HNS on marine biota. Effort in filling information gaps should be focussed on priority HNS. Priority HNS can be selected on the basis of their known toxicity and carcinogenity, Bioaccumulation, Biodegradation, physico-chemical properties, incidence of previous spills and the likelihood of future spillage at sea. On this basis aniline, butyl acrylate, hexane and trichloroethylene were selected as priority chemicals to gather toxicity data Four marine species, *Tisbe batagliai, Pomatoceros triqueter, Fucus vesiculosus* and *Ceramium tenuicorne* were tested across a range of concentrations of these four priority HNS, test endpoints were mortality, embryonic development, growth and germination plus growth respectively. Tests were carried out in well plates and included solution renewal at regular intervals. Average LC50's (n=3) for *Tisbe* were 3.83 and 7.48mg/l for aniline and butyl acrylate respectively. *Pomatoceros* $EC_{50's}$ were 34.4 and 10.6mg/l for aniline and butyl acrylate. Hexane did not produce an effect for *Tisbe* but an EC_{50} of 172mg/l was calculated for *Pomatoceros*. Trichloroethylene did not produce an effect on either animal species. *Ceramium* showed an EC_{50} of 2.01mg/l for aniline whilst the three remaining chemicals elicited a positive growth response. *Fucus vesiculosus* was not affected by any of the chemicals at the concentrations tested. The different levels of effect between chemicals reflect their physico-chemical properties, hexane and trichloroethylene have the highest vapour pressures of the chemicals tested and so are likely to be lost from tests solutions more readily, this is reflective of the dynamic exposure conditions during a marine spill. Aniline is the most soluble of the chemicals tested and so produced the greatest effect. To the authors knowledge this is the first toxicological data for butyl acrylate on marine species, and the first results for any of the chemicals tested on marine algae species. These results can be used to develop post spill risk assessments for these chemicals. *This work has been carried out with support from Defra, Project CHIME E5204 and in the frame of ARCOPOLplus project, co-funded with ERDF through the Atlantic Area Transnational Programme*

Periphyton as bioindicator and community model – critical review, work in progress, future perspectives (P)

MO074

Development of a tiered approach for the characterization of periphyton on the genetic and functional level

L. Sgier, A. Kroll, Department of Environmental Toxicology; R. Behra, Eawag / Department of Environmental Toxicology

Periphyton is a taxonomically diverse and dynamic community of bacteria, algae, and fungi that provide essential ecosystem services to streams. The sensitivity of periphyton to environmental conditions including anthropogenic stressors makes it an important bioindicator. However, the complexity and dynamics poses a challenge to identifying appropriate descriptors, a useful level of detail and linking observed changes to understand underlying mechanisms. Against this background we aim to establish a tiered assessment of periphyton status using flow cytometry as first-tier followed by more detailed analysis of diversity and structure, as genetic diversity (community fingerprinting by Automated Ribosomal Intergenic Spacer Analysis [ARISA]), 3D structure (by Confocal laser scanning microscopy [CLSM]), and extracellular polymeric substances (EPS). Flow cytometry and corresponding data analysis are being adapted to the characteristics of periphyton to analyze changes of functional groups (i.e. organism size, growth form, pigmentation) representing biological characteristics that are connected to ecosystem functions. This data will be linked with information on the genetic diversity and taxonomic species composition as well as structure and extracellular chemistry and integrative endpoints such as biomass and photosynthetic activity. These suggested tiered approach to periphyton characterization will finally be applied to asses effects of the herbicide Terbuthylazin (TBA) and insecticide Imidacloprid (IMI), that in preliminary experiments have shown to affect periphyton. To this end, we have established an indoor colonization setup for long-term culturing of periphyton and exposure to chemicals and are in the process of the molecular diversity analysis, whereas we currently are developing primers specific for green algae, diatoms and cyanobacteria. Keyword: Periphyton, First-tier approach, Flow cytometry

MO075

Approaching real complexity: toxic impact of a mixture of diuron and propranolol on periphyton.

C. Bonnineau, UCLouvain / Institut des Sciences de la Vie; M. Ricart, Institute of Aquatic Ecology; L. Proia, Catalan Institute for Water Research ICRA; A.M. Romani, University of Girona / Institut dEcologia Aquàtica; S. Sabater, Catalan Institute for Water Research ICRA; H. Guasch, University of Girona / Institute of Aquatic Ecology

The efforts done in water resource management have allowed to reduce concentrations of priority pollutants in rivers; however an increasing number of chemicals can now be found at low concentrations in the aquatic environment. Where agricultural lands are next to urban areas, it is not rare to find known chemicals (herbicides, pesticides, etc...) in mixture with emerging pollutants (pharmaceuticals, personal care products or nanoparticules). To approach such a complexity it is essential to assess mixture toxicity on multi-species systems rather than assessing toxicity of single substance on single species. Within aquatic ecosystems, periphyton have been shown to be good indicators of toxicity and so represent a pertinent community model for ecotoxicology. From this perspective, acute toxicity of the herbicide diuron (photosynthesis inhibitor) and of the β-blocker propranolol (pharmaceutical product included in the list of emerging pollutants) towards periphyton has been assessed, both singles substances were tested as well as an equitoxic mixture. The effects observed on communities were also compared to effects observed on a single-specie population of the diatom *Cyclotella menegheniana* to highlight the pertinence and the power of the community approach. Indeed the community approach allowed revealing both direct and indirect effects of these 2 chemicals on periphyton. Indeed, photosynthetic efficiency was directly affected by diuron (EC_{50}=8.11 µg/L) but also by propranolol (EC_{50}= 3.1 mg/L). Moreover, the toxicity of these 2 chemicals in equitoxic mixture followed the Concentration Addition concept, indicating that even if propranolol is present at very low concentration in rivers, it would participate in the photosynthesis inhibition due to a mixture of diuron-propranolol. Each contaminant tested separately had no effet on bacterial activity (leucine-aminopeptidase extracellular enzyme activity) of periphyton nevertheless exposure to the mixture of diuron and propranolol provoked an increase in bacterial activity, reaching 140% of control activity at the highest concentration tested. This study illustrates the importance of the community approach to detect direct and indirect effects of toxic mixture on communities. Moreover, it highlights the

importance of mixture effects on ecosystems since even at low concentrations emerging pollutants can participate to the overall toxicity.

MO076

Experimental study of arsenic detoxification by periphyton

L. Barral, University of Girona / Environment; M. Rovira, G. Urrea, K. Magellan, E. Garcia-Berthou, University of Girona; H. Guasch, University of Girona / Institute of Aquatic Ecology

Arsenic pollution in water has an important impact in human and ecosystem health. In this experiment, arsenic detoxification was studied using periphyton or fluvial biofilm, an indicator of the ecological status of aquatic ecosystems, and the influence of the fish *Gambusia holbrooki*. These organisms were exposed for 13 days to 130 μg/L of arsenic (specifically As^V). The experiment comprised four treatments: control (fish), periphyton, arsenic, and periphyton with arsenic. Results showed a negative effect of arsenic on algal periphyton biomass and photosynthetic capacity. Arsenic also caused a stress effect in fish that resulted in increased ammonia excretion. Moreover, phosphate production via bacterial mineralization of fish faeces proved important. In conclusion, arsenic contributed to eutrophic conditions and impaired periphyton's purification capacity.

MO077

Influence of epipsammic biofilms on the retention and speciation of arsenic in freshwater environments

D.M. Prieto, University of Santiago de Compostela / edafologia y quimica agricola; D.A. Rubinos, University of Santiago de Compostela / Soil Science and Agricultural Chemistry; R. Devesa-Rey, University of Vigo / Centro Universitario de la Defensa; V. Pineiro, University of Santiago de Compostela / Unidad de Análisis Elemental RIADT; F. Diaz-Fierros, M.T. Barral, University of Santiago de Compostela / edafologia y quimica agricola

Arsenic (As) is a highly toxic metalloid which causes severe health problems worldwide. In aquatic environments, As may undergo transformations in its chemical form due to its interaction with mineral surfaces, but also through (micro-)biologically mediated reactions (biotransformation), which can strongly affect its mobility, bioavailability and toxicity. In this work, the influence of biofilms developed onto riverbed sediments on the (bio-)adsorption and/or (bio-)uptake, mobility, and (bio-)transformation of As^V was studied in microcosm systems. The results obtained were linked with toxicity assessment. Biofilm enhanced the removal of As^V from the water up to 91% of its initial concentration, while the removal was only 63% in the sediment without biofilm, after 14 days exposure. The presence of equimolar P concentrations enhanced the amount and the rate of As removal in the systems with biofilm, but had not effect in absence of biofilm. Biofilms strongly changed the speciation of As in the water column. For the sediment/biofilm system, aqueous As was mostly (~98%) As^V, whilst As^{III} accounted for 1.2% of total aqueous As. MMA^V and DMA^V represented only the 0.6 and 0.7% of total As. In contrast, As^{III} accounted for 39% of aqueous As when biofilm was absent, with the remaining (61%) in the form As^V. Methylated aqueous species were negligible in absence of biofilm. The distribution of As in the biofilm showed that ~30% of the As retained was “extracellular As” (extracted by phosphate), most of it (>99.5%) in the form of As^V. In contrast, in the absence of biofilm, phosphate extracted up to the ~65% of sorbed As, ~12% of which was As^{III}. In comparison with sterilized sediments, biofilms decreased the release to water of previously taken As from 8.5% in absence of biofilm to 4.3%. Most of the released As was As^V (94%), with only 3% as As^{III}, when biofilm was present. In contrast, As^{III} accounted for 21% of the total released As in the systems without biofilm. It is concluded that biofilms covering riverbed sediments play a key role in the cycling of As in river environments. They not only promote the removal of As^V from the water and decrease the subsequent remobilization of As, but also strongly affect the speciation of As in the water column by inhibiting the occurrence of aqueous As^{III}. This fact has noteworthy toxicological and geochemical relevance, as for remediation purposes, considering the higher toxicity and mobility of As^{III} species.

MO078

Kinetics of arsenite removal and (bio)transformation by a natural multi-species biofilm growth on riverbed sediments

D.A. Rubinos, University of Santiago de Compostela / Soil Science and Agricultural Chemistry; D.M. Prieto, University of Santiago de Compostela / edafologia y quimica agricola; V. Pineiro, University of Santiago de Compostela / Unidad de Análisis Elemental RIADT; M.T. Barral, University of Santiago de Compostela / edafologia y quimica agricola

Arsenite (As^{III}) is the form of As exhibiting the highest toxicity and mobility in natural media. Biofilms can play an important role taking up and biotransforming As to less toxic chemical forms. In this work, the uptake and biotransformation of As^{III} by a natural biofilm was studied at microcosms scale. Biofilm-rich sediment samples (~500 g wet weight, 35% wc) from the Anllóns River (NW Spain), which runs through an As-rich gold mining area, were incubated under controlled conditions. Cultivated biofilm was exposed to As^{III} (300 µg/L, 99%, 2.2 µgAs/L after 14 d) and fast (>95%, 8.0 µgAs/L, in 1 d). In these systems, As^V predominated in the water (65–95% of total As) at any time, whilst the fraction of aqueous As^{III} decreased from 34% after 2 h to 12% after 14 d exposure (271 ng As^{III}/L). The ratio As^V/As^{III} increased from ~2 (2 h) up to ~20 after 8 d exposure, suggesting oxidation of As^{III} took place. The concentration of DMA^V increased up to 615 ng/L after 14 d, suggesting detoxification by biomethylation also ocurred in the biofilm. Volatile As forms accounted for < 1% of removed As. In contrast, in the absence of biofilm the concentration of aqueous As was much higher (10–40 fold) and the removal kinetics was slower than in presence of biofilm. Besides, the ratio As^V/As^{III} increased with time from ~0.3 to ~2. As^{III} predominated (~75%) within 7d exposure, then As^V predominated onwards (65% at 14d). The concentration of As^{III} decreased with time from 63 (2 h) to 7 µg/L (14 days), whilst the As^V concentration was roughly constant at 15±4 µg/L. DMA^V was also found in these systems only after 8 d of incubation (563 ng/L). Biofilms growing on riverbed sediments not only rapidly take up soluble As^{III}, but they also greatly inhibit its occurrence in the water column; conversely this As form predominates when As^{III} is added to sediments devoided of biofilm. This presumably would reduce As toxicity and mobility, as make easier remediation actions.

MO079

Extracellular enzymatic activity of intact heterotrophic biofilms is decreased upon exposure to TiO2 nanoparticles and environmentally realistic UV radiation

H. Schug, Eawag Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology; C.W. Isaacson, Environmental Protection Agency Athens GA / ERD; A. Amman, Eawag Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology; L. Sigg, K. Schirmer, Eawag / Environmental Toxicology

The growing use of TiO_2 nanoparticles (TiO_2 NPs) will inevitably result in an increased environmental release of these materials, which may pose a risk to aquatic communities, such as heterotrophic freshwater biofilms. Depending on the water chemistry, TiO_2 NPs entering aquatic environments are prone to agglomeration and sedimentation. These processes result in increased exposure of biofilms to TiO_2 NPs, with thus far little knowledge about potential consequences. Since TiO_2 NPs are highly photoactive and generate reactive oxygen species (ROS) upon irradiation, one possible mechanism by which TiO_2 NPs may affect biofilm function is through ROS damaging components of the biofilm. As part of the biofilm matrix, extracellular enzymes might represent a first site of encounter for ROS produced by TiO_2 NPs.\nIn this work we investigate, if the extracellular activity of three enzymes essential for nutrient cycling in intact heterotrophic biofilms is decreased by simultaneous exposure to TiO_2 NPs and environmentally realistic UV intensities. Exposures were conducted with intact heterotrophic biofilms and TiO_2 NPs coated with different substances, including environmentally (rutin, tannic acid) and biologically relevant coatings (dopamine, phenylalanine, ascorbic acid) and more general coatings such as acidic and basic, nonpolar organic and molecules with different chromophores. These coatings mimic the variety of engineered and naturally occurring surface modifications that may be present for TiO_2 NPs and allow for the determination of the mechanism by which particle behavior is affected.\nExposure to UV and TiO_2 NPs coated with catechol and alizarin red and P25 decreased activity of the extracellular enzyme β – glucosidase (carbon – cycling). This was linked to the efficient production of ROS by these particles, with P25 being the most active. L – leucin aminopeptidase (nitrogen – cycling) activity was attenuated only by P25 exposure and the alkaline phosphatase (phosphorus – cycling) did not decrease following exposure to any of the TiO_2 NP and UV combinations. Comparing the impact on extracellular enzymes in intact biofilms with the effects observed for an isolated enzyme furthermore demonstrated that extracellular enzymes within the biofilm are better protected against ROS than enzymes present freely in solution. Overall, the significant decrease in activity may adversely affect nutrient acquisition by the biofilm and nutrient cycling in freshwater environments.

MO080

Ecotoxicology of polycyclic aromatic hydrocarbons (PAHs) at the eukaryote-prokaryote boundary: eukaryotic zoospores and PAH-degrading bacteria

R. Sungthong, Instituto de Recursos Naturales y Agrobiologia de Sevilla IRNASCSIC; J. Ortega-Calvo, Instituto de Recursos Naturales y Agrobiologia / Agroquimica y Conservacion del Suelo

This contribution focuses on the ecotoxicological impacts of PAHs in microbial communities formed by oomycetes and PAH-degrading bacteria. Here, we aim to evaluate the production, chemotaxis and settlement of eukaryotic zoospores produced by a rhizosphere oomycete, *Pythium aphanidermatum*, under a variety of ecological scenarios that mimicked the pollution by PAHs, including an active biodegradation by the bacteria. Among a common set of PAHs, phenanthrene and naphthalene revealed the strongest negative effect on the induction and production of the zoospores. The co-existence with PAH-degrading bacteria allowed zoospore production in these PAH-polluted scenarios. Zoospore chemotaxis was tested with selected environmental matrices (humic acids, organic solvents and root exudates). An attraction to these matrices occurred, or even it was enhanced, in the presence of PAHs (naphthalene and phenanthrene) and PAH-degrading bacteria. The zoospore settlement on the surface of liquid hydrocarbons (hexadecane and heptamethylnonane) occurred through selective sensing by the zoospores, which colonized hexadecane but not the methyl-branched hydrocarbon. Co-settlement with bacteria was only observed on hexadecane. We propose that the quantitative assessment of production and chemotaxis of the zoospores could be developed as a model to evaluate the environmental risk of PAHs. Furthermore, the community of both zoospores and bacteria seemed to provide a unique commensalism lifestyle in PAH-polluted ecosystem, which could be a strategy for further development of co-culture approaches in bioremediation of PAHs.

MO081

Development and validation of advanced monitoring systems for waterborne organic priority pollutants using microalgae biosensors

S. Gonzalez; D. Baquero, R. Lopez-Roldan, CETaqua Water Technology Centre; L. San Juan, J. Llorca, Labaqua; D. Solier, J. Dolera, Aqualogy Aqua Ambiente; C. De la Hera, D. Haigh, G. Orellana, Dpmt of Organic Chemistry Faculty of Chemistry Universidad Complutense de Madrid

The Water Framework Directive 2000/60/EC requires that Member States shall ensure the establishment and/or implementation of emission controls based on best available techniques. So far, the time-to-analysis required in commonly used monitoring methods determine a slow and in some cases ineffective response to detect accidental spills. In this context, it seems clear that cost-effective technologies and methodologies for real-time and average concentration monitoring will be necessary. For the real time detection a prototype has been developed with two main components a Filtration-Concentration-Clean Up unit (FCCU), which is devoted to concentrate the water sample up to 100 times using the principle of solid phase extraction, improving in this way the sensitivity; and the optical biosensor that contains selected microalgae immobilized into porous silicone (biomembrane) as the recognition element, and an O2-sensitive luminescent thin film as transducer of the photosynthetic status. A fiber-optic optoelectronic device, based on emission phase-shift measurements, interrogates the O_2 transducer that is placed in close contact with the biomembrane. The biosensor comprises a dual sensing head (Patent PCT/ES2008/000465). One of them contains a sensitive strain and the other a resistant one. To measure the average concentration a continuous flow integrative sampler (CFIS) was used. It consists of a peristaltic pump that flows the sample alternately through a sorbent material that retains the dissolved pollutants and a particle filter that retains the suspended particle, which facilitates the analysis of the priority pollutants in the dissolved fraction. Experiments were performed in a wastewater treatment plant located in the metropolitan area or Barcelona (Spain) where both devices were installed for half year. The monitoring system has been validated for quantification of seven target priority pollutants. Validations of both devices were carried out by determination of quality parameters such as detection limit, selectivity, response time, precision, accuracy, repeatability and reproducibility. Results show that those are valuable tools to quantification of the presence of priority pollutants in effluents. AKNOWLEDGEMENTS This work was supported by the LIFE+ Programme of the European Commission through AQUATIK project (LIFE 10 ENV/ES/000521). Authors acknowledge Prof. E. Costas for the work done in the selection and growth of microalgae used in biosensor.

MO082

Effect of temperature on the toxicity of mercury in different periphyton communities

J. Val, CSIC Spanish National Research Council; S. Muniz, San Jorge University; M. Pino, Universidad San Jorge; E. Navarro, CSIC Spanish National Research Council / Biodiversity conservation & Ecosystems Restoration

The present study describes the research conducted about the effect of increasing temperature on the toxicity of mercury on 3 different periphyton communities, which were obtained through natural colonization of substrates positioned in 3 ecosystems of Gallego river basin (NE Spain): High Mountain, chemical pollution area and agricultural pollution area. Obtained communities were transported to the laboratory for a microcosm experiment, where an acute toxicity test was performed. A structure was built with 12 methacrylate channels connected by hoses to the containers with different contents of mercury concentrations, all of them submerged in a tank with circulating water to the desired experimental temperature: each site actual average temperature and +5ºC. In order to quantify the biofilm photosynthetic efficiency according to each toxic concentration, fluorescence emitted by chl-a biofilm was measured with Mini-PAM (Pulse Amplitude Modulated) Fluorometer. These measures were used to estimate the effective concentration that reduces the photon yield by 50 % (EC_{50}). Results show an increase in toxicity of the compounds in all communities when increasing temperature. Furthermore, communities affected by chemical contaminants have greater resistance to the toxic than the other two communities, at both the current temperature and at 5 ° C more, which could be due to Pollution-induced community tolerance (PICT).

MO083

Responses of diatoms exposed to a fungicide and a petroleum distillate in stream mesocosms: sensitivity of trait-based metrics and community indices

Y. Bayona, INRAAgrocampus Ouest / UMR; M. Roucaute, INRA / UMR ESE; K. Cailleaud, Total Petrochemicals France / PERL; A. Basseres, TotalFinaElf / PERL; L.L. Lagadic, INRA / UMR INRAAgrocampus Ouest Ecology and Ecosystem Health; T. Caquet, INRA / UMR ESE

Diatom communities are widely used in biomonitoring of the quality of aquatic environments through a variety of biological indicators. Nevertheless, community responses have poorly been used in Ecological Risk Assessment of chemicals at higher tier studies (*i.e.*, mesocosms). Recent studies have encouraged the definition and use of diatom biological and ecological trait-based approaches which are supposed to be more integrative of environmental changes. In this study, traits defined in the literature were tested using classification into three ecological guilds (*i.e.* high profile, low profile and motile), identification of ecological traits of individual taxa (*i.e.* substrate relationships, mobility…), occurrence of life-form traits (colony, no-colony, fixed, mobile), and distribution into taxa size-class traits (5 size-classes). Moreover, the structure of diatom communities was investigated through biomonitoring indices, such as DBI (Diatom Biological Index) and PSI (Pollutant Sensitivity Index), and taxonomic approaches. Outdoor flow-through mesocosms were used to assess the effects of chemicals on diatoms in realistic and complex experimental environment including abiotic and biotic interactions. They also allowed assessing the sensitivity of the various endpoints cited above during the treatment period and the ability of communities to recover from disturbance. Chemicals, thiram (dithiocarbamate fungicide) and a petroleum distillate, were chosen with respect to their specific modes of action. Loadings were 35 and 170 μg/L for thiram and 0.01, 0.4, 2 and 20 mg/L for petroleum distillate. All treatments were performed in duplicates and four systems were kept as the controls. Streams were continuously treated for 3 weeks, followed by a two month-long post-treatment period. Diatoms were sampled every three weeks, before, during and after treatment period. Our results showed no effect of exposure using biomonitoring indices whereas some traits and the taxonomic structure clearly highlighted effects. In particular, the use of ecological guild, size-class and life-form response allow grouping taxa according to their their ecological profiles, providing better overview of ecological changes due to chemical exposure and highlighting short- and long-term effects on the biofilm structure and functioning. This demonstrates higher sensitivity of diatom traits to chemical exposure, thus supporting their interest in ERA. Keywords : Abundances, long-term vs. short-term effect, recovery dynamics, different scales comparison.

MO084

Long-term effects of triclosan on marine periphyton communities in flow-through microcosms

M.M. Eriksson, Chalmers Technical University / Department of Shipping and Marie Technology; H. Johansson, V. Fihlman, University of Gothenburg / Department of Biological and Environmental Sciences; A. Grehn, Univeristy of Gothenburg / Department of Biological and Environmental Sciences; K. Sanli, Department of Biological and Environmental Sciences; H. Blanck, Goteborg University / Department of Biological and Environmental Sciences; T. Sircar, University of Gothenburg / Dept of Biological and Environmental Sciences; A. Arrhenius, T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences

Triclosan is a broad spectrum antibacterial and antifungal agent, used in formulations as diverse as plastics in children’s toys, kitchenware, toothpaste, clothes, soaps, carpets and first aid products. Several studies have shown triclosan to be toxic to bacteria and fungi, but it has also been shown to be highly toxic to algae with multiple mechanisms of action. We have investigated the long-term effects of triclosan on marine periphyton communities in a flow-through microcosm study. Results show that triclosan induce community tolerance, detected as short-term inhibition of photosynthesis, according to the Pollution-Induced Community Tolerance (PICT) concept. PICT was accompanied by stimulated chlorophyll *a* content and incorporation of radiolabelled carbon at 100 nM. Whether these changes originate from increased biomass or increased chlorophyll *a* synthesis and photosynthesis is, however, unclear. At the same exposure level the pigment composition in these communities were altered. Although the tolerance mechanism(s) is not known, photosynthesis and pigment composition seem important for tolerance to triclosan in algae and cyanobacteria. In addition we studied multivariate catabolic capabilities of bacteria in control and exposed communities using Biolog EcoPlates. These data are currently being analysed and will also be presented on the poster.

MO085

Is the composition of fungal populations in surface waters an appropriate parameter for the risk assessment of multiple pesticide loads from fruit cultivation?

A. Talk, Helmholtz Zentrum Muenchen Deutsches Forschungszentrum; S. Kublik, Helmholtz Zentrum Munchen / Research Unit Environmental Genomics; R. Berghahn, Federal Environmental Agency / Field Station Marienfelde; S. Mohr, Umweltbundesamt / IV; M. Engel, M. Uksa, G. Welzl, M. Schloter, Helmholtz Zentrum Munchen / Research Unit Environmental Genomics
So-called 'application sequences' in apple cultivations consist of many pesticides, which are repeatedly applied in short time intervals one after the other. The risk assessment of pesticides, however, includes only the evaluation of single substances so far. Pesticide loads reach surface waters through several pathways such as e.g. spray drift and runoff. This raises the question, whether continuous contamination of surface waters with pesticides over time may lead to negative effects on aquatic ecosystems although the individual substances should not have effects on aquatic organisms. Aquatic fungi are important for surface water ecosystems because they supply energy through litter decomposition. In ecotoxicological risk assessments aquatic fungi are not yet included as standard organisms although 'application sequences' comprise especially fungicides. In a mesocosm study the effect of an 'application sequence' scenario on the diversity of aquatic fungi was examined through fingerprinting of fungal communities colonizing Alnus glutinosa leaves in order to find out if this is a good parameter for the risk assessment of pesticides. •In general fingerprinting is a promising tool to examine aquatic fungal communities since the temporal succession in fungal communities could be displayed. •However, fingerprinting alone may not be sensitive enough for the detection of minor effects originating from multiple pesticide loads. •Sequencing may allow for a deeper look into the fungal communities.

Waste and Wastewater effluents: chemical and ecotoxicological characterisation (P)

MO086
In situ GamTox test to assess toxic pulses and monitor water quality
A. Gerhardt, LimCo International GmbH
Gammarus spp. are widely spread pollution indicators in brooks and streams. GamTox represents a simple field test to assess and monitor toxic stress caused by both point and diffuse pollution sources. The test has been applied in different case studies and pollution scenarios, such as three WWTPs, one horticulture and one wood processing industry. The test has been performed at each site as follows: 5 replicate plexiglass tubes sealed on both ends with nylon net caps (0.5 mm mesh size) containing each 10 parasite-free medium-sized gammarids and one conditioned alder leaf were placed in a basket and fixed on the streambed and at the banks. Survival and feeding rate (% leaf loss) were monitored on a weekly basis for a duration up to 6 weeks. Test animals were caught in the same catchment at unpolluted head stream sites. Gammarids responded within two weeks of exposure to pesticide/neurotoxic insecticide pollution and pharmaceuticals from WWTPs. No responses could be recorded as effects of a wood processing industry (Fenoxycarb). We discuss the application of GamTox in routine biomonitoring as screening and diagnostic tools, as well as the limits of the method regarding e.g. stream type, reliability of feeding as test parameter, etc.

MO087
Monitoring and diagnosis of pollution peaks in waste water treatment plants: concept and case study
A. Gerhardt, N. Rastetter, LimCo International GmbH; M. Hofer, Unimon GmbH / ISWA; B. Kuch, University of Stuttgart / ISWA; C. Bühler, Limeco GmbH
Urban waste water treatment plants face the challenge to operate optimal purification processes independent of varying concentrations and composition of substances in the incoming pollution cocktail. During a purification process of several hours the ecotoxic potential needs to be eliminated to protect aquatic biota in the receiving water bodies. Moreover, waste water and sludge will be submitted to re-use and re-cycling of nutrients and energy in the near future. To achieve these ambitious goals several measures are necessary to secure water and sludge quality: 1) monitoring of the inflow, 2) optimisation of the purification, 3) monitoring of the outflow. While chemical online monitoring has already become a routine tool, biological-ecotoxicological online monitoring starts to receive attention, too. Online biomonitoring with ecological relevant and pollution-sensitive running water bioindicators such as *Gammarus* spp. allow for the evaluation of both short-term responses and long-term effects of the waste water on the receiving ecosystem. In case of an alarm situation such as increased mortality a water sample can directly be taken for subsequent chemical diagnostics and additional ecotoxicological testing. This 3 step approach: biomonitoring- analytics- ecotox testing represents a cost-effective, rapid, sensitive and reproducible quality assurance and control to 1) detect polluters in the catchment, 2) safeguard optimal operation of the biological proecesses, 3) evaluate if 4th purifiaction steps are needed and which measures will be the most effective and 4) protect ecosystems. We present results from a 1 year online biomonitoring of the effluent (3 step purification process), followed by chemical diagnostics and ecotoxicological testing in alarm cases. For example, we could discern certain carbamates in the inflow to disrupt the biological purification and to affect gammarid survival in the Multispecies Freshwater Biomonitor. These carbamates show a certain rate of metabolisation during the purification process shown by chemical analytics and toxicity tests comparing inflow and effluent.

MO088
Ecotoxicological evaluation of inorganic fraction present in effluent delignification of linter produced by an explosive industry
F.T. Silva, E.C. Almeida, Sao Paulo University / Biotechnology; T.C. Paiva, University of São Paulo USP / Biotecnology
The effluents from explosive industries are potentially polluters. They can affect aquatic environments, due to the presence of toxic compounds, such as organochlorine compounds, lignin, 2,4,6-TNT and its metabolites , in addition to high concentration of inorganic ionic compounds. Often, with the treatment of these effluents, there is reduction of physico-chemical parameters such as BOD (biochemical oxygen demand), COD (chemical oxygen demand) and color, but the toxicity is not eliminated and in some cases may still suffer strong elevation. In this work, the effluent of the delignification of linter, generated from the production of nitrocellulose from an industry of explosives, was characterized chemically, for determination of pH, conductivity, turbidity, total phenols, color, BOD, COD, soluble and insoluble solids, total carbon, total organic carbon and total inorganic carbon. From this final analysis was generated a synthetic sewage containing NaCl, NaF, $CaSO_4.2\ H_2O$, $Ca(OH)_2$, KOH, $Mg(OH)_2$ and NaOH in the same industrial effluent concentrations. The synthetic sewage was then used in ecotoxicological tests with aquatic organisms. The chronic toxicity was determined using the green algae Pseudokirchneriella subcaptata and Ceriodaphnia dubia and the acute toxicity, using Daphnia similis. The results showed that the synthetic effluent presented high acute and chronic toxicity. The physical and chemical parameters analyzed showed high values of conductivity and pH, and may be considered as some of the factors responsible for toxicity. The inorganic fraction of the effluent of the delignification linter represents, therefore, a significant role in the toxicity of this, indicating that the same would need to go through a rigorous treatment to decrease this effect, thus avoiding large environmental impacts.

MO089
The effects of cadmium and zinc in a Flemish stream on the development and physiology of the zebrafish embryo.
E.D. Michiels, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; A. Hagenaars, Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences; L. Bervoets, University of Antwerp / Biology; D. Knapen, University of Antwerp / Biology department
The production and commercialization of chemicals increases every year. Part of these substances end up in aquatic ecosystems, causing individual or mixed toxic effects. Unfortunately, risk assessment of environmental samples and effluents is almost solely based on chemical analyses, physicochemical characteristics and the existence of nutrients and micro-organisms. This results in the lack of information concerning the biological effects of complex environmental samples and effluents. Therefore, the goal of this study is to assess the biological effects of waste water and effluents by using the zebrafish embryo as a model. The advantage of this alternative method is that they are not considered as test animals until 120 hours post fertilization (hpf) and that the used volumes are small enabling the assessment of environmental samples in the laboratory. As the homeostasis range of zebrafish embryos for a lot of physicochemical characteristics of water is not yet known, this was tested prior to exposing embryos to environmental samples. Dose-response curves for both pH and salinity were made to detect the limits of the homeostasis of the embryos. Subsequently, zebrafish embryos were exposed to water samples of a Flemish industrial contaminated stream, 'Scheppelijke Nete', which contains high levels of cadmium and zinc. Sampling was performed upstream a pollution point (SN1), at a pollution source (DITCH) and downstream of the pollution source (SN2). The dissolved Cd and Zn concentrations were measured using ICP-OES. The highest concentrations of Cd and Zn were found in the DITCH and SN2 water respectively. The pH and salinity of the samples fell within the homeostasis range of zebrafish embryos The embryos were exposed to the samples and scored every 24h until 96 hpf for morphological and physiological parameters. The embryos exposed to SN2 and DITCH water had a delayed hatching and a lower hatching success compared to the control and the SN1 embryos. In order to determine if this effect was caused by Cd, Zn, a combined effect of both substances or by unknown substances, an experiment will be set up with pure Cd and Zn and with a combination of both at the same concentrations found in the samples, and compared with the hatching results of the three different water samples. In future research the zebrafish embryo will be further established as a model in risk assessment of environmental relevant samples such as river water samples and effluents.

MO090

The use of aquatic bioassays in the risk assessment to surface and groundwater from the application of organic wastes as soil improvers
P. Alvarenga, Polytechnic Institute of Beja / Departement of Tecnologies and Applied Sciences; C. Mourinha, M. Farto, Polytechnic Institute of Beja; P. Palma, Instituto Politécnico de Beja / Department of Tecnologies and Applied Sciences
Abstract The Proposal for a European Soil Framework Directive recognized that "soil degradation or soil improvers have a major impact on other areas, (…) such as surface waters and groundwater, human health, climate change, protection of nature and biodiversity, and food safety". This study aims to assess the potential impact on surface and groundwater from the application of different organic wastes as soil improvers. For this purpose, sewage sludge, composted sewage sludge with agricultural wastes, agro-industrial sludge, mixed municipal solid waste compost (MMSWC), compost produced from agricultural wastes, pig slurry digestate (PSD), municipal slaughterhouse sludge, and paper mill wastes (sludge and ashes), were analyzed considering their main physicochemical characteristics, and their trace elements (TEs) total concentrations (Cd, Cr, Cu, Hg, Ni, Pb and Zn). In order to assess their potential impact on surface and groundwater, a leachate was obtained using DIN 38414-S4 method (1984). Several aquatic bioassays were used in order to assess the leachate ecotoxicity: luminescence inhibition of the marine bacteria *Vibrio fischeri*, *Daphnia magna* immobilization, *Thamnocephalus platyurus* survival, and seed germination (*Lolium perenne* and *Lactuca sativa*). Considering the total TEs concentrations in the organic wastes, and their organic contaminants concentrations, the sludge samples characterized in the study can be used for agricultural purposes, in accordance with the European Community Directive 86/278/EEC and with the Portuguese legislation. As for the compost samples, they can also be land applied considering the DG Env.A.2. Working document on "Biological Treatment of Biowaste – 2nd draft": mixed municipal solid waste compost is a Stabilized Biowaste, composted sewage sludge with agricultural wastes is a Class I compost. However, compost produced from agricultural wastes and pig slurry digestate cannot be land applied, due to their Ni and Zn content, respectively. Despite the fact that some organic wastes are allowed to be land applied according to the existing regulations, their leachates can be very toxic towards some organisms. That toxicity was difficult to be predicted from the total TEs concentrations, which are one of the main criterions to be accomplished when evaluating organic wastes risk – PSD and MMSWC were the organic wastes with overall higher total TE concentrations and were not identified as having higher toxicity.

MO091
Effect-directed investigations of selected effluents and receiving waterbodies in the Meuse and Scheldt basins: overall toxicity and endocrine disruption assessment.
Y. Marneffe, Inst Scientific de Service Public / Ecotoxicology Department; C. Chalon, ISSeP
Bioassays are a holistic and meaningful way of assessing effects of environmental samples and wastes on ecosystems. A study was carried out with complementary tools in different rivers of the Meuse and Scheldt basins (water and/or sediments), upstream, downstream and in the effluent of selected industries and urban wastewater treatment plants. An effect directed active monitoring using bioassays was carried out, combining ecotoxicological and physico-chemical measurements. A yeast estrogen screen (YES) assay was conducted as effective first-tier screening tool to assess the estrogenic potential of surface water, effluent or sediment samples. Moreover, we used a battery of short term and chronic bioassays with the bacteria *Vibrio fischeri*, the alga *Pseudokirchneriella subcapitata*, the rotifer *Brachionus calyciflorus* and the microcrustacea *Daphnia magna* to assess their overall toxicity. Polar organic chemical integrative samplers (POCIS) were also used at some locations to sample hydrophilic compounds such as pharmaceuticals, personal care products, hormones, and pesticides having low log *n*-octanol-water partition coefficents (Kows < 3). POCIS extracts were screened for the presence of estrogenic chemicals using the yeast estrogen screen (YES) assay and analyzed by gas chromatography/mass spectrometry (GC/MS) and we used AMDIS (Automated Mass Spectral Deconvolution and Identification software) and the NIST 2.0 mass spectral library for the identification of the compounds. Results from the YES indicated important estrogenicity in different small rivers such as River Haine and River Hain (>15 ng eq E2/l), whereas samples collected in more important rivers like the River Meuse showed lower estrogenic activities (

MO092
Making wood energy sustainable – Ecotoxicological study of wood ash from untreated fuel
L.S. Jagodzinski, University College Cork / Biological Earth and Environmental Sciences; M. Jansen, University College Cork / School of Biological Earth and Environmental Sciences Environmental Research Institute; F. van Pelt, University College Cork / Department of Pharmacology and Therapeutics Environmental Research Institute; J. O'Halloran, University College Cork / School of Biological Earth and Environmental Sciences
When it comes to sustainability perception of energy from biofuels, carbon budgets are the predominant concern, but accruing ash waste is still seldom considered. Whereas in some countries wood ash is used for fertilization and liming, in most counties the ash is still regarded as waste and its after-use hampered by the lack of ecotoxicological data. The current practice of ash disposal is a widely acknowledged weakness in the use of biofuels. A battery of standard OECD aquatic toxicity tests (representing all trophic levels) was applied to assess the effects of bottom and fly ash accruing from a power plant fired with untreated wood fuel. The results show that (1) bottom ash samples exhibited lower toxicity than fly ash, (2) alkalinity was a major contributing factor in overall ash toxicity, (3) although EC_{50} values were established within one order of magnitude (e.g. native bottom ash EC_{50} in algal growth inhibition, Microtox, duckweed growth inhibition, daphnia immobilization and fish survival tests were 3.7 $g{\cdot}L^{-1}$, 4.8 $g{\cdot}L^{-1}$, 36.9 $g{\cdot}L^{-1}$, 55.5 $g{\cdot}L^{-1}$ and 97.8 $g{\cdot}L^{-1}$ respectively) they appeared to increase with the complexity of the biological models (4) while pulverization of the samples had little effect on their toxicity, re-ignition of the ash resulting in complete mineralization led to an increase of toxicity probably due to increased mobility of elementary components and their effect on the sample pH. In general fly ash is considered to pose a considerably greater hazard than bottom ash. Although our data confirm higher toxicity of fly ash, the observed differences in EC_{50} values for the two ash types from untreated wood fuel are not substantial (e.g. EC_{50} for native bottom and fly ash in algal growth inhibition and Microtox tests were 3.7 and 1.9 $g{\cdot}L^{-1}$, 4.8 and 3.6 $g{\cdot}L^{-1}$ respectively). The findings also illustrate that an increased degree of combustion reduces the level of organic contaminants and results in increased mobility of mineral components and higher pH. The presented data will facilitate the risk assessment for after-use of ash from untreated wood fuels in Ireland, might support the reconsideration of ash fate and thereby increase the actual sustainability of wood biofuels.

MO093
Toxicity assessment in photocatalytic degradation of BPA using nano-sized and mesoporous TiO2
J. Jung, Korea University / Professor; A. Jo, Korea University; Y. Park, University of Seoul
Advanced oxidation processes (AOPs) including Fenton reaction, UV photocatalysis and ozonation have been widely studied in treatment of refractory organic pollutants. However, most studies have focused on removal efficiency of the organic pollutants without toxicity assessment of their degradation products. In the previous study, we found that acute toxicity of phenol and monochlorophenols to *Daphnia magna* was dramatically increased by gamma-ray treatment doses as low as 1 kGy. Thus, the aims of this study were: (1) to investigate photocatalytic degradation of bisphenol A (BPA) using the commercial Degussa P25 (NP-TiO_2) and hierachically mesoporous TiO_2(HM-TiO_2); and (2) to evaluate the changes in toxicity toward *Vibrio fischeri* (luminescent bacteria) during the treatment. Photocatalytic treatment in the presence of NP-TiO_2 was efficient to remove BPA ($1{\times}10^{-5}$ M), thus around 95% of BPA was degraded within 64 min. Meanwhile, photolysis, hydrolysis and adsorption processes were not significant compared to the photocatalytic reaction in this treatment. With the HM-TiO_2, the efficienty of photocatalytic treatment was decreased to some degree, thus around 94% of BPA was removed in 180 min. Acute toxicity of BPA to *V. fischeri* was dramatically increased by photocatlytic treatment with NP-TiO_2, where toxicity was gradually decreased in the presence of the HM-TiO_2. The different toxidity results are likely related to different formation of intermediates in the photocatalytic treatment, and this should be further identified. Photocatalytic treatment seemed to be effective in degrading BPA, but the removal rate and toxicity change largely depended on the property of catalysts used. For instance, degradation of BPA with the commercial Degussa P25 (NP-TiO_2) gave an extraordinary toxicity increase. Therefore, the reaction mechanism and by-products should be fully characterized to idenfify the cause of toxicity in the photocatalytic treatment.

MO094
Molecular biomarkers in oysters Crassostrea gigas exposed in situ to sanitary sewage discharges - Five years of studies
A.C. Bainy, J.J. Mattos, R.P. Gomes, T.B. Pessatti, T. Miguelao, F.L. Zacchi, Universidade Federal de Santa Catarina / Bioquimica; S. Taniguchi, University of São Paulo / Physical Oceanography department; S.t. Sasaki, Instituto Oceanografico da Universida de Sao Paulo / Oceanografia Química; M. Bicego, University of São Paulo; F.F. Nunes, Universidade Federal de Santa Catarin / Bioquimica
Among the main causes of the coastal contamination around the world are the discharges of untreated sanitary sewage, which has chronically affected the health of aquatic organisms. In view of the ecologic and economic importance of oysters to coastal areas, understanding their biology and susceptibility to these pollutants have become an important issue in ecotoxicology. In particular, transcriptomic studies have received special attention due to the enhanced possibility of elucidate different mechanisms of adaptation to contaminant exposure. The aim of this study was to identify genes from *Crassostrea gigas* as candidate to be used as biomarkers of exposure to the complex mixtures of sanitary sewage in the real world situation.

Since 2008, annually oysters have being caged at sites contaminated by sanitary sewage discharges and at two reference sites (areas used for oyster culture) in Santa Catarina Island, south of Brazil. Levels of linear alkyl benzenes (LABs), polycyclic aromatic hydrocarbons (PAHs) and fecal steroids were analyzed in tissues of oysters before and after the exposure in all sites. The mRNA from gill and digestive gland were extracted, purified and the cDNA was synthesized according conventional protocols. qPCR were carried out to quantified the levels of transcription of previously identified genes as *fatty acid binding protein* (*FABP*), *glutathione S transferase omega class* (*GSTO*) and different *cytochrome P450 isoforms* (*CYP356A1*, *CYP2AU2*, *CYP30C1*). The experiments carried out along these five years showed a consistent induction of transcription of FABP, GSTO and these CYPs in gills of oysters exposed to sanitary sewage discharges, comparing to the oysters kept at the reference sites. These data are corroborated by the significant levels of bioaccumulation of LABs, PAHs and fecal steroids in the tissues of oysters. Based on these data, we suggest the use of these early warning molecular tools as complementary techniques to monitor the impact of sanitary sewage discharges in coastal areas. Supported by CNPq, INCT-TA.

THE TOXICITY OF LEACHATES FROM INDUSTRIAL WASTE CONTAINING ANTIMONY

C. Grandison, DSTO; S.M. Reichman, School of Civil and Environmental Engineering RMIT University; D. Nugegoda, RMIT University / School of Applied Sciences

Antimony (Sb) is a metalloid with broad industrial applications. Despite the wide use of antimony and associated compounds there exists a lack of reliable information with regard to the environmental toxicity of antimony and associated compounds and their effects in aquatic ecosystems. The study investigated the toxicity of 'artificial' leachates from an EPA supplied industrial dry waste sample, known to contain high levels of Sb.. Inductively Coupled Plasma Mass Spectrometry (ICPMS) was used to quantify the levels of Sb present in the sample. Two bioassays were then conducted to assess the toxicity of this leachate, comprising (1) a MicrotoxÒ test using the luminescent bacteria *Vibrio fischeri,* and (2) a test utilising the sensitive freshwater micro invertebrate *Hydra* spp. ICPMS analysis of the produced leachates determined an antimony concentration of 10.51 and 106.09 mg/L in acidic and alkaline mediums, respectively. Bacterial testing using the MicrotoxÒ acute toxicity test protocol recorded a fifteen-minute EC_{50} value of 36.4 mg/L for Sb solution. The leaching fluid of pH 9.2 was the most toxic of all leachate solutions tested to *Vibrio fischeri* and its toxicity increased with time. In contrast, the toxicity of the leachates at pH 2.9 showed little change with time over 15 minutes. 96 hour acute toxicity testing was also performed using the freshwater cnidarian *Hydra*. 96 hourEC_{50} and LC_{50} values for antimony solution were 0.698 mg/L and 1.66 mg/L, respectively. The acidic leachate was less toxic to *Hydra* sp. with a 96 hourEC_{50} and LC_{50} values of 3.25 % and 4.42 % (v/v of the original solution), respectively, while the alkaline leachate had EC_{50} and LC_{50} values of 1.11 % and 1.77 % (v/v of the original solution), respectively. . Comparison of determined toxicity endpoints with an aquatic hazard classification scheme suggests that antimony had a similar toxicity to arsenic and that at the very least, antimony has the potential to cause harm to aquatic biota.

MO096

DETERMINATION OF TOXICITY OF WASTEWATER IN SLAUGHTERHOUSE ORIGINATED IN THE BENEFICIATION PROCESS OF BEEF

T.C. Paiva, University of São Paulo USP / Biotecnology; E.L. Pereira, University of São Paulo USP / Biotechnology; F.T. Silva, Sao Paulo University / Biotechnology

The Brazil is a great producer and exporter of meat. During the processing of meat are used large amounts of water, leading to generation of high volumes of wastewater from slaughterhouse. As altas concentrações de matéria orgânica, formas nitrogenadas e fósforo, aliada a diversidade de íons, tornam esse efluente propício a ser tratado por processos biológicos. The high concentrations of organic matter, nitrogenous and phosphorus forms, added to a high diversity of ions, make this effluent able to be treated by biological processes. The presence of organic compounds such as carboxylic acids, aldehydes and alcohols, may cause toxic effects and harmful to the aquatic environment. The present study aimed to evaluate the toxic potential of wastewater from slaughterhouse from the green line, generated iby processing of beef of a fridge, located in the region of Vale do Paraíba, SP, Brazil. The organisms used for the acute toxicity tests were the microcrustáceo *Daphnia similis* ($EC_{50\ 48\ h}$), the bacteria *Pseudomonas putida* ($EC_{50\ 6:0}$) and *Escherichia coli* ($EC_{50\ 6:0}$). For chronic toxicity test were used the algae *Pseudokirchneriella subcaptata* ($LC_{50\ 96\ h}$) and microcrustaceans *Ceriodphnia dubia* and *Ceriodphnia silvestri* ($LC_{50\ 192\ h}$), OEC, NOEC and CV. The results showed the effluent toxicity to tested organisms. The EC50 values were 1.56% (1.28 -1.89), 4.47% (93.75 -5.33) and 39.77% (33.47 -47.19) for *D. similis*, *P. putida* and *E. coli*, respectively. The tests using the *C. dubia* and *C. silvestri* showed chronic toxicity to the effluent, with values of less than 0.3% NOEC and LC50 of 1.16% and 0.56%, respectively. For *P. subcaptata* the NOEC values were of 4.17 and LC50 of 7.3%.The evaluation of physico-chemical parameters revealed that the effluent had high concentrations of total solids, total volatile acids, organic matter, nutrients and alkalinity, that may be the agents of toxicity. According to the results obtained, the effluent tested is toxic and its launch, without treatment, in bodies receivers could compromise the aquatic life. ***Acknowledgement:***Fapesp, CNPq e Capes

Implementation of the test-battery approach into routine effluent control in Lithuania

L. Manusadzianas, Institute of Botany NatureResearch Centre / Institute of Botany; R. Karitonas, Institute of Botany / Institute of Botany; R. Vitkus, Nature Research Centre / Institute of Botany; K. SADAUSKAS, Lithuanian University of Educology; R. Juknys, Vytautas Magnus University; J. Zaltauskaite, Department of Enviromental Sciences

Recently, HELCOM, expressing a concern on the status of the Baltic Sea, has initiated several international programmes such as Cohiba, BaltHaz, etc., particularly targeted to promote the usage of Whole Effluent Assessment (WEA) methods in routine regulation. Contrary to the control of individual substances, which is based on knowledge of a single concentration, municipal and industrial effluents can be regulated directly on basis of harmful effects that occur in testing organisms. Various countries use laboratory toxicity tests to monitor effluent discharges into surface waters in various degrees. For example, acute and chronic toxicity tests are used in the USAand Sweden, whereas acute tests are used in Canadaand several European countries. Up to date, the majority of countries provide chemical-based effluent controls, however, the progressive increase of chemicals under control and difficulties in measuring them make individual-substance approach problematic. In some countries, toxicity data are included for taxation purposes, in parallel to chemical-based taxation. For example, toxicity data obtained from *D. magna* acute and fish embryos tests used inFrance andGermany, respectively. In 2011, the Ministry of Environment of Lithuania put forward a national programme with the aim to elaborate a system of effluent control by implementing toxicity tests. The outcome of this programme includes appearance of necessary environmental juristic documents and/or their updates, selection of test-batteries, selection of the cumulative index for toxicity evaluation and performance of initial stage of effluent inventory monitoring. The evaluation of potential harm for aquatic environment is limited to the application of end-of-pipe principle, the assessment of effluent by acute and/or chronic toxicity test-batteries as well as effluent-and stream-flow rates. The polluters will be grouped according to the criteria of the type of economical activity and discharge rate. During one-year inventory period, respective test-battery(ies) will be applied and then the most sensitive test(s) prescribed for routine effluent control. In this study, a system for municipal and industrial effluents control as well as simultaneous steps of its implementation into routine will be overviewed.

MO098

Impact of wastewater treatment plant effluent on Gammarus fossarum´s feeding rate and vitellogenin levels

B. Ganser; C. Kienle; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; N. Homazava, Swiss Centre for Applied Ecotoxicology EawagEPFL; E. Vermeirssen, Eawag / Dept of Environmental Toxicology; C. Moschet, Eawag / Uchem; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

Wastewater treatment plant (WWTP) effluents release complex mixtures of organic and inorganic micropullutants, including endocrine disrupting compounds, into receiving water bodies. These substances may cause adverse effects in aquatic communities. To uncover potential implications on the endocrine system of crustacean species as well as on their part in ecosystem functions, i.e. leaf litter decomposition, the key shredder *Gammarus fossarum* was exposed four times during April – May 2012 for one week periods up- or downstream of a WWTP located close to Zurich, Switzerland. Additionally, the induction of vitellogenin (vg) was assessed in animals exposed to Cyproterone as reference chemical and wastewater *in situ* and in the lab. Furthermore, estrogenic activity of the river water was measured. For this purpose, extracts from passive samplers, which were installed in the receiving stream during in situ experiments, as well as water samples taken once per week were analyzed using a yeast estrogen screen (YES) assay. Additional water was analyzed for transformations products. The gammarid´s feeding rate was significantly reduced 100, 200 and 400 m downstream of the WWTP relative to the 100 m upstream site. While YES results showed elevated estrogenicity at downstream sites, vg concentrations in amphipods were not significantly changed. This lack of responsiveness was corroborated in lab experiments. In conclusion, the results of this study indicate that wastewater released into natural aquatic ecosystem may considerably affect the ecosystem function of leaf litter breakdown, while effects on the endocrine system of crustaceans were not detectable.

MO099

Toxicity of solid wastes formed and released after wastewater treatment with nanomaterials

V. Nogueira, Universidade de Aveiro / Biology; I. Lopes, University of Aveiro / CESAM Biology Department; T. Rocha-Santos, ISEIT Instituto Piaget Viseu Cesam; F. Goncalves, University of Aveiro CESAM / Department of Biology; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; A.d. Duarte, University of Aveiro & CESAM / Chemistry; R. Pereira, University of Aveiro / CESAM, Center of Environmental and Marine Studies, University of Aveiro

Nanomaterials (NMs) are being widely recommended for water and wastewater treatments due to their unique physical and chemical properties. Several studies reporting the different advantages of nanotechnology in the remediation of wastewaters are numerous in the literature, but limited research effort has been directed toward understanding the fate and potential impacts of the solid residuals, that could persist in the treated effluent, being accidentally released to the receptor freshwater ecosystems, after the application of such technologies. The treatment of wastewaters containing organic and inorganic contaminants with NMs will result in solid wastes containing NMs, used for the treatment, and several chemicals bound to them. It is then imperative to assess the environmental safety of these wastes. The present work aimed at investigating the ecotoxicity of solid wastes resulting from the treatment of three effluents (olive oil mill, kraft pulp mill, and mining drainage) with two (TiO_2 and Fe_2O_3) NMs. Since these residues will eventually accumulate in the sediment of the aquatic compartment, the invertebrate *Chironomus riparius* was selected as test organism and exposed to the residues. A 10-day static laboratory bioassay was performed by exposing first instar larvae to artificial sediment spiked with solid residues of nano-TiO_2 (22.7-38.0 mg TiO_2 Kg^{-1} d.w. of soil) and nano-Fe_2O_3 (21.3-35.3 mg Fe_2O_3 Kg^{-1} d.w. of soil) resulting from the treatment of each effluent. These solid residues were chosen from previous work, from the treatments with best performance in ameliorating the chemical characteristics and the toxicity of each effluent. The effect on percentage of survival and growth (measured body length and extrapolated from the width of the head capsule) was assessed. Results showed that the residues from the treatments TiO_2/H_2O_2 and Fe_2O_3/H_2O_2 from olive oil mill effluent and Fe_2O_3/H_2O_2 from kraft paper mill effluent did exhibited lethal toxicity to *C. riparius* larvae, as the percentage of survival reached 60%. Only the exposure with residues from the treatment Fe_2O_3/H_2O_2 applied to the kraft paper mill effluent significantly affected the growth rate extrapolated from the head capsule width. In terms of growth rate computed through the measures of body length, it decreased significantly after exposure to the residues from the treatments TiO_2 (1.0 g L^{-1}) and Fe_2O_3/H_2O_2 of kraft paper mill effluent and Fe_2O_3/H_2O_2 of olive oil mill effluent.

MO100

Which chemicals drive biological effects in wastewater and recycled water?

J.Y. Tang, The University of Queensland / ENTOX; F. Busetti, J. Charrois, Curtin University / Curtin Water Quality Research Centre; B.I. Escher, Helmholtz Centre for Environmental Research GmbH UFZ / Cell Toxicology

Compliance monitoring of drinking water and recycled water in Australia is predominantly based on chemical assessments using instrumental analysis. Bioanalytical tools have the potential to assess the mixture effects according to the mode of toxic action and can complement chemical analytical monitoring. In this study, grab samples were collected from an Australian Wastewater Treatment Plant (WWTP) with secondary treatment processes, including activated sludge treatment, followed by treatment in an Advanced Water Recycling Plant (AWRP). Advanced treatment included ultrafiltration, chloramination, reverse osmosis (RO) and UV disinfection. Analysis of 278 compounds was undertaken at different points along the treatment train. Treatment efficiently removed most organic compounds mainly by reverse osmosis. Detected analytes after RO were below the Australian Guidelines for Water Recycling (AGWR) and as such would not be expected to pose any health risk and complete removal was observed in the post-UV water. In parallel, a battery of cell-based bioassays covering a wide range of modes of action were used to evaluate the samples. In laboratory studies, identified chemicals were grouped into major categories (including pesticides, herbicides, pharmaceuticals, endocrine disrupting compounds and X-ray contrast media) and were mixed in the concentration ratios they were detected in water samples prior to RO. The mixtures were dosed into the bioassays. The effects caused by these designed mixtures were compared to the effects of the corresponding entire samples. Generally antibiotics dominated the mixture effects in WWTP effluent, while post RO pharmaceuticals and pesticides became more important. The contribution of the type of chemical to overall effect was also dependent on the toxicity endpoint. For receptor-mediated biological endpoints such as photosynthesis inhibition, where a small number of well-defined chemicals are known to be active, the majority of effects could be explained by the presence of identified compounds. For non-specific bioassays such as cytotoxicity or oxidative stress response, where all or many compounds contribute to the mixture effects, the detected chemicals could explain less than 1% of the measured effect, meaning that non-target chemicals and transformation products contribute to the mixture effects.

MO101

Establishment of an elution method of three beta-blockers for aquatic ecotoxicity testing with pills

J. Bressling, Institut für Siedlungswasserwirtschaft RWTH Aachen / Institute of Environmental Engineering; D. Athanasiadou, RWTH Aachen University; W. Gebhardt, RWTH Aachen University / Institute of Environmental Engineering; J. Pinnekamp, RWTH Aachen University / Environmental Engineering

Pharmaceuticals and their metabolites have been emitted in large amounts to the aquatic environment for many years, mostly as complex mixtures in the effluents of sewage treatment plants and sludge. One of the most important groups of prescription drugs are beta-blockers, which play a significant role for the therapy of cardiovascular diseases. Three of the major active ingredients used in Germany are: atenolol (55.5 million defined daily doses, DDD), bisoprolol (659 million DDD) and metoprolol (892.2 million DDD). As a consequence of high volume of usage, beta-blockers are likely to have a more or less constant presence in the aquatic environment, detected in the influent and effluents of sewage treatment plants as well as in rivers. For the assessment of the ecotoxicological relevance of atenolol, bisoprolol (as bisoprolol hemifumarate) and metoprolol (as metoprolol tartrate) in the aquatic environment, the acute *Daphnia magna* immobilisation assay according to ISO 6341 was used. Due to testing of unknown pharmaceuticals as pure substances in analytical grade is often very expensive for EC_{50}-range-finding, an elution method with pills of these beta-blockers was established. For the assessment of a suitable elution method, primarily by acute data, definition of stock solution for testing was carried out according to ECOSAR using SAR for aliphatic amines of beta-blockers as baseline toxicants. For comparison of two different elution methods, stock solutions with a total of 500 mg pills per litre water were prepared. Immobility of *D. magna* was observed after 24 and 48 h with the latter being the endpoint for effect calculation. For chemical and ecotoxicological characterisation of filtered water extracts, EC_{50}-range-finding was performed in combination with chemical analysis by detection of compound content using LC/MS. For evaluation of a suitable elution method with pills, the recovery rate of atenolol (83.6 %), bisoprolol (93.8 %) and metoprolol (76.2 %) was calculated by the measured compound content in the water extracts. Risk classification was carried out by means of observed EC_{50}-values according to Technical Guidance Document. Metoprolol would be classified as harmful to aquatic organisms (10-100 mg/L), while atenolol and bisoprolol would be classified as non-toxic (>100 mg/L). These investigations reveal a suitable elution method with pills for the environmental relevance of unknown pharmaceuticals and their metabolites in sewage treatment plants.

MO102

Is the zebrafish embryo test a suitable tool to evaluate the efficiency of wastewater treatment plants?

P. Thellmann, Tübingen University / Animal Physiological Ecology; H. Köhler, University of Tubingen / Animal Physiological Ecology; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology

\n The entry of various bacteria and micropollutants in surface waters occurs to a great extent through wastewater treatment plants (WWTPs) and storm-water overflow systems. Both incomplete purification of wastewater in WWTPs and low storage capacity of stormwater overflow basins (SOBs) during heavy rain events contribute to this. As a consequence, micropollutants emerge in surface waters and partly accumulate in sediments. This can result in negative consequences on the development of fish and other aquatic organisms in the affected surface waters. By upgrading the WWTPs with additional purification steps such as ozonation, sand filtration and activated carbon filters, it is possible to improve the elimination rates of micropollutants and pathogens. The joint project "SchussenAktiv*plus*" investigates the efficiency of three WWTPs of different size and two types of stormwater overflow basins (SOBs) before and after the startup of additional purification steps. For this purpose, various chemical and microbiological analyses and biological *in vitro* and *in vivo* tests are conducted by several co-operation partners. The present part of the project focuses on the investigation of the cleaning efficiency of WWTP and SOB upgrading with regard to potential developmental toxicity of treated waste water. For this, wastewater is investigated before and after passing the additional purification steps by using a zebrafish (*Danio rerio*) embryo test. The three examined test systems in this project are the WWTPs Langwiese, Eriskirch and Merklingen and the SOBs Mariatal and Tettnang (Germany). The WTTPS Langwiese and Eriskirch and the SOB Mariatal are located at the Schussen River, a tributary of Lake Constance. No significant differences were found between the conventional cleaning and the additional purification steps with respect to embryotoxicity, but some tendencies towards less pronounced adverse effects after WWTP upgrading became obvious. Compared to embryotests with trout which can be conducted in the field, the zebrafish embryotest only provides information on embryotoxic potentials in environmental samples. It is easier to conduct but generally less sensitive.

MO103
Evaluation of DEET cytotoxicity on Perna perna mussels
G.d. Martini, S.O. Rogero, IPENCNENSP; J.d. Azevedo, Federal University of Sao Paulo / Biological Sciences; J.R. Rogero, IPENCNENSP
Recent studies have identified the presence of several emerging pollutants in aquatic environments. The occurrence in different environmental matrices has been continuously reported, highlighting the need for toxicity studies. Developed in the 1940s and present in many commercially available formulations, the DEET (*N,N-diethyl-meta-toluamide*) is the active agent used in most insect repellents. Several studies have been identified the DEET presence in surface water and in wastewater treatment plant (WWTP) effluent, so this compound is considered an emerging pollutant and studies indicate that DEET is only slightly toxic to aquatic organisms. Even nowadays the environmental destiny of DEET is not completely understood. Although DEET is considered a compound resistant to degradation and commonly found in surface water, there are not complete assessments for ecological risk of DEET, including studies evaluating chronic toxicity to aquatic organisms. In this study was evaluated the DEET toxicity and the effects caused in lysosomes of *Perna perna* mussels hemocytes. For this purpose, firstly was performed the acute toxicity assay to identify the DEET concentration that causes 50% mortality of exposed organisms to DEET concentrations in the range of 75 to 400 mg L^{-1} and the obtained lethal dose (LC50) was 114.27 mg L^{-1}. To assess the stability of the lysosomal membrane in organisms exposed to this compound was carried out the cytotoxicity assay utilizing DEET concentrations in a range of 0.001 to 1.0 mg L^{-1}. In fact, is important reinforce that the data of DEET cytotoxicity showed disturbances in *Perna perna* mussels in all tested concentrations.

MO104
Phytotoxicity assessment of discharge waters: Focus on germination and root elongation tests
A. Priac, Université de FrancheComté / Laboratoire Chronoenvironnement; P. Badot, University of FrancheComte CNRS / Laboratoire Chronoenvironnement; S. Gavoille, C. Lagarrigue, Agence de lEau Rhône Méditerrannée Corse; G. Crini, University of FrancheComte CNRS / Laboratoire Chronoenvironnement
Surface Treatment Industry is well known to be one of the largest chemicals and water consumer. It thus generates a large amount of complex and toxic waste water. Seed germination and root elongation tests, using as indicator higher plants like cucumber, radish, wheat and lettuce, are commonly used to evaluate their ecotoxicity. Indeed these bioassays present many advantages as they are simple, very reproductible, rapid and only require a small amount of sample. However these tests are carried out under national and international recommendations (US FDA, US EPA, OECD), some parameters remains variable. Our research group historically uses the lettuce *Lactuca sativa* (L.) as bio-indicator in ecotoxicological bio-monitoring. The aim of this study is to assess which factor(s) can be seen as critical in the water discharge toxicity evaluation. We particularly focus on control water quality, seed abundance or lettuce variety. We tested four waters as control (mineral, osmozed, ultra pure and distilled water) and three abundances (15, 20 and 30 seeds per Petri dish). After 7 days in controlled conditions (dark; 24°C±1°C), results show no significative differences on both germination rate and root elongation endpoints. Nevertheless, we find out that when watered with industrial waste water, the four lettuce varieties (Batavia dorée de printemps, Kinemontepas, Appia and Grosse Blonde Paresseuse), randomly chosen among more than 1500 commercial cultivars, show significatively different responses. From the comparison, it is clearly evident that a differential sensitivity scale exist among nor species but varieties.

MO105
Toxic potential of different types of sewage sludge as fertilizer in agriculture: ecotoxicological effects on aquatic and soil indicator species
N. Rastetter; A. Gerhardt, LimCo International GmbH
Phosphorus is a non-renewable, essential but limited resource for plant growth. Waste water and sewage sludge usually contain substantial concentrations of phosphorus. In order to use sewage sludge as a sustainable phosphorus resource for agriculture, it has to be proven that no ecotoxicological effects on target species in soil and receiving water bodies are generated. Therefore, three test species were chosen to cover the environmental compartments water, sediment and soil. To evaluate acute effects of sewage sludge on a higher aquatic plant, the duckweed *Lemna minor* was monitored via its growth inhibition, discoloration and colony break-up. Acute toxicity of sewage sludge in water and sediment was investigated with regard to mortality and behavior (movement activity and feeding behavior) of *Gammarus fossarum*, a key organism in stream ecosystems. The toxic effects of sewage sludge in soil on a decomposer - the earthworm (*Eisenia fetida)* - were monitored by its avoidance behavior. Chemical assessment included nutrients, organic micropollutants and heavy metals. \n For example, the assessment of a non-dewatered sludge resulted in an inhibition of growth of *Lemna minor* starting from 2,5 volume-percentage after 7 days (EC_{50}: 5,1% S). Concentrations below 1% supported plant growth (hormesis effect). *G. fossarum* displayed significantly decreased movement activity at 2 and 5% sludge concentration during an exposure time of 2 days, leading to decreased survival after 4 days of exposure in 2% sample concentration (LC_{50}: 1,95% S). After 2 days *E. fetida* exhibited an increased avoidance behavior of contaminated soil from 1% sewage sludge (EC_{50}: 1,7% S). 100% avoidance of contaminated soil was obtained at 5%. The dewatered sludges had a higher toxic effect on *E. fetida* and *G. fossarum* but a lower toxic effect on growth inhibition of *L. minor*. *G. fossarum* was the most sensitive species in the applied test setup.\n In conclusion, for all three test species all three sewage sludges tested have to be classified as toxic at high concentration levels under laboratory conditions. In order to get reliable information about practical doses for agricultural soil, field studies under real environmental conditions will be performed to verify the current results.\n The research project P-REX is supported by the European Commission under the Seventh Framework Programme (Priority: "From Prototype To Market"/ Contract No. 308645).

MO106
LogNormality of trace contaminant concentrations in sewage effluents
M. Gardner,
Summary: This poster summarises a detailed examination of the nature of the data frequency distributions of trace contaminant in wastewater treatment works' effluents. Cumulative distribution plots are illustrated for both between-works average values and within over 150 works. **Abstract:** It is important to understand the statistical distribution of monitoring data for them to be of value in determining the parameters of environmental models. No such distributional information has been available for many trace contaminants in sewage effluents. This work applies the data of a major UK sewage works' effluent monitoring programme to determine the validity of the common assumption that data are logNormally distributed. Effluent quality was monitored at 162 wastewater treatment works over one year, generating over 3,000 results for each of over forty substances, including metals, trace organic substances, pharmaceuticals etc. It is demonstrated that the logNormal assumption is clearly justified for the great majority of substances in the spatial case - for annual average effluent concentrations across different treatment works. In the site specific, temporal case – for individual determinations of concentration at a single site over an annual period – logNormality is generally supported, but not demonstrated so unequivocally for all site/substance combinations. The principal source of uncertainty for within works data was lack of sufficient numbers of observations reported to adequately low reporting limits.

MO107
Detection and fate of synthetic musks in wastewater treatment plants – a review
V. Homem, J. Silva, University of Porto / LEPABEDEQFEUP; N. Ratola, LEPAE University of Porto / Physics of the Earth; L. Santos, Faculty of Engineering - University of Porto / Chemical Engineering; A. Alves, Faculty of Engineering - University of Porto
Synthetic musks are used as fragrance additives and fixative compounds in personal care (e.g. perfumes, lotions, shampoos, deodorants) and household products (e.g. detergents, fabric softeners, air fresheners). Due to their high incidence and widespread use, synthetic musks are continuously introduced into the environment, mainly through urban sewer systems. Since these compounds are pseudo-persistent, bioaccumulative, have a lipophilic nature and are only partially biodegradable, they are usually not completely removed when they reach wastewater treatment plants (WWTPs). Therefore, their effluents are the main source of contamination. In fact, the use of biosolids as fertilizers in agricultural fields is a direct input of musks into the soil, whereas the wastewater effluents discharges are the major route for surface water contamination. To the author's best knowledge, this is the first compilation of studies about concentration levels and fate of synthetic musks in WWTPs and discusses the efficiency of the traditional removal methodologies applied in these plants. In this study, it was seen that polycyclic musks are the most detected, namely galaxolide (HHCB), tonalide (AHTN) and DPMI (cashmeran). They are found in effluents at concentrations from 5 to 10525 ng/L. Nitromusks are detected in a small number of effluents, but when detected, their concentrations ranged from 0.3 to 542 ng/L in wastewater. The most detected are musk xylene (MX) and musk ketone (MK). As expected, due to their lipophilic behaviour, musk compounds tend to accumulate mainly in sludge (0.05 - 117000 ng/g). Although synthetic musks were studied throughout the entire WWTP system, only a few studies dealt with measurements of the surrounding air. These revealed that musk compounds tend to accumulate in the gas-phase (0.23 – 344306 ng/m^3), being HHCB and AHTN the prevailing ones. Looking at the different stages of a traditional WWTP, secondary treatment is the process that most contributes for the removal of these kind of compounds, mainly due to sorption onto sludge. Acknowledgements The authors wish to thank Fundação para a Ciência e a Tecnologia (FCT - Portugal) for the project PTDC/AGR-CFL/102597/2008 and grant SFRH/BPD/76974/2011. This work has been partially funded by the European Union Seventh Framework Programme-Marie Curie COFUND (FP7/2007-2013) under UMU Incoming Mobility Programme ACTion (U-IMPACT) Grant Agreement 267143.

Record sediment concentration of retene, a highly potent fish teratogen, is buried into a lake site near closed pulp factory in Fennoscandia
A.O. Oikari, University of Jyvaskyla / Biology and Environmental Science; H. Ramaenen, T. Sahoo, University of Jyvaskyla; M. Lahti, Finnish Food Safety Authority Evira
Lake Lievestuoreenjärvi (LLTJ) with the pulp factory on its shore, closed in 1985, is a national landmark of environmental history in Finland. During years of its operation since 1927, primarily by sulphite process , production of chlorine bleached softwood pulp resulted effluent discharges to LLTJ. In 2009, we sampled a 30 cm cores from the deposited sediment in the nearest deep (19 m), and sliced it into 2.5 cm subsamples for GC-MS analyses of wood- and municipality-derived chemomarkers. The highest concentration of retene (5765 μg/g dry w.) was found in the layer 10-12.5 cm, similar to the maximum of total resin acids, RAs (3532 μg/g; dominated by dehydroabietic acid, the primary precursor of retene). The uppermost core section, above 7.5 cm, contained dramatically lesser concentrations of any wood-derived extractive. While microbial aromatization of RAs into retene (7-isopropyl-1-methyl phenantrene) requires anaerobic conditions, we suggest that, besides evoked serious hypoxia due to pulpmill effluents, the domestic sewage discharged from the nearby village Lievestuore (ca. 3000 inhabitants) has maintained over decades the formation of retene inside burying sediment layers. This deduction is supported by synchronic presence of cholesterol and coprostanol , two human origin sterols, in the same layers with industrial wood extractives.

MO109
Automated detection of suspected and non-targeted metabolites in sewage water after biological and chemical treatment
O. Scheibner, S. Westrup, Thermo Fisher Scientific; C. Portner, Institute of Energy and Environmental Technology IUTA eV / Enviromental hygiene micropollutants; J. Tuerk, Institute of Energy and Envionmental Technology eV IUTA
Water purification and treatment of sewage water is a well-known topic to the scientific community for a long time. Nevertheless, the question of the fate of contaminants in the different stages of treatment remains a complex matter and an analytical challenge. Triple stage quadrupole mass spectrometry equipment enables analytical chemists to conduct searches for known and suspected metabolites and transformation products, but separation from matrix signals stays critical and result confirmation difficult. The ongoing development of high resolution accurate mass (HRAM) mass spectrometric instrumentation (Orbitrap, TOF) opens up the door to more sophisticated ways of detection and confirmation of contaminants and their metabolites and transformation products, respectively. With these instruments, the detection mostly is done in full scan experiments, accompanied by different types of fragment scans for additional processing and confirmation. The power of resolution serves for unambiguous separation from the surrounding matrix signals, while mass accuracy is the key for reliable identification, including the isotope pattern for confirmation. Since all steps of detection, identification and confirmation take place post acquisition, the bottleneck is found to be the ability to process large amounts of data in appropriate time. For this study we took different water samples from a waste water treatment plant in western Germany with biological and chemical (ozonation) treatment facilities. We show how data, acquired with bench top Orbitrap HRAM LC-MS instrumentation can be analyzed in a fully automated matter with Thermo Scientific Compound Discoverer™ software. We show how the targeted search for known and suspected metabolites and transformation products by application of known and postulated biological and chemical transformation steps can be carried out easily in short time. Additionally, we show the detection of putative transformation products unknown so far by application of a generic component detection algorithm and application of mass defect filtering for specific parent components.

MO110
UKWIR Chemicals Investigation Programme – Phase 2 - from generic assessment to specific characterisation of effluent quality
M. Gardner; A. Thornton, Atkins Limited; L. Wilson,
Summary: This poster summarises the developing approach adopted in the UK to challenges posed by management of chemical in wastewaters. Where previous investigation focused on characterisation of effluent quality in terms of the presence and variability of substances in effluents, work currently in progress has moved in the direction of action to manage contamination. **Abstract:** Phase 1 of the UKWIR Chemicals Investigation Programme has provided a generic overview of trace contaminant concentrations in UK wastewater treatment works effluents, the effectiveness of current treatment processes in reducing contaminant concentrations and a novel insight into the sources of substances in sewer catchments. The second phase of this programme (CIP2) has been developed as an extension and expansion of an already substantial (€30M) CIP1 programme. The risk-based approach that has been widely used to scope the scale of measures required to meet Environmental Quality Standards (EQSs) for trace contaminants must now be supplanted with a clear view of actual environmental status. In order to meet this challenge, it is necessary to gather a suitably substantial and reliable body of evidence relating to compliance with quality standards. The intention is that resources expended in these investigations will ensure that the potentially far greater investment in possible remedial action will be directed where it can be shown that there is a demonstrable need and where responsibility can be apportioned such that the "polluter pays". Equally importantly, the data from CIP2 should make it possible to differentiate between sites where the case for action is clearly demonstrated and those where it is weak or non-existent. The way in which monitoring will be supported by definition of clear strategies for stakeholder engagement in substance source control and scoping of further improvement or upgrading of wastewater treatment processes, will also be described.

MO111
Persistence of wastewater-related xenobiotics during transport along an urban river segment
M. Schwientek, Water and Earth System Science; G. Guillet, Universite Pierre et Marie Curie; H. Ruegner, University of Tubingen / Water Earth System Science; B. Kuch, Institute for Sanitary Engineering Water Quality and Solid Waste Management University of Stuttgart; P. Grathwohl, University of Tuebingen / Center for Applied Geoscience
Xenobiotics are increasingly produced by industrial processes and introduced into the environment. Many of them are not completely eliminated by conventional waste water treatment plants (WWTP) and enter the receiving waters by WWTP outfalls or combined sewer overflows. In many cases, little is known about their toxicity, persistence and transport behavior in aquatic systems. In this study, the behavior of selected organic pollutants along a 4 km long urban river segment was studied by an experimental approach. The Steinlach River in southwest Germany with a total catchment area of 140 km^2 receives treated wastewater from a WWTP a couple of kilometers upstream of its confluence with the Neckar River. In its further course, the river channel is largely straightened and does not receive any larger tributaries. For this segment, a detailed mass balance was determined over a complete 24 h cycle. To this end, 2 h composite samples (sampling interval: 15 min) were taken using automated samplers at the upstream and downstream ends of the segment, respectively, and analyzed in the lab. A model-based analysis of the data demonstrated, on the one hand, that substances were persistent to a variable degree during the transport along the river segment. On the other hand, transformation processes seemed to be dependent on the time of day. The investigated compounds could be separated into a conservative (e.g. the phosphorous flame retardants TCPP und TDCPP and the pharmaceutical carbamazepine) and a reactive group. The latter comprised substances that were eliminated mainly during daytime (e.g. the disinfectant triclosane und das phosphorous flame retardant TDCP) and others that were transformed as well during nighttime (e.g. the synthetic fragrance HHCB and the pharmaceutical oxcarbazepine). A likely explanation is the variable sensitivity to photodegradation. Next steps will be a more detailed investigation of the processes involved and the factors regulating them. Also toxicological potentials and effects will be further studied.

MO112
Source Apportionment of Trace Contaminants in Urban Sewer Catchments
S. Comber, Plymouth University / Environmental Science; M. Gardner; V. Jones, Atkins Ltd; B. Ellor, UKWIR
Sampling and analysis of Water Framework Directive priority chemicals was undertaken in 9 urban catchments across the UK. Over 9,000 samples were collected from a number of different catchment sources including tap water, domestic waste water, surface water runoff, trade discharges, town centre and light industrial estate wastewaters. Determinands included the main trace metals of interest, PAHs, persistent organic pollutants and a number of common pharmaceuticals, as well as the common wastewater constituents including nutrients, organic carbon, BOD, COD and suspended solids. Loads of the chemicals from each catchment entering the local wastewater treatment works were estimated and were shown to be relatively consistent between different catchments after taking population into account. The study highlighted the importance of domestic wastewater as a source of contaminants, including metals and trace organic substances (such as EDTA, bisphenol A, nonylphenol and TBT). Concentrations in trade discharges were important in some locations in the cases of nonylphenol, EDTA, TBT as well as for some metals such as copper, zinc and nickel. Runoff exhibited significant concentrations of PAHs, lead, and TBT. Contributions to the total load from town centre and light industrial estate sources were generally less than 10% of the total.

MO113
Long-term monitoring of volatile methylsiloxanes (VMS) in aquatic environments impacted by wastewater effluent: experimental design and results from the first three years of collection.
D.E. Powell, Dow Corning Corporation / Health Environmental Sciences; J.A. Durham, Dow Corning Corp / Health and Environmental Sciences; R.M. Seston, Dow Corning Corporation / Health Environmental Sciences; R. Gerhards, T.

Boehmer, Evonik; N. Suganuma, K. Kobayashi, Silicone Industry Association of Japan (SIAJ)
Volatile methylsiloxanes (VMS) are widely used in consumer applications. Because wastewater represents the major post-use disposal route for VMS, the Silicone Industry Associations in North America, Europe, and Japan initiated a global monitoring program on VMS in surface sediment and aquatic biota. Aquatic environments that were selected as study areas for the monitoring program were impacted by municipal wastewater effluents and included Lake Pepin (USA), Lake Ontario (on the border between Canada and the USA), Oslofjord (Norway), and Tokyo Bay (Japan). The target objective of the monitoring program was to determine if VMS concentrations were stable or changing, based on detecting with 80% power (β=0.20) a statistically significant (α=0.05) annual rate of change of ±6% per year over a 5 year period (net change of -27% to 34%). Target matrices for each study area include surface sediments, a high trophic level piscivorous fish, and several low trophic level forage fish and benthic invertebrates near the base of the food chain of the predator. The expected minimum project duration of 5 years was estimated from a temporal trend power analysis that was optimized using the within-year variability for VMS concentrations observed during prior monitoring programs conducted on Lake Pepin and Oslofjord. Project duration and experimental design are annually re-evaluated and modified as needed to maintain or improve upon the defined objectives of the project. This presentation will provide an overview of the project and the experimental design for each study area. Available results from the first three years of sample collection and analysis will also be discussed.

MO114
Occurrence and distribution of 12 phenolic compounds in wastewater treatment plant and rivers surrounding a chemical industrial park in China
Q. Xian, Nanjing University; C. Chen, Environment Institute
Abstract: Due to the high toxicity, phenolic compounds were recognized as important pollutants in the environment. Now, phenols were widely used in chemical industry, such as plasticizers, resins, colors, detergents and antioxidants. A GC-MS method of derivatives was developed for determination of 12 phenols in wastewater and surface from a chemical industrial park (CIP) which was located in Yangtze River Delta,East China. Wastewater samples were collected from wastewater treatment plant (WWTP) of the CIP and one chemical company using phenols as raw material in CIP. Surface water samples were collected from the rivers alongside the CIP. Solid phase extraction was used as pre-treatment methods. The total concentrations of phenols in influent and effluent of wastewater treatment station from chemical factory were 1153μg/L and 45.67μg/L. And the effluent was transported into WWTP. In addition, the total concentrations were 366.3μg/L, 254.9μg/L, 81.49μg/L, 56.38μg/L, 122μg/L and 72.47μg/L respectively from the influent, regulation tank, fluidized bed, aeration tank, secondary sedimentation tank and effluent of WWTP. The results showed more than 80% phenols were removed. However, the levels of phenols in secondary sedimentation tank were higher than that in fluidized bed and aeration tank, which implied phenols were formed in secondary sedimentation tank. The total concentrations inChuheRiverlocated in the north of CIP were 41.56μg/L, 24.25μg/L, 20.42μg/L and 18.88μg/L, which showed a decreasing trend from upper to low reach along the CIP. The Yangtze River was located in the south of CIP where there was a drink water source calledJiajiangRiverwith lower concentrations, 3.22μg/L. While the total concentrations were 58.50μg/L, 115.0μg/L, 93.55μg/L, 68.38μg/L, 39.67μg/L and 32.11μg/L at 6 sampling sites from upper to low reach ofYangtze River. This indicated that wastewater containing phenols from CIP and other pollution sources was discharged intoYangtze River, resulting in higher concentration in the middle reach than that in upper and low reach. Overall, the distribution and fate of phenols are important for us to recognize chemicals risk around the CIP, and for government to conduct chemical management of the CIP such as reducing, replacing and recycling. **Keywords:** Phenolic compounds; fate;ChemicalIndustrial Park; GC-MS analysis

MO115
Ozonation or powdered activated carbon: Comparing the ecotoxicity of wastewater after two advanced treatment steps
C. Kienle; D. Baumberger, A. Schifferli, Swiss Centre for Applied Ecotoxicology Eawag/EPFL; S. Santiago, Soluval Santiago; M. Weil, ECT Oekotoxikologie GmbH; M. Kopf, W. Locher, ProRheno AG; C. Fux, TBF Partner AG; A. Joss, A. Wittmer, Process Engineering Swiss Federal Institute of Aquatic Science and Technology EAWAG; R. Frei, ProRheno AG; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology
For an elimination of micropollutants advanced treatment of wastewater using ozonation or powdered activated carbon is recently being implemented in wastewater treatment plants. Questions have been raised regarding the efficiency of these treatments and the potential toxicity of transformation products. Bioassays are a suitable tool to address these questions. This was demonstrated in the project "Strategy Micropoll" of the Swiss Federal Office for the Environment (FOEN) as well as in a number of other studies. In order to choose the best advanced treatment method at the wastewater treatment plant (WWTP) Basel, two technologies were assessed: (i) ozonation followed by a moving bed reactor (MBR), and (ii) powdered activated carbon addition followed by membrane filtration (PAC). Samples were analyzed for organic micropollutants and ecotoxicological effects before and after treatment. The focus lay on studying the removal efficiency for polar, persistent and bioactive substances as well as possible ozonation by-products. Ecotoxicological effects of the treated and untreated wastewater were assessed using green algae, water flea, amphipods and early life stages of rainbow trout. The estrogenic potential of the wastewater was evaluated using a yeast estrogen screen (YES) assay. It was demonstrated that both ozonation-MBR and PAC treatment are useful measures to reduce the effects of micropollutants in waterbodies. The overall elimination rate (conventional tertiary treatment plus advanced treatment) regarding specific effects (estrogenic activity and inhibition of algae photosynthesis (photosystem II)) was generally above 90%. Overall, advanced treatment led to a reduced toxicity in bioassays, and thus a lowered risk of adverse effects. One assay, the chronic reproduction assay with *Ceriodaphnia dubia*, revealed higher toxicity in ozonated and/or MBR-treated wastewater in two of three measurement campaigns. These results should be verified in further studies. All bioassays applied were generally well suited to assess the performance of the advanced wastewater treatment methods. Both test types, cell-based *(in vitro)*-bioassays as well as tests with whole organisms (*in vivo)* yielded valuable results. The quality of treated effluent was significantly improved ultimately resulting in improved surface water quality. The observed toxicity on *C. dubia* in the ozonation and/or MBR-treatment should be investigated further.

MO116
Optimization of biosorption of copper (II) ions from wastewater on the cone biomass of black pine (Pinus nigra L.)
M. Andjelkovic, Petnica Science Center / Department of Chemistry; D. Trajkovic, Faculty of sciences University of Nis; M. Kuntic, Faculty of physical chemistry Univerity of Belgrade; L. Peric, Petnica Science Center / Department of Chemistry
Biosorption is a physicochemical process that occurs naturally in certain biomass (biosorbent) which allows it to bind contaminants, in this case metal ions of salt dissolved in water. It is a reversible chemical process resulting from varied affinity of ions for deprotonated biosorbent. It also has significant advantages compared to other processes of water purification: treated water can be reused, and a biosorbent can often be regenerated. The aim of this study was optimization of Cu^{2+} adsorption from aqueous solutions on the cone biomass of black pine (*Pinus nigra L.*), as well as regeneration of biosorbent. Sieved powder of ground mature scales of black pine cones (particle size ≤125 μm) was used as biosorbent. The biosorption equilibrium level was determined as a function of contact time, pH, temperature, and biosorbent concentrations. The amount of Cu^{2+} adsorbedon the biosorbent was defined as the difference in concentration of Cu^{2+} in the solution before and during biosorption. Concentration of remaining (nonadsorbed) Cu^{2+} was determined by atomic absorption spectroscopy. The entire set of performed measurements showed that adsorption of Cu^{2+} from aqueous solutions increased with pH and temperature of the solution. The maximum copper biosorption of 99.27% occurred at 70ºC and pH 7.20. Biosorption equilibrium has been reached in 80 minutes, and the biosorbent concentration for adsorption of 10 mgL^{-1} Cu^{2+} from 0.5 L solution was 800 ppm. Acidic conditions proved to be better for the regeneration of biosorbent compared to alkaline conditions. The best fit to the data was obtained with the Langmuir adsorption isotherm. Our results indicatethat the cone biomass of *Pinus nigra L.* represents a suitable biosorbent for the removal of Cu^{2+} from wastewaters with high adsorption capacity.

MO117
Eco-engineered systems for removal of micro-pollutants from WWTP effluents: technical and scientific recommendations for optimal design of intermediate areas discharges downstream WWTP
J. Serre, VERI; S. CASAS, K. Seriki, S. Sourisseau, VEOLIA Environnement Recherche et Innovation; C. PAGOTTO, Veolia Eau
The protection and recovery of aquatic ecosystems, required by the Water Framework Directive, led to consider new refining wastewater treatment processes, to remove nitrogen, phosphorus as well as priority substances. Eco-engineered techniques develop and are likely to be effective in downstream areas in order to remove these substances, if the technique and the design are properly chosen. In France, more than 550 intermediate WWTP discharge in downstream areas were identified in 2011 (IRSTEA, 2012). The feedback on the treatment efficiency of eco-engineered systems and the conditions of removal of individual substance of interest are badly known; yet, the biodiversity potential is often emphasis for these areas. The wide variety of eco-engineered systems and the different architecture designs enable different configurations in intermediate areas: for example the use of one or several different systems, in combination or not. In this context, it is important to understand how they work and to test their performance. For this, a research project is implemented within Veolia Environment Research & Innovation. This project aims to provide technical guidelines for the implementation of eco-engineered systems in intermediate areas of WWTP's

discharge (sizing, order, techniques etc.) and establish performance levels of various techniques by families of substances. First, a compilation of the available knowledge on eco-engineering systems for advanced treatment of WWTP effluent was done, with the aim of assessing removal mechanisms likely to occur in each system (adsorption, photodegradation etc.). In parallel, relevant compounds, regarding their occurrence and ecotoxicity were sought and selected, and knowledge in literature on the removal mechanism of each micropollutant was reported. In a second phase, the project aims to experiment various eco-engineering techniques as tertiary treatment of wastewater in order to check their treatment capacities for the list of substances selected. This step is necessary for a deeper understanding of processes in eco-engineered systems, especially the relevance of the different removal mechanisms and conditions for removal for each individual micropollutant of interest. Finally, rules and design guidelines will be delivered for eco-engineered systems targeting the removal of specific micro-pollutants and their removal rates in each system.

MO118
Degradation of recalcitrant micro-pollutants in designed soil biofilters
M.E. Casas, Aarhus University AU; K. Bester, Aarhus University / Environmental Science
Soil biofilters are efficient to remove micro-pollutants from water so they could be used as a supplementary step in wastewater treatment plants. However, soil biofilters mechanisms are not well understood. Regular soil biofilters can be difficult to control due to sorption to the matrix and formation of water pathways. In contrast, designed soil biofilters are easy to operate because the sorption is controlled; they present an even pore-distribution and are simple to reproduce and up-scale. Two different designed biofilters were studied under aerobic conditions and at ten different flows. The transport and degradation kinetics of typically recalcitrant compounds including pharmaceuticals, fungicides and X-ray contrast has been examined at real wastewater levels in the designed soil biofilters. The transport was studied by controlling the compound's elution with an on-line biofilter-HPLC-UV system. The concentrations of these compounds were off-line analyzed by means of HPLC-MS/MS at the inlet and outlet of the biofilters. The sand biofilter showed to be a good system to study compound degradation because the removal of the compounds was mainly controlled by biodegradation and not sorption. When operating an intermediate flow of 11.8 L m^2h^{-1} the removal efficiencies of the sand biofilter were: 41, 94, 17, 58, 58, 57 and 85% for diclofenac, propranolol, propiconazole, tebuconazole, iopromid, iohexol and iomeprol correspondingly. These results will be compared to a biofilter containing peat to increase the contact time of the compounds in the biofilter. Initial tests revealed higher removal rates in the peat-amended biofilter. For most of the compounds the removal efficiency was contact time dependent and followed first order kinetics, which allowed to calculate removal rates. Propiconazole and tebuconazole did not show any correlation with the contact time.

MO119
Removal of compounds with estrogen-, androgen- and dioxin-like activities by various waste water treatment technologies studied by in vitro bioassays
M. Benisek, Masaryk University Faculty of Science / Faculty of Science RECETOX; R. Osterauer, R. Triebskorn, University of Tuebingen / Animal Physiological Ecology; L. Blaha, Masaryk University / Faculty of Science RECETOX
Endocrine disruptors and compounds with dioxin-like activities are widely present in wastewater effluents and can cause negative effects in aquatic biota. Wastewater treatment plants (WWTPs) can partially remove these compounds during primary and secondary treatment. However, substantial amounts of these compounds can still remain in treated effluents. Recently, some tertiary treatment steps like ozonation or active carbon filter were installed in some advanced WWTPs to remove micropollutants more effectively. The present study focused on various WWTPs from localities at the river Schussen, a tributary to lake Constance. Dioxin-like activity and also endocrine activities like anti/estrogenicity and anti/androgenicity were measured in effluents of the WWTPs after different treatment (primary or secondary treatment, ozonation, charcoal and sand filter etc.) using different *in vitro* bioassays. Estrogenic activity was relatively high in effluents after primary treatment step (influents), and it was significantly lowered after the secondary treatment. Interestingly, estrogenic activity of the samples collected after the tertiary treatment steps were often similar or slightly higher then effects after secondary treatment step only. Majority of the samples (both influents and effluents) did not show any antiestrogenic potential in our assay. Some of the influents had significant androgenic activity and most of the influents also caused antiandrogenicity. On the other hand, no significant anti/androgenicity was found in the effluents. Significant dioxin-like activity was found only in few of the influents. However, it was high in effluents of most samples after secondary treatment. Effect potentials were again removed (non significant effects) when tertiary treatment was applied. In summary, although the study demonstrated successful removal of majority of bioactive contaminants during different WW treatment steps in situ, some activity in the effluents (especially estrogenicity) can still be of ecotoxicological concern. [Research is part of the project SchussenAktiv*plus* which is funded by the German Federal Ministry for Education and Research (BMBF, funding number: 02WRS1281A) within the RiSKWa programme and cofounded by the Ministry of Environment Baden-Württemberg].

MO120
Effects of differently treated wastewater effluents observed with selected in vivo test systems
L. Vorberg, ECT Oekotoxikologie GmbH; A. Abbas, Goethe Universität Frankfurt / Aquatische Ökotoxikologie; I. Schneider, Goethe Universität Frankfurt; G. Knopp, P. Cornel, Technische Universitat Darmstadt / Institut IWAR; T. Ternes, Federal Institute of Hydrology; A. Coors, ECT Oekotoxicologie GmbH
Anthropogenic micro-pollutants are substances that are released into the aquatic environment at very low concentrations mainly by sewage treatment plants. Micro-pollutants are often poorly biodegradable, and their removal through sorption to sewage sludge may be limited by their polarity. Concern is growing that conventional methods of wastewater treatment and purification of drinking water are not sufficient to eliminate these substances. Therefore, the development and large-scale application of advanced wastewater treatment procedures has become an important scientific and political issue in recent years. Some methods, e.g. ozonation, can result in the formation of transformation products that may show similar or even greater toxicity than the parent compound. Our study is part of the research program of the BMBF (Federal Ministry of Education and Research, Germany) funded project TransRisk (Characterization, communication and minimization of risks originating from emerging contaminants and pathogens in the water cycle). The study aims to investigate the potential reduction or enhancement of toxic effects of differently treated wastewater effluents. Investigated advanced treatment methods are: ozonation, membrane bioreactor treatment, activated carbon- and biofiltration. *In vivo* exposure experiments are carried out *in situ* with a flow-through system. This has the advantage to cover peak and average concentrations of micro-pollutants and their transformation products in chronic exposure scenarios. The following *in vivo* test systems are chosen based on previous investigations indicating their sensitivity, and in order to cover different trophic levels and taxonomic groups: the reproduction test with *Daphnia magna*, the sediment-water toxicity test with *Lumbriculus variegatus*, and the growth inhibition test with *Lemna minor*.

MO121
Human pharmaceuticals and industrial chemicals in wastewater effluents – first steps toward a combined risk assessment
A. Coors, ECT Oekotoxicologie GmbH; F. Sacher, DVGW-Technologiezentrum Wasser; T. Juffernholz, German Federal Environment Agency UBA / Section IV Chemicals; W. Drost; D. Gildemeister, Umweltbundesamt Federal Agency of Environment / IV Pharmceuticals; U. Kuehnen, Federal Environment Agency
While the environmental risk assessment of human pharmaceuticals and chemicals contained in consumer goods is regulated in different legal frameworks in the European Union, these substances are in principle released together into the aquatic environment via wastewater treatment plants. Hence, the consideration of the potential combined toxicity of these substances may be needed to fully evaluate environmental risks across different regulatory frameworks. In order to develop a concept for this need and experimentally verify its applicability, a number of pharmaceuticals and industrial chemicals were selected to be tested singly and in combination. First results regarding the toxicity of the single substances toward green algae (growth inhibition) and *Daphnia magna* (reproduction) will be presented. The determined effect concentrations will be compared to predicted environmental concentrations (PEC), if available, and measured concentrations in wastewater effluents in order to support a single-substance based risk assessment. Prospectively, this single-substance risk assessment will be compared to a risk assessment taking into account joint effects based on prediction and experimental observation.

MO122
Environmental Risk Assessment of Effluent from wastewater treatment plants along Henares-Jarama-Tajo river basin (Madrid, Spain)
E.M. Beltrán, INIA National Institute for Agricultural and Food Research and Technology / Environmental; M. Porcel, INIA National Institute for Agricultural and Food Research and Technology; J. Pro, M. Torrijos, INIA; C. Fernandez, INIA National Institute for Agricultural and Food Research and Technology
The presence of pharmaceuticals and personal care products and (PPCPs) in the environment is due to their incomplete elimination in wastewater treatment plants (WWTP). So these substances are found in wastewater treatment plant effluents and surface waters. Even low concentrations of these substances may lead to undesired effects in aquatic systems. The goal of this work is to assess the environmental risk of 49 PPCPs along the Henares-Jarama-Tajo river basin (Madrid, Spain). The concentrations of the PPCPs, measured during four seasonal periods representing the different flow conditions of the river, were compared with PNECwater values to assess the potential risk of sub-lethal effects on aquatic organisms. Twelve

sampling sites were selected up- and downstream of neighbouring cities. Seasonal and spatial variations of the PPCPs in surface waters of the Henares river basin were visualised by transferring the results to a Geographic Information System (1.12.0 gvSIG Association). This study was funded by Spanish projects RTA2010-00004 and CTM2010-19779-C02-01/02

MO123
Fish cell-based biosensor for evaluating water quality
L. Tan, Eawag Swiss federal Institute of Aquatic Science and Technology
Cell-based tests play a central role and mark a major trend of the development of alternative assays to animal tests in environmental risk assessment. Millions of fish are used worldwide each year for evaluating water effluent, in the fish acute toxicity tests that take days to complete and use death as the benchmark. In addition to the societal and ethical concerns, the comparative sensitivity of the test is also an issue to be addressed. We have previously shown that the viability-based *in vitro* assay of the rainbow trout (*Oncorhynchus mykiss*) gill cells indicated very good agreement with the *in vivo* fish tests for a wide range of chemicals[1]. This suggests the great potential of adopting the cell system for evaluating water conditions. It therefore serves as the basis for our current project of developing a fish cell-based biosensor in the frame of the Swiss Nanotera project Envirobot (http://www3.unil.ch/wpmu/envirobot/), which aims to build a robotic system for autonomously sampling and analysing water quality. We use the fish gill cells for the bio-recognition of pollutants based on their overall adverse effects on the cells. Cells are cultured on purposely built biochips with embedded electrodes that detect changes, through the measurement of cell impedance, in a variety of parameters including cell growth, migration, morphology, cell-to-matrix and cell-to-cell interactions. The perturbation of the cells by chemical stimuli is read out as changes in the cell impedance, and monitored continuously. Our results of the cell exposure to varying concentrations of the toxicant sodium dedocyl sulphate (SDS) indicates that this system is effective and sensitive in detecting cytotoxicity, even in low doses of SDS which caused no detectable change in microscopy. In addition, conventional end-point viability assays including Alamar Blue, CFDA-AM and Neutral Red that measure vital signs of cellular metabolism, membrane integrity and lysosome integrity, respectively, were also carried out in parallel to the cell-impedance assay. Sensitivity of the cell-impedance based method was comparable or slightly more sensitive to the conventional end-point viability assays, with the advantages of being non-invasive, label-free and monitored in real-time. These results provide the basis for our future steps to test a large scale of chemical pollutants in water without using the whole fish, to optimize the system and integrate it into the Envirobot for field use.

The chemical behavoir of Cu, Zn, Cd and Pb in a eutrophic reservoir: speciation and complexation capacity
A.E. Tonietto, Universidade Federal de São Carlos / Botany; A. Lombardi, Universidade Federal de São Carlos; R.B. Choueri, Universidade Federal de São Paulo; A.A. Vieira, Universidade Federal de São Carlos / Botany; M.G. Melao, Universidade Federal de São Carlos / Hidrobiologia
This research aimed at evaluating metals speciation and interactions with\n natural dissolved organic materials in a eutrophic reservoir. Water\n samples were obtained in dry and rainy seasons, and PCA identified\n seasonal influences of metal input sources into the reservoir. The results\n showed higher labile Zn and Pb in the dry season, but complexed Zn\n dominated during the rainy season. Total dissolved Cu and Pb\n concentrations were higher in the dry season, with the concentration order\n Zn > Cu > Pb > Cd. Higher percentile of Cu and Zn remained complexed with\n the dissolved fraction, while Pb was associated with particulate\n materials. Cd, Cu, Pb and Zn complexation capacity indicated higher ligand\n concentration for Cu, followed in decreasing amounts Pb, Zn and Cd.\n Nevetheless, the strength of association for all metals and the respective\n ligands were similar.

Pesticides reduce regional biodiversity of stream invertebrates
M.A. Beketov, UFZ Helmholtz Centre for Environmental Research / Department of System Ecotoxicology; B.J. Kefford, University of Canberra / Department of Environmental Science; R. Schaefer, University Koblenz Landau; M. Liess, UFZ Center for Environmental Research / Department of SystemEcotoxicology
The biodiversity crisis is one of the greatest challenges facing humanity, but our understanding of the drivers remains limited. Thus, after decades of studies and regulation efforts, it remains unknown whether to what degree and at what concentrations modern agricultural pesticides cause regional-scale species losses. We analyzed the effects of pesticides on the regional taxa richness of stream invertebrates in Europe (Germany and France) and Australia (southern Victoria). Pesticides caused statistically significant effects on both the species and family richness in both regions, with losses in taxa up to 42% of the recorded taxonomic pools. Furthermore, the effects in Europe were detected at concentrations that current legislation considers environmentally protective. Thus, the current ecological risk assessment of pesticides falls short of protecting biodiversity, and new approaches linking ecology and ecotoxicology are needed. For details see: Beketov M.A., Kefford B.J., Schäfer R.B., Liess M., 2013. Pesticides reduce regional biodiversity of stream invertebrates. PNAS, 110: 11039-11043.

Ecological community sensitivity – tame the unpredictable or an evidence from a cross-Eurasia experiment
M.A. Beketov, UFZ Helmholtz Centre for Environmental Research / Department of System Ecotoxicology; N.C. Stampfli, UFZ Helmholtz Centre for Environmental Research / Dept system ecotoxicology; Y. Yurchenko, O. Belevich, Institute of Systematics and Ecology of Animals; S. Knillmann, HelmholtzCentre for Environmental Research UFZ; Y.A. Noskov, Institute of Systematics and Ecology of Animals; M. Liess, UFZ Center for Environmental Research / Department of SystemEcotoxicology
Ecology has a reputation of science with poor predictive potential. Responses of biological communities to stressors are frequently considered as case-specific and unpredictable. We suggest that predictability depends on the parameter considered, and modulations in integrative parameters such as community sensitivity can be predictable. We performed an experiment with artificial ponds located in Central Europe (Germany) and Northern Asia (Siberia, Russia). The pond zooplankton communities were exposed to an insecticide and their environment was manipulated to alter the community sensitivity. The results showed unprecedented consistency of the community sensitivity modulations between the two regions, with the sensitivity differing by a factor of up to 100. Furthermore, the results suggest that integrative parameters can be predictable, while describing the community reaction in terms nomenclature-based changes lacks generality and predictability. For details see: Beketov M.A., Stampfli N.C., Yurchenko Yu.A., Belevich O.E., Knillmann S., Noskov Yu.A., Liess M., 2013. Ecological community sensitivity – tame the unpredictable or an evidence from a cross-Eurasia experiment. in preparation.

MO127
Comparison of lipid normalized concentrations of cyclic volatile methylsiloxanes in differing lipid matrices of fish collected from marine and freshwater systems
J.A. Durham, Dow Corning Corp / Health and Environmental Sciences; D.E. Powell, R.M. Seston, Dow Corning Corporation / Health Environmental Sciences
To best understand the movement of environmental contaminants through an aquatic food chain, concentrations of these contaminants are determined in whole body homogenates of fish and normalized for lipid content. Due to the necessary equipment to properly homogenize potentially large fish, some researchers and agencies prefer to select individual tissue types for contaminant analysis. Additionally, if the focus of the research is to estimate human exposure, only the edible portions of the fish may be analyzed. The overall objective of this study was to determine if concentrations of cyclic volatile methylsiloxanes (cVMS) in differing lipid matrices would become equivalent once normalized for the lipid content of those matrices. Liver, skin-off fillet, and the remaining carcass of Atlantic cod collected from Oslofjord had concentrations of cVMS that differed, with skin-off fillets having the lowest concentration and liver having the highest concentration when normalized for the lipid content. The results showed a high degree of variability across the 6 fish analyzed with a distinct difference between the liver matrix and skin off fillets when normalized for lipids. Five additional fish species were collected from Lake Champlain Vermont, USA and were analyzed as skin off fillets and remaining carcass. This work also indicated a lower concentration when normalized for lipids of the skin off fillets. Samples were extracted by a standard solvent extraction method and analyzed by GC-MS. This work was supported by Silicones Europe on behalf of the Global Silicones Council.

MO128
Gas phase reaction rates of cyclic volatile methyl siloxanes with the hydroxyl radical as a function of temperature
A. Safron, Dept of Applied Environmental Science ITM; M. Strandell, ITM Stockholm University / Dept of Applied Environmental Science ITM; A.H. Kierkegaard, Stockholm University / Dept of Applied Environmental Science ITM; M. MacLeod, ITM Stockhom University / Dept of Applied Environmental Science ITM
Cyclic volatile methyl siloxanes (cVMS) are major constituents of many personal care products that are emitted and partition mainly into air in the environment. In ambient air, the main degradation pathway of cVMS is likely to be reaction with the hydroxyl radical (˙OH). Because cVMS partition mainly into air, this degradation rate largely determines their persistence in the environment. We measured rate constants for the gas-phase reaction of several cVMS with ˙OH using the relative rate technique at temperatures between 313 and 363K, using an experimental design based on the work of Anderson and Hites (1996). The reactions were carried out in a 195 ml reaction chamber with continuous monitoring of the concentrations of cVMS and reference substances by a mass spectrometer operating in electron ionization mode. ˙OH was generated *in-situ* in the reactor from ozone by irradiation with ultraviolet light in the presence of water vapor. These are the first measurements reported for the reaction rates of the cVMS species D_6 and D_7 with ˙OH, and the first temperature-dependent rate constants reported for the cVMS species D_3, D_4 and D_5. The Arrhenius expressions can be extrapolated to values at 297K that agree well with earlier measurements conducted by Atkinson (1991). The Arrhenius expression estimated for the reaction of D_5 with ˙OH is: ln $k = -22.7 \pm 1.3 - 9500 \pm 3600 / (R \cdot T)$ Where k is the second-order reaction rate constant [$cm^3 molec^{-1} sec^{-1}$]. The Arrhenius expressions for the other cVMS are reported on the poster. The activation energies for reactions with ˙OH are similar for all the cVMS studied. The relative reaction rate between two cVMS is therefore nearly independent of temperature. Anderson, P. N.; Hites, R. A., *ES&T* **1996,** *30* (1), 301-306. Atkinson, R., *ES&T* **1991,** *25* (5), 863-866.

MO129
Hydrolysis and Volatilization of Linear Volatile Methylsiloxanes in Soil
S. Xu, Dow Corning Corporation / Health and Environmental Sciences; P. Bauer, C. Bryant, Dow Corning Corporation
Linear volatile methylsiloxanes (LVMS) such as hexamethyldisiloxane (L2), octamethyltrisiloxane (L3) and decamethyltetrasiloxane (L4) are a group of low-molecular-weight silicone fluids primarily found as an impurity in silicone products and personal care products. The objective of this study was to determine the effect of their molecular structure on their hydrolysis and volatilization rates in soil. In a previous project, the hydrolysis and volatilization rates for L3 in two soils have been measured, including the Londo soil from Michigan. In the current study, the hydrolysis and volatilization rates of ^{14}C-labeled L2 and L4 were measured in the same Londo soil at four moisture levels: 32 % RH, 42%RH, 92%RH and 100% RH. In closed systems, the recoveries of the LVMS radioactivity under various moisture levels (including 100% RH) were close to 100%. At 22.5 °C, the hydrolysis half-lives of L2 and L4 varied from 1.4 days for L2 at 32%RH to 107 days for L4 at 100%RH. In open system at the same temperature under 100%RH, volatilization rates varied from 3 hours for L2 to 4 days for L4. Combined with the data for L3 from the previous study, the hydrolysis half-lives (τ_h in days) for all three LVMS at 22.5 °C was found to be related exponentially to the number of D (dimethylsiloxane) units (N_D): log $\tau_h = 0.36\ N_D + 0.88$ ($r^2 = 0.993$). Similarly, the volatilization half-lives (τ_v in days) of three lVMS in open systems at 100%RH was also related to N_D exponentially: log $\tau_h = 0.74\ N_D - 0.92$ ($r^2 = 0.991$). Based on those data, hydrolysis of LVMS should be the predominant removal mechanism in dry soil, while volatilization should be predominant in wet soil. Nevertheless, LVMS, once released to soil, should not be expected to remain long in soil under either dry or wet conditions

MO130
Organic carbon/water partition ratios (Koc) of cyclic volatile methylsiloxanes
D. Panagopoulos, Stockholm University / Department of applied environmental science; A.H. Kierkegaard, Stockholm University / Dept of Applied Environmental Science ITM; M. MacLeod, ITM Stockhom University / Dept of Applied Environmental Science ITM; A. Jahnke, Stockholm University / Department of Applied Environmental Science ITM
The environmental fate of cyclic volatile methylsiloxanes (cVMSs) has recently attracted the attention of environmental chemists and regulators due to their large production volumes, their persistence, and their potential for bioaccumulation [1]. cVMSs degrade within days or weeks when they are released to the atmosphere [2], but their residence time in surface waters is substantially longer [3]. When cVMSs are released to surface waters they are sorbed to suspended particles coming out of wastewater treatment plants and eventually fall to the sediment. From the sediment, cVMSs can move back to the water column and from there volatilize to air or undergo hydrolysis. Their release from the sediment depends on i) the amount and the quality of the organic carbon present and ii) their partitioning between organic carbon and water [4]. We studied this behaviour in a series of laboratory experiments and interpreted it with mathematical modelling. In the experiments various amounts of sediment were spiked with cVMSs and immersed in a volume of water. The water was continuously stirred and the headspace was purged by a nitrogen stream, which carried the cVMSs to an ENV+ column. The amount of the chemicals in the ENV+ was measured at various time points over the course of the experiment (72 hours). Aside from cVMSs, the sediments were also spiked with dichlorobenzene and polychlorinated biphenyls, which were used as benchmarking chemicals for the water-to-air and sediment-to-water mass transfer coefficients. The data for the benchmarking chemicals acquired from the experiment were used to calibrate a fugacity-based multimedia model, which in turn was used to estimate the organic carbon/water partition ratios (KOC) of cVMSs. We compared and contrasted the Koc values for the CVMSs derived from our experiment with other measurements [4] and QSAR models. References [1] Environment Canada, 2008. Registry Number 541-02-6. MO131
Understanding the fate and bioaccumulation of cyclic volatile methyl siloxanes in Arctic lakes
I.S. Krogseth, N.A. Warner, Norwegian Institute for Air Research; K. Breivik, Norwegian Inst for Air Research; M. Whelan, University of leicester / Geography; A. Evenset; G.N. Christensen, Akvaplanniva; I.H. Wassbotten, Unilab analyse AS
Cyclic volatile methyl siloxanes (cVMS) are used in personal care products and are frequently found in the environment. There is an ongoing scientific debate regarding cVMS bioaccumulation potential in aquatic organisms with contradicting results from recently reported studies. In this study we describe a holistic investigation of the environmental behavior of cVMS in lake Storvatn (70 °N, 23 °E), an Arctic lake in northern Norway that receives wastewater emissions. Existing and newly developed methods using headspace gas chromatography are applied to analyze the occurrence of cVMS in water and sediment, while established liquid extraction methods are used to analyze cVMS in biota from the lake. The measurements are used in combination with models to facilitate a mechanistic understanding of the environmental behavior of cVMS in the system. More specifically, a dynamic multimedia environmental fate model, parameterized for the physical and chemical characteristics of the lake, will be used to drive a bioaccumulation model. Preliminary simulation results indicate that concentrations of cVMS in the water column will increase during winter, which highlights the importance of seasonal characteristics such as low temperature and ice cover in these kinds of systems.

MO132
ANALYSIS OF UV STABILIZERS IN LIQUID AND SOLID TREATMENT PLANTS PRODUCTS AND THEIR FATE IN ENVIRONMENTAL SAMPLES FROM GRAN CANARIA ISLAND (SPAIN)
s. montesdeoca, Departamento de Química; R. Guedes-Alonso, Universidad de Las Palmas de Gran Canaria / Chemistry; Z. Sosa-Ferrera, J. Santana-Rodriguez, Universidad de Las Palmas de Gran Canaria / Departamento de Química
Within the wide range of Personal Care Products (PCPs), the UV filters are a group of compounds which use have notedly increased in the last decades. Due to the growing concern about the link between sunlight exposure and skin cancer, they are added not only in sunscreem but also in variety of cosmetic such as lip gloss, shampoos, hair dyes, makeup, etc., to reflect and absorb the solar radiation. After be used, these compounds can reach the environment through recreational activities such as swimming and bathing in oceans, lakes or rivers (direct inputs) [1] or after passing throughout wastewater treatment plants without be removed. One type of the most used UV filters is the Benzotriazole UV stabilizers (BUVSs) family, compounds with a phenolic group attached to a heterocyclic structure with three N atoms. It has been demonstrated that their derivatives can present negative effects over aquatic systems. For example they are mutagenic in bacterial systems and toxic in plants and can exert adverse effects on the fecundity and reproduction of fish [2]. We evaluated, for first time, the presence of seven BUVSs in liquid and solid samples from Gran Canaria Island (Spain) using on-line solid-phase extraction (On-line SPE) for liquid samples and microwave-assisted extraction followed by On-line SPE (MAE-On-line SPE) for solid samples, both coupled to ultra-performance liquid chromatography with tandem mass spectrometry detection (UHPLC-MS/MS). The sensible optimized methodologies provides LODs between 0.73-4.18 $ng \cdot L^{-1}$ and 53.3 to 146 $ng \cdot kg^{-1}$ for liquid and solid samples, respectively, and they allows the detection of some BUVSs in the different products from several treatment plants and environmental samples taken in Gran Canaria Island (seawater collected in different points of the coast, sand of different beaches and marine sediments collected near to a wastewater submarine outfall). Occurrence of synthetic musks in mainland Portugal – a biosampling approach using pine needles
J. Silva, S. Ramos, V. Homem, University of Porto / LEPABEDEQFEUP; N. Ratola, LEPAE University of Porto / Physics of the Earth; L. Santos, Faculty of Engineering - University of Porto / Chemical Engineering; A. Alves, Faculty of Engineering - University of Porto
Vegetation has been used as a passive biosampler to evaluate atmospheric pollution. In particular, pine trees are commonly chosen due to their widespread occurrence and evergreen leafs (needles). Pine needles morphology presents an

outer waxy cuticle, which offers a remarkable capacity to entrap compounds like semi-volatile organic pollutants. Our work team has earned experience in the use of this kind of matrix, studying several of these contaminants, namely PAHs, pesticides and flame retardants, among others. Concern about synthetic musks has been rising in recent years. Their common use as fragrance fixatives in scented products allied to their lipophilicity, persistence and potential biological effects may pose a risk to ecosystems. Although several studies have been published regarding their occurrence in water, sludge and fauna, information about atmospheric levels is still scarce. As opposed to active or other types of passive air sampling, employed in those studies, biomonitoring using pine needles avoids a previous sampling site set-up and may act a "biological data loggers" of pollution as needles remain in the tree for several years. To the author's best knowledge, this is the first study employing vegetation for the detection of synthetic musks. An analytical method employing ultrasound assisted extraction, followed by solid-phase extraction and gel permeation chromatography clean-up was previously developed and validated, allowing the assessment of levels of 5 nitromusks and 6 polycyclic musks. Needles of the two most common pine species in Portugal (*Pinus pinaster* and *Pinus pinea*) were collected at 30 sites of different exposure pattern types. Cashmeran and galaxolide were the most commonly detected musks. The mean total concentrations ranged between < 1 ng/g and 460 ng/g. Pine needles proved to be suitable for the monitoring of the atmospheric presence of musks. Acknowledgements The authors wish to thank Fundação para a Ciência e a Tecnologia (FCT - Portugal) for the Projects PTDC/AGR-CFL/102597/2008 and EXPL/AAG-MAA/0981/2013 and grant SFRH/BPD/76974/2011. Polycyclic musks whistle-blowing in the environment: appraisal of anthropogenic impact on fresh water systems

R. Duering, Justus Liebig University Giessen; L. Boehm, C. Pereira, Justus Liebig University Giessen / Institute of Soil Science and Soil Conservation

With a multi-tracer approach including different physical-chemical parameters, sum parameters, nutrients, and two polycyclic musk compounds (PMCs: galaxolide and tonalide) the small river Wetter in Hesse, Germany was investigated from its source to mouth (64 km length). By this, the impact of land-use on its water quality was assessed by involving 20 sampling points at 4 sampling campaigns. Within this catchment area of 516 km^2 more than 50% are used by highly productive agriculture, approx. 35% are forested land, whereas ca. 12% are settlement area. As an approximation, population equivalents which are attributed to the connected sewage treatment plants, are used to assess the impact of municipal waste water on the river Wetter. Discharge values at several control points were used to calculate loads of nutrients and PMCs. Galaxolide and tonalide were determined by a head-space solid phase microextraction method which enables to discriminate between total and freely dissolved amounts of these compounds. Precision of this highly efficient and sensitive method was confirmed by exemplary standard addition measurements. This techniques allows high sample throughput which is indispensible for such analyses on a landscape scale. Nutrients were introduced by diffuse sources from agricultural land-use and municipalities and only phosphate and nitrite could slightly indicate impact of different land-use by increasing concentrations downstream. Mean concentrations of galaxolide and tonalide were, depending on the impact of sewage treatment plants, increased up to 243 ng L^{-1} and 83 ng L^{-1}, respectively. By the calculation of PMC loads, impact of population on the water quality could be explained with a coefficient of determination of 0.98. This resulted in daily loads per population equivalent of 0.19 mg and 0.08 mg for galaxolide and tonalide, respectively. With this study, the appropriateness of both galaxolide and tonalide as reliable indicators for the impact of municipal waste water could be proven. Sediment samples for PMC residues are in progress.

Key-words: tracer analysis, galaxolide, tonalide, land-use

MO136

An evaluation of the ecotoxicological effects and risks of the biocide benzalkonium chloride on freshwater ecosystems

R. Oliveira, University of Brasilia / Department of Genetics and Morphology; A. Rico, Wageningen University / Aquatic Ecology and Water Quality Management; S.P. Pereira, University of Aveiro / Depart Biologia Universidade de Aveiro; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; A.J. Nogueira, University of Aveiro / Departament of Biology CESAM; I. Domingues, University of Aveiro / CESAM Department of Biology

Benzalkonium chloride (BKC) is a quaternary ammonium biocide widely used in personal care products, hospitals, wood and food industries (e.g. aquaculture). The potential environmental risks of BKC to aquatic ecosystems have been poorly investigated. The main goal of this study was to assess the toxicity of BKC to aquatic organisms through a battery of toxicity tests that allowed a preliminary risk assessment of BKC to four different trophic levels of aquatic ecosystems. Toxicity tests were performed for decomposers, primary producers, primary consumers, and secondary consumers. The results from the toxicity tests were used to build Species Sensitivity Distributions (SSD) and to calculate the BKC median Hazardous Concentrations (HC5% and 50%), separately to each trophic level. Moreover, using Measured Environmental Concentrations (MEC) of BKC, the Potentially Affected Fractions of species (PAFs) were estimated for four different scenarios (raw and wastewater treatment plants effluents and surface water) by joining SSDs and distributions of MEC. Among primary producers, *Pseudokirchneriella subcapitata* was found to be the most sensitive (72h-EC50=69 μg/l) species, followed by *Chlorella vulgaris* (72h-EC50=94 μg/l) and *Lemna minor* (168h-EC50=1340 μg/l). Primary consumers were highly sensitive to BKC (*Daphnia magna*: 48h-EC50=52 μg/l and *Tamnocephalus platyurus*: 24h-EC50=84 μg/l), whereas fish species showed to be slightly sensitive (*Oreochromis niloticus* embryos: 96h-LC50=370 μg/l, *Danio rerio* adults: 96h-LC50=2350 μg/l and embryos: 2060 μg/l). The SSD analysis indicated that primary consumers (HC5=10.8 μg/l) and primary producers (HC5=11.4 μg/l) are the most sensitive groups, followed by decomposers (HC5=152 μg/l) and secondary consumers (HC5=217 μg/l). Due to the high BKC concentrations measured in hospital, laundry and industrial effluents, the PAFs values obtained were > 5% for the four trophic levels studied, suggesting high toxicity of these effluent to aquatic biota. Even after treatment, monitored BKC concentrations in sewage treatment plant effluents and surface water are high enough to exert toxic effects on primary producers and consumers (PAFs > 5%). The results of this study show that there is a need to regulate the use of BKC, to increase the removal efficacy of treatment plants for disinfectants such as BKC, and to include BKC as part of chemical and biological monitoring studies in aquatic ecosystems.

MO137

Chronic toxicity of azo and anthracenedione dyes to embryo-larval fathead minnow

J.L. Parrott, Environment Canada / Water Science and Technology Directorate; A.J. Bartlett, Environment Canada; J.R. Hill, Environment Canada / Ecological Assessment Division; V. Balakrishnan, L AEPRD / Aquatic Ecosystem Protection Research Division

Synthetic dyes are extensively used in many fields, including paper production, leather tanning, food colouring, personal care products (e.g., hair colour, deodorant, etc…), as well as in textiles and paints. We assessed several azo and anthracenedione dyes from Canada's Chemicals Management Plan (CMP) to determine sublethal toxicity in embryo-larval fathead minnows. Fathead minnow newly fertilized embryos were exposed through the egg stage (5 days) up until 14 days post-hatch, with dye solutions renewed daily. The anthracenedione dyes Acid Blue 80 (AB80) and Acid Blue 129 (AB129) were both non-toxic at the highest measured concentrations tested of 7,700 and 6,700 μg/L, respectively. Both azo dyes Disperse Yellow 7 (DY7) and Sudan Red G (SRG) were highly toxic to larval fish after 20-day exposures to concentrations in the μg/L range. LC50s (based on measured concentrations of dyes in fish exposure water) were 25.4 μg/L (95% CI 24.5-26.4 μg/L) for Disperse Yellow 7 and 16.7 μg/L (95% CI 15.6-17.8 μg/L) for Sudan Red G. Exposure to both azo dyes caused a delayed toxicity response, with larval fish succumbing 4-5 days after hatch. This is important for fish bioassay exposure times and endpoints, as if these dye exposures were ended at the embryo stage or just after hatch, the toxicity of these two dyes would be greatly underestimated. This LC50 fathead minnow embryo-larval toxicity data for the azo dyes is much lower than previously reported in a literature review of dyes where LC50s were generally over 1 mg/L. The predicted environmental concentration for these dyes in the literature review was 20 μg/L, which is similar to the concentrations causing toxicity in our exposures of fathead minnow larvae. Although the two azo dyes were quite toxic in our tests, the concentrations of dyes in the Canadian environment were very much lower than those that caused effects in the current tests. In a total of 100 samples of municipal wastewater effluent from across Canada assessed for these dyes, all were below detection limits (detection limits: 0.122 μg/L (DY7); 0.0389 μg/L (SRG); 1.52 μg/L (AB129); and 33.4 μg/L (AB80)). The similarities of the structures and toxicity responses for the two azo and two anthracenedione dyes in this study support the use of read-across data for risk assessment of these classes of compounds.

MO138

Gene expression analysis of Mysid Crustacea exposed to Triclosan and Triclocarban using DNA microarray

K. Arizono, Prefectural University of Kumamoto / Faculty of Env Symbiotic Science

Triclosan (TCS) and Trichlorocarban (TCC) are widely used as antibacterial agent in various industrial products, such as textile goods, soap, shampoo, liquid toothpaste and cosmetics, and often detected in wastewater effluent. The aim of this study was to investigate toxicologically significant effects of TCS and TCC exposure on gene expression in mysid (*Americamysis bahia*) using DNA microarray. Juvenile mysid were exposed to 0.5 µg/L of TCS and 0.05 µg/L of TCC for 24 hours, and mRNA expression profiles in their whole bodies were analyzed.

We identified statistically significant (p 3) in 312 genes responding to 0.5 µg/L of TCS and 264 genes responding to 0.05 µg/L of TCC. There were merely 231 genes found responding to both exposures of TCS and TCC. The up-regulation in response to TCS and TCC was observed in vitellogenin and clottable protein. These genes are expressed more than 30 times in both experimental plots, which indicates the applicability of them in serving as biomarkers of antibacterial agents in mysid. These results suggested that endocrine disrupting effect of TCS and TCC would be potent for marine crustacean.

MO139

Upregulation of hormonal signaling genes in insect embryos and larvae after exposure to UV filters

I. Ozaez, UNED / Grupo de Biología y Toxicología Ambiental; J. Martinez-Guitarte, UNED / Fisica Matematica y de Fluidos; G. Morcillo, UNED / Grupo de Biología y Toxicología Ambiental

Organic UV filters are emerging aquatic contaminants due to the extensive use in a large variety of products. There is an increasing evidence indicating that several UV filters might have endocrine disruptive effects. Numerous studies have evaluated hormonal effects in vertebrates, mainly reporting estrogenic and androgenic activities in mammals and fishes. Nevertheless, there is still scarce information of hormonal activity in invertebrates endocrine systems. In this work, the effects of UV filters were investigated in different developmental stages of *Chironomus riparius* (Diptera), a reference organism in aquatic toxicology. Expression levels of the gene coding for the ecdysone receptor (*EcR*) and the heat shock gene *Hsp70* were quantified by Real Time PCR following short exposures to five frequently used UV filters: octyl-p-methoxycinnamate (OMC) also called 2-ethylhexyl-4-methoxycinnamate (EHMC); 4-methylbenzylidene camphor (4-MBC); 4-hidroxybenzophenone (4-HB); octocrylene (OC); and octyldimethyl-p-aminobenzoate (OD-PABA). Tje results revealed that all the UV filters tested are able to elicit a fast activation of the ecdysone receptor, a key transcription factor for the ecdysone-genomic response in arthropods. Embryos seem to be much more sensitive to these compounds. Similarly, exposure to UV filters triggered the activation fo the *Hsp70* gene increasing mRNA levels in embryos and larvae. The capability of UV filters to stimulate the expression of hormonal signaling genes that are essential both for larval and embryonic development suggests the possibility of a broad and long-term effect on invertebrate endocrine pathway. These findings strengthen the need for further research about the ecotoxicological implications of chronic exposure to these compounds in aquatic invertebrates.

MO140

Effect of mosquito repellents on aquatic non-target organism: Vertical distribution and predator avoidance in Daphnia

E. von Elert, University of Cologne / Biology; C. Effertz, University of Cologne; P. Fink, University of Cologne / Aquatic Chemical Ecology

DEET (CAS 134-62-3), Icaridine (CAS 119515-38-7) and EBAAP (CAS 52304-36-6) are the most common active ingredients in insect repellents, being mainly used against mosquitoes. Application of these repellents to human skin and subsequent wash off leads to environmentally relevant concentrations of these compounds in surface waters. Here we hypothesize that input of these repellents into the epilimnion of stratified lakes might affect the non-target organism Daphnia and lead to (i) avoidance of the upper strata of the lake by Daphnia, and (ii) interfere with the chemically mediated avoidance of Daphnia of its major predator fish. We test this using an indoor bioassay system in which we monitor the vertical distribution of Daphnia in a stratified water column in response to DEET, EBAAP and Icaridine in concentrations ranging of from ng/L to μg/L.

MO141

Analysis of Personal Care Products in Human Placental Tissue

J. Valle-Sistac, IDAEACSIC / Environmental Chemistry; D. Molins-Delgado, Environmental Chemistry; S. Diaz-Cruz, IDAEACSIC / Environmental Chemistry; D. Barcelo, IIQABCSIC / Environmental Chemistry

Last decade, ingredients in personal care products (PCP) have been described as chemicals of increasing environmental concern because of their toxicity, persistence, bioaccumulation, and ubiquity. PCPs are produced in extremely large quantities, thousands of tons per year. Parabens (PB) and UV filters (UV-F) are chemicals widely used as preservatives and sun blocking agents, respectively by personal care products, pharmaceutical and food industries. Many studies show the tendency of UV-F to bioaccumulate in living organisms due to their lipophilicity and stability versus biotic degradation [1, 2]. The ubiquity of these compounds in the environment and even human fluids [3-5] makes necessary further studies to fill the current knowledge gap. This study aims to provide evidence of the bioaccumulation of UV-F and PB in humans. The work describes the development of a new analytical method for multiclass determination of selected UV-F and PB based on high-performance liquid chromatography-quadrupole-linear ion trap-tandem mass spectrometry (HPLC-QqLIT-MS/MS) in women placental tissue. Target compounds were selected by their endocrine disruption activity and frequency of detection in the environment, i.e. benzophenone-1 (BP1), benzophenone-2 (BP2), benzophenone-3 (BP3), benzophenone-4 (BP4), 4-hydroxibenzophenone (4HB), methylparaben (MPB), ethylparaben (EPB), propylparaben (PPB), and butylparaben (BPB). The method involves a liquid-liquid extraction step prior to the HPLC-MS/MS analysis. Detection was carried out by MS/MS under electrospray ionization in negative mode (ESI-), and selective reactions monitoring (SRM). The LC-mobile phase was MeOH and H_2O, both with ammonium acetate 5 mM. The quality parameters of the method along with the suitability of its application to real samples will be presented. **References** 1. Kim J.W., Ramaswamy B.R., Chang K.H., Isobe T., Tanabe S. J. IFRA ENVIRONMENTAL STANDARDS: RISK AND HAZARD ASSESSMENT UPDATE FOR 2014

A. Lapczynski, RIFM / Environmental Specialist; D.T. Salvito, Research Institute for Fragrance Materials Inc / Department of Environmental Science; M. Vey, IFRA

To assure safety of fragrance ingredients in consumer products, International Fragrance Association expanded the fragrance industry's self-regulatory safety program with the development of IFRA Environmental Standards for both risk and hazard in 2008. Fragrance material risk assessments for these Standards are incorporated in the Research Institute for Fragrance Materials' (RIFM) testing program in coordination with its Expert Panel. To identify materials for risk assessment refinement, fragrance materials were screened using the RIFM Environmental framework and 2008 IFRA volume of use survey as reported for both Europe and North America. The Framework for this evaluation was published in Environment Toxicology and Chemistry (Salvito et al., 2002, 1301-1308). In addition, hazard assessment on these materials was also performed and reviewed. As a result nearly 3,000 materials were screened with preliminary risk quotients estimated to rank priority materials for risk assessment refinement. In an effort to provide greater transparency to the IFRA Environmental Standards, RIFM reports the most recent results of these additional tests (for both risk and hazard assessments) at both the annual SETAC NA and Europe meetings. These studies include persistence testing (ready biodegradation tests and die-away studies)), bioaccumulation, and acute and chronic aquatic toxicity. Incorporating these new data in a second tier risk and hazard assessment for these materials will also be presented.

MO143

Analysis and ecotoxicological investigations of Poorly Soluble Cosmetic Compounds – an approach for a reliable environmental risk assessment (ECOSM)

F. Stibany, RWTH Aachen / Institute for Environmental Research Biology; A. Coors, ECT Oekotoxicologie GmbH; H. Hollert, RWTH Aachen University / Institute for Environmental Research; K. Rettinger, IKW Industrieverband Koerperpflege; C. Schulte, Umweltbundesamt / Chemicals; J. Steber, German Cosmetic Toiletry, Perfumery and Detergent Association; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research

Personal Care Products (PCP) - often referred to as cosmetics - include a broad range of compounds that are poorly soluble in water, i.e. below 1 mg/L. Due to the high production volumes of PCP, and their typical 'rinse off' application, substantial amounts of these poorly soluble chemicals end up in waste-water treatment plants and may subsequently enter river systems with the effluent. This causes the need for a reliable assessment of their environmental behavior and toxicity to organisms, as requested by the European REACH-Regulation. Due to their high lipophilicity, resulting in extensive adsorption to surfaces like test vessels and organisms, standard ecotoxicity tests are not suitable for poorly soluble substances. The lack of consistent, reliable results due to the difficulties in maintaining constant test concentrations may lead to improper assessment of possible environmental risks. A promising approach addressing this problem is the so called 'poorly solubles approach' making use of an 'ecotoxicological threshold concentration of no concern' (ETNCaqua) for inert substances with a narcotic mode of action. Substances with solubility below this threshold concentration, are expected to have neither acute nor long-term adverse effects on aquatic organisms. The aim of the project ECOSM (ECOtoxicity investigations of COSMetic ingredients) is to develop pragmatic tools to test the ETNCaqua hypothesis in order to allow better environmental risk assessment of poorly soluble substances. At this stage of the project the surfactant precursor Dodecylbenzene has been selected as a suitable model compound. Different techniques for chemical analysis using gas chromatography have been developed successfully. These allow the detection of substance concentrations at the solubility threshold. Using these techniques the

maximum solubility of Dodecylbenzene in different media was exactly determined. Additionally passive dosing techniques have been established to maintain constant substance concentrations at the solubility threshold throughout the duration of various existing ecotoxicity tests with organisms of different trophic levels as proposed by OECD guidelines (e.g. algae, daphnia, fish eggs, and fish). Further methods to reach constant exposure conditions are under development and first ecotoxicity tests have been carried out. The adaptation of the test guidelines to these methods will be discussed.

MO144

How to focus experimental tests only on priority Personal Care Products

S. Cassani, University of Insubria / DiSTA; P. Gramatica, University of Insubria / QSAR Res Unit Environ Chem Ecotox Dep Theoretical Applied Sciences DiSTA

Several ingredients in Personal Care Products (PCPs) are now of recognized increasing environmental concern for their distribution, persistency, bioaccumulation and toxicity (PBT behavior). These ingredients have highly heterogeneous chemical structures and very different properties, for the majority of them persistence and toxicity data are lacking and the environmental behavior is unknown. Moreover, the determination of all the dangerous properties, required by REACH and Cos-me-tics Directive (Council Directive 76/768/EEC), is a long and difficult task. Due to the high variety of these chemicals and the big number of end-points that should be studied it is very important to have tools able to highlight the most dangerous compounds, diminishing the experiments because they could be focused only on the selected compounds. In this study, we propose tools for prioritizing the most dangerous ingredients in PCPs, thus reducing the costs and the animal tests as required by the new Regulations. A big number of chemicals (more than 500), such as flavor and fragrance agents, parabens, phthalates and UV filters have been screened for their cumulative PBT behavior, their acute toxicity on *Pimephales promelas* and their soil sorption on organic carbon. This screening has been done by the corresponding models (PBT-Index, *P.promelas* tox, and Koc) implemented in the software QSARINS and in the new module QSARINS-Chem, using also some chemometric method as Principal Component Analysis (PCA), MultiCriteria Decision Making (MCDM). The results of this screening/ranking study are a valid help for the understanding of the environmental behavior of hundreds of PCP ingredients, belonging to various chemical classes and for the reduction and focus of experimental tests.

MO145

QSAR study of Fragrance Biodegradability for safer alternatives

L. Ceriani, ICPS International Centre for Pesticides Health Risk / QSAR Department of Theoretical and Applied Sciences; E. Papa, QSAR Res Unit Environ Chem EcotoxDep Theoretical Applied Sciences DiSTA; s. kovarich, SIN Soluzioni Informatiche Srl / QSAR Res Unit Environ Chem Ecotox Dep Theoretical Applied Sciences DiSTA; R.S. Boethling, US EPA; P. Gramatica, University of Insubria / QSAR Res Unit Environ Chem Ecotox Dep Theoretical Applied Sciences DiSTA

Fragrance materials are a group of structurally heterogeneous compounds which have been widely used as ingredients in many consumer and personal care products. Their environmental occurrence, mainly in air and water compartments, is of potential concern for both humans and wildlife. After entering into the enviroment, fragrances may persist, and bioaccumulate into aquatic organisms, likely causing toxicity and endocrine disruption. Biodegradability is a basic information for the evaluation of environmental fate and persistence carried out in human and environmental risk assessment. Predictive approaches, such as those based on quantitative structure-activity relationships (QSARs), can be used to predict biodegradability of untested fragrances as well as support experimental data in a weight of evidence approach. The objective of this work is to propose valid QSAR models for the prediction of ready biodegradability that are specifically applicable to fragrance material. QSAR classification models were developed based on ready biodegradability data measured for a heterogeneous set of 189 fragrances, including nitro-, polycyclic and macrocyclic musks, cinnamates, terpenes, and linalool derivatives. Two different classification methods, namely classification and regression tree (CART) and k-Nearest Neighbors (k-NN), were applied to perform the modelling. Models were validated for their robustness and external predictivity, and the structural applicability domain was verified. A comparison was carried out between the here presented QSARs and U.S. EPA - BIOWIN models, showing a general higher specificity of our QSAR models in recognizing not ready biodegradable fragrances. In conclusion, robust and predictive QSAR models for the prediction of ready biodegradability of fragrances are presented in this study. These QSARs are based on transparent algorithms and on descriptors that are either commercially available or freely calculable, which guarantees a wider applicability and reproducibility of the models. The proposed models can be applied for the screening of fragrance chemicals, even before their synthesis, to support experimental data and to design safer alternatives that are less persistent than existing ones, as also required by REACH Regulation.

Fate and effects of nanoparticles under environmentally realistic conditions (P)

MO146

Impacts of differing nanomaterial surface chemistry on Daphnia magna

J. Bozich, UWMSFS / SFS; S. Lohse, University of Illinois at Urbana-Champaign / Chemistry; M. Torelli, UW-Madison / Chemistry; C. Murphy, University of Illinois at Urbana-Champaign; R.J. Hamers, Universtiy of Wisconsin-Madison / Chemistry; R. Klaper, University of WisconsinMilwaukee / School of Freshwater Sciences

In order to create nanomaterials that are sustainable with little potential environmental impact the mechanisms that govern nanomaterial toxicity need to be understood. Yet there are still questions as to the properties of nanomaterials that lead to toxicity. Variations in nanomaterial surface chemistry may influence nanoparticle toxicity by changing nanoparticle interactions with organisms and directly contributing to toxicity. In this study, the impacts of differentially functionalized gold and diamond nanoparticles on mortality, reproduction, and body size in the toxicological model species, *Daphnia magna,* were compared over acute and chronic exposures. Acute and chronic assays show that negatively charged gold nanoparticles are orders of magnitude less toxic than the positively charged gold nanoparticles. Certain ligands used in nanoparticle functionalization can directly contribute to and increase toxicity of nanomaterials. We also show that nanomaterials can increase the toxicity of ligands by increasing their delivery to the organism and therefore localizing ligand concentration and exposure. In addition, similarly functionalized diamond and gold nanoparticles have differing toxicities in Daphnia which indicates that toxicity is not solely due to surface charge but also dependent upon other properties such as ligand density, structure or particle stability. These results demonstrate that specific nanomaterial properties have great implications for determining nanomaterial toxicity and need to be considered in order to design sustainable nanomaterials.

MO147

Toxicity effects of silver nanoparticles synthetized using Arbutus unedo leaf extracts to the cladoceran Daphnia magna

S.F. Goncalves, Department of Biology CESAM University of Aveiro / Department of Biology CESAM; R.S. Lopes, Universidade de Aveiro / Departamento de Biologia CESAM; P.C. Pinheiro, T. Trindade, University of Aveiro / Department of Chemistry; P. Kouvaris, N. Michailidis, Aristotle University of Thessaloniki / Physical Metallurgy Laboratory, Mechanical Engineering Department; S. Loureiro, Universidade de Aveiro / Biology

Silver nanoparticles (AgNP) are used worldwide and can be found in many types of products, such as domestic disinfectants, cleaning products and even in pharmaceuticals, due to their bactericidal properties. This high use will inevitably lead to an increase release and high impact to the environment. For the past years silver nanoparticles have been synthesized using several physical and chemical methods. Biological and eco-friendly green synthesis processes have also been applied using different plant extracts, like leafs, to reduce metal ions to nanoparticles. This study aimed at comparing the toxicity of AgNP synthesized using different proportions of *Arbutus unedo* leaf extracts on the survival, reproduction and feeding rates of the cladorecan *Daphnia magna*. Toxicity was evaluated through acute and chronic tests (48h and 21 days exposure, respectively) in order to evaluate effects on survival and reproductive output. Feeding rates were evaluated through 24h feeding inhibition tests. Results revealed higher toxicity for AgNP synthesized with a lower proportion of leaf extract, which may be a consequence of a higher release of silver ions compared to the AgNP synthesized with a higher proportion. Using also time as a key variable, and looking at NPs storage time, although acute toxicity levels between both AgNP become similar with time, chronic toxicity continues to show differences between AgNP, where lower proportions of leaf extract continues to induce higher toxicities.

MO148

Toxicity of silver and gold nanoparticles, produced in the gas phase, to the aquatic plant Lemna minor

P. Minogiannis, University of the Aegean / Dept of Environment; M. Valenti, Delft University of Technology / Department of Chemical Engineering; V. Kati, Benaki Phytopathological Institute; O. Kalantzi, Dept of the Environment; G. Biskos, Department of Chemical Engineering

The increasing use and applications of engineered nanoparticles (ENPs) in consumer products has raised many questions with regard to their potential toxic behavior. Although an increasing number of studies have focused on the toxicity of ENPs, little information is available on their toxic effects on aquatic plants. This study assesses the effects of silver (AgNPs) and gold nanoparticles (AuNPs) on *Lemna minor* under modified ISO 2079 test conditions. The nanoparticles used in these tests were synthesized using an innovative aerosol-based method (namely the spark discharge generator), which yields nanoparticles of very high purity and provides good control over their size, morphology and composition. Spherical nanoparticles having diameters in the range from 20 to 80 nm were produced in high purity Ar gas and inserted in deionised water. Tested concentrations of AgNPs and AuNPs were 0, 5, 10, 20 and 40 μg L^{-1}. After 7 days exposure to a 10 μg L^{-1} solution of AgNPs *Lemna* cultures showed a statistically significant inhibition of frond numbers ($p < 0.05$). Growth inhibition by up to 90% was observed for all tested concentrations. A 7-day exposure of *Lemna* to the lowest concentration of AgNPs (5 μg L^{-1}) also caused a significant reduction in its relative growth rate (RGR). AuNPs on the other hand, had a positive effect on frond numbers when their concentration was 5 and 10 μg L^{-1}. For these concentrations the relative growth inhibition was 70 and 50%, respectively. At higher concentrations (i.e., 20 and 40 μg L^{-1}) AuNPs exhibited a statistically significant inhibitory effect on frond number ($p < 0.05$). Compared to Ag, AuNPs also enhanced root length and dry weight at 5 μg L^{-1}. Evidently, high-purity AgNPs and AuNPs prepared with the same method have different effects on *Lemna minor* growth. AgNPs were found to be toxic to *Lemna minor* at the lowest tested concentration of 5 μg L^{-1}, whereas AuNPs exhibited a positive effect for some growth parameters tested. This is of particular importance considering the increasing production and use of silver and gold nanoparticles in consumer products, which will render these toxic concentrations more environmentally relevant in the future.

MO149

Fate and effects of 107Ag nanoparticles in Daphnia magna under realistic environmental test conditions

A. Macken, NIVA / Ecotoxicology and Risk Assessment; I. Nerland, Ecotoxicology and Risk Assessment; A. Laycock, Imperial College London; K. Ndungu, NIVA; K. Thomas, NIVA / Product Metabolism

At present there is a worldwide focus on engineered nanoparicles (ENPs) in the environment, the possible risks they pose and the potential need for nanospecific environmental risk assessment and legislation. The ENPERA project (Engineered nanoparticles interactions with the environment: towards and understanding of the risk they pose) specifically targets engineered nanoparticles and how they influence "system and process understanding" and "what are the effects of distribution of NPs and how can these be dealt with". The project seeks to establish a knowledgebase that will inform the process of understanding the risks posed to the environment from ENPs, specifically focusing on environmentally relevant exposure scenarios and consideration of toxicity and fate of ENPs in the environment and within target organisms. This poster presents the evaluation of the fate and effects of a stable isotope silver particle (^{107}AgNP) in the standardised test organism *Daphnia magna*. Silver nitrate was and used as a comparative "bulk" silver for all experiments. Both short term acute and longer term chronic exposures were conducted followed by an examination of the uptake and depuration within the test organism. As well as assessing a more realistic exposure (e.g. presence of food, natural organic matter (NOM)) the aim was to allow the work to feed into the regulatory process by employing standardised methods (e.g. OECD). The acute toxicity of $AgNO_3$ was greater than ^{107}AgNPs in all experiments. In addition differences in the behaviour of the ENP were observed compared to $AgNO_3$ when assayed with varying environmental parameters e.g. in the presence of food the toxicity of the NPs was reduced but the toxicity of $AgNO_3$ was observed to increase. Additionally the uptake of AgNP was greater than $AgNO_3$ with increasing concentration, indicating a possible nano specific mechanism for uptake of silver. The data was then compared with existing data to asess the suitability of standard methods and compare the toxicity of these NPs with NPs of similar size and composition in the literature.

MO150

Engineered nanoparticle fate model – simulating realistic conditions in a complex natural river system

N. Sani-Kast, ETH Zurich; A. Praetorius, ETH Zurich / Institute for Chemical and Bioengineering; J. Labille, CNRS; P. Ollivier, BRGM; M. Scheringer, ETH Zuerich / Institute for Chemical and Bioengineering; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

An increasing concern regarding engineered nanoparticles' (ENPs) environmental impact is derived from their increasing production, unconventional properties and mostly unknown behaviour in the environment. As of now, environmental concentrations of ENPs cannot be measured by in-situ quantification due to analytical challenges. Consequently, the design of meaningful toxicity tests and ENP risk assessment have to rely on rational estimations of ENP environmental concentrations. In this study we present the design and evaluation of an ENP fate model capable of incorporating environmental complexity to predict realistic environmental concentrations of ENPs. This model is based on a designated fate model for ENPs in surface waters first developed by Praetorius et al. in 2012. As in the original model, heteroaggregation between the ENPs and suspended particulate matter (SPM) is assumed to be a key process determining ENP transport. Realistic conditions were introduced by defining variable SPM composition and concentration along the river and time dependent emissions. We evaluated our model by investigating the predicted fate of nano-TiO_2 in the lower Rhône River (France) since this river is characterized by a unique SPM variability. In order to constrain our model with a realistic SPM composition, the SPM parameters employed were derived from a recent sampling campaign of that river. Since the attachment efficiency - α_{hetero}, a fundamental parameter governing the heteroaggregation process, is not easily measured, we evaluated our model's predictions for all possible α_{hetero} values between the measured SPM and nano-TiO_2. Our model results provide spatially resolved concentration values for the free nano-TiO_2 particles as well as the nano-TiO_2 bound to SPM, both in the water and sediment compartments along the course of the river. The combination of all results was then analysed to obtain the most probable transport profile of nano-TiO_2 in the lower Rhône This novel approach provides a powerful tool for predicting realistic ENP concentrations in surface waters, thereby enabling the design of rational toxicity tests and supporting the risk assessment process of ENPs.

SimpleBox4nano predicts environmental behavior of nanomaterials

J. Meesters, Radboud University Nijmegen / Institute of Wetland and Water Research; J.T. Quik, RIVM / Aquatic Ecology and Water Quality Management Group Department of Environmental Sciences; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group Department of Environmental Sciences; T. Traas, National Institute for Public Health and the Environment RIVM; D.T. Sijm, Head Bureau REACH; D. van de Meent, RIVM / Institute of Wetland and Water Research

A new version of the multimedia mass balance model SimpleBox has been released. In SimpleBox4 (platform presentation "SimpleBox Solution"), new insights in substance-specific transport and transformation mechanisms have been incorporated to allow exposure modeling of chemicals with a more complex structure than the traditional chemicalsubstances. Recently published approaches to model typical colloidal processes have been added to enable environmental fate simulation of nanomaterials. Functionality of the new "SimpleBox4nano" has been explored by modeling a suite of hypothetical nanomaterials, using slowly emerging measurement data from literature, as obtained from the Nanomaterial Registry (https://www.nanomaterialregistry.org). It appears that there are two dominant influences on exposure concentrations of nanomaterials in air, water and soil, which have not been accounted for in traditional multimedia mass balance models (i) rate of dissolution in water, and (ii) rate of aggregation and subsequent deposition. Particularly the latter may be important, since colloidal dispersions of nanoparticles in air and water are usually rather unstable and rapidly form homo- and heteroaggregates, followed by often rapid deposition from atmosphere and water column. The results of this study demonstrate the importance of quantitative knowledge of the (in)stability of colloidal dispersions under environmental conditions. Ideally, rate constants for transport by aggregation/deposition (e.g. from water to sediment) should be written as explicit functions of physical-chemical characteristics of the nanomaterials and water chemistry, using the well-established DLVO-theory of colloid stability. Practically, application of this theory to nanoparticles in environmental systems is still underdeveloped, so that predictions of environmental exposure concentrations need to be based on reported empirical observations.

MO152

Toxicity of fresh and aged suspensions of silver nanoparticles to Pseudokirchneriella subcapitata (Korshikov)

G. Libralato, Veneto Nanotech SCpA / Department of Environmental Sciences Informatics and Statistics; D.M. Mitrano, EMPA Technology Society Lab / Environmental Risk and Management; M. Zanella, A. Pigozzo, Veneto Nanotech SCpA; L. Manodori, ECSIN - Veneto Nanotech SCpA; D.A. Vignati, CNRS / LIEC UMR

Silver nanoparticles (AgNPs), with their demonstrated antimicrobial effects, are increasingly found in consumer products. However, incomplete information is known about their environmental impacts. Due to their multiple uses, especially in textiles, AgNPs are expected to enter the aquatic environment mainly through the wastewater collection and treatment system. In this study, the short-term chronic toxicity (72 h) to *Pseudokirchneriella subcapitata* (Korshikov) of eight commercial AgNPs (20 – 100 nm) was investigated in reconstructed freshwater according to ISO standard 8692 using a fluorimetric method and accounting for quenching phenomena. The relative importance of coatings and dispersants was assessed in addition to the effects of ionic silver. The experimental design focused on how aged AgNPs suspensions of 1, 4, 7, 14 and 21 days may behave differently from their pristine counterparts and thus influence their ecotoxicity depending on their changed chemistry through the ageing process. Recognizing transformation of NPs occurred during the aging process, solution and particle characterization complemented the determination of EC50 values of the exposed algal populations for each experiment. Total Ag was quantified by ICP-MS after acid digestion of the NPs suspensions, while the fraction of ionic and/or small Ag complexes/aggregates was measured by ICP-MS after filtration. The ionic fraction was determined via Ag ion-selective electrode. After analysis of variance, toxicity effects were deemed as averagely independent ($p < 0.05$) between treatments from the age of the suspension. Regardless, within a single treatment the age of the testing media influenced the ecotoxicological effects, which tended to increase at later time points thus with aging of the suspensions. In some cases, the AgNPs toxicity was equal to that generated by the Ag ionic form representing the reference positive control (6 ±

2 µg/L, n = 5). Particularly, the toxicity varied with the age of the suspension for uncoated NPs, but much less for coated NPs. As a general statement, it was observed that the ageing time of AgNPs suspensions may influence the resulting toxicity effects in a way that depends upon the characteristics of the single AgNP formulation.

Aqua-Nano project: Fate of engineered nanoparticles and effects on marine pelagic ecosystem

M. Tsapakis, Institute of Oceanography; S.A. Pergantis, University of Crete / Chemistry; E. Sarropoulou, Hellenic Centre for Marine Research Crete / Institute of Marine Biology Biotechnology and Aquaculture; P. Pitta, Hellenic Centre for Marine Research Crete / Institute of Oceanography; I. Kalanzi, Hellenic Centre for Marine Research / Institute of Oceanography; K. Kordatos, National Technical University of Athens / School of Chemical Engineering; C. Zeri, Hellenic Centre for Marine Research / Institute of Oceanography; E. Kaberi, Hellenic Centre for Marine Research

Aqua-Nano project has been funded by the General Secretariat of Research and Technology, Hellenic Ministry of Education, Lifelong learning and Religious Affairs. This project will address the urged need to study the physicochemical and biological behavior of engineered nanoparticles in marine ecosystem. Engineered nanoparticles are materials which are produced purposefully by human activity and are less than 100 nm in size. Very little is, however, known about the fate, transport, and transformation of nanoparticles in aqueous systems. How and to what extent nanoparticles influence aquatic ecosystems is not yet clear. Aim of this project will be the development and applied an ecosystem approach for understanding the mechanisms of natural and engineered nanomaterial impacts on marine planktonic ecosystem. The core idea of the project is to use HCMR mesocosm facilities (http://mesoaqua.eu/cretacosmos) and a food web approach in order to study the effects of engineered nanomaterial on planktoning system. The use of mesocosm experiments is an innovative approach on ecosystem response and it will be the first time such approach will be used.. These in situ mesocosms represent a community level approach and will enable us to examine the bioavailability of specific nanoparticles on marine food web and also perform toxicity tests. Novel analytical chemical procedures and biological (eg. real time PCR) will be developed. Investigating the Behavior of Metal-containing Nanoparticles (NP) in Seawater Environments will be performed using Single-Particle Inductively Coupled Plasma Mass Spectrometry. The project will analyse the effects of silver and titanium nanoparticles on natural plankton communities. NP size distribution, number concentration, and metal mass fraction, for the NPs occurring in both the seawater and in marine biota will be analysed. Furthermore, the synergistic effect of co-occurrence on Silver nanoparticles and organic pollutants on marine pelagic ecosystem will be investigated.

MO155

A biodynamic description of the uptake and depuration of different sized CuO nanoparticles in the freshwater gastropod Potamopyrgus antipodarum

S.R. Tangaa, F.R. Khan, Roskilde University / ENSPAC; K. Schaumburg, Roskilde University / NSM; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change

Copper (Cu) and copper oxide nanoparticles (CuO NPs) are used in a wide range of industrial and consumer products; e.g. antimicrobial textiles, bioactive coatings and skin products. Consumers and ecosystems are therefore likely to be exposed to these particles, and previous studies have shown, that NPs from various sources will be released into the environment. The particles will eventually reside within sediment ecosystems where they can be inadvertently ingested by sediment-dwelling organisms. However, the environmental impact and dietary bioavailability of these particles remains largely unknown. **'In-house' synthesized CuO NPs (20nm) and commercial poly-dispersed CuO NPs (≈100 nm) was used to examine the accumulation kinetics of the freshwater gastropod, *Potamopyrgus antipodarum*, exposed to dietary copper oxide NPs or aqueous Cu (administered as $CuCl_2 \cdot H_2O$). Due to the small size and high surface-to-volume ratio of NPs, it is believed that the uptake of these particles will happen more easily than for the bulk material, with smaller size leading to a higher degree of uptake. Hence, the 20nm CuO NPs are expected to be more bioavailable for the organisms compared to the poly-dispersed CuO 100nm NPs.\n**20nm NPs was synthesized by reducing $CuCl_2 \cdot H_2O$ (aq) with ascorbic acid, followed by continuously stirring and heating for 16h. Polyvinylpyrrolidone (PVP) was added in order to stabilize the NPs, and they were characterized using several methods, including Transmission Electron Microscopy (TEM). The size distribution was 19.6±5.3nm and visual imaging showed that the particles were spherical, coated copper NPs. \nTo quantify dietary uptake, *P.antipodarum* was exposed for 2-4h to carbon-cleaned natural sediment, mixed with algae (*Nitzschia palea* (Kützing) W.Smith) to ensure a sufficient organic content, and subsequently spiked with a range of NP and Cu^{2+} concentrations. Elimination was determined over a depuration period of 15days. \nExperimental determination of unidirectional uptake and elimination rate constants using the biodynamic model permits modeling steady state Cu concentrations within the organism, which in turn can inform upon the potential toxicity of NPs. We will discuss how bioavailability is affected by the size of NPs using the biodynamic parameters.

MO156

Bioaccumulation of Cu2O NPs in Potamopyrgus antipodarum exposed to spiked biofilm

R. Windfeld, ENSPAC; C. Svendsen, CEH Wallingford / Pollution and Ecotoxicology; M. Matzke, Centre for Ecology Hydrology NERC / Molecular Ecotoxicology; K. Schaumburg, Roskilde University / NSM; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change

Nanoparticles (NPs) possess new technological properties due to their increased reactivity and higher surface-to-volume ratio compared to their bulk counterparts. Engineered NPs come with different coatings which may affect the stability of the particles and their environmental fate. NPs are thought to sediment when introduced to natural aquatic environment, and subsequent uptake of the particles through digestion can therefore become a risk for benthic deposit-feeders. NPs are assumed to bind to organic compounds in the environment and thus to be incorporated into biofilms. Must surfaces in aquatic environment will be sporadically covered with biofilm. The use of spiked biofilm as a food source represents a realistic uptake route for benthic deposit-feeders. The aim of this study was to examine bioaccumulation and toxicity of Cu from biofilm spiked with Cu_2O NPs in the gastropod *Potamopyrgus antipodarum*. Biofilms were grown for 96 hours prior to spiking under controlled temperature and light conditions in natural river water and were then exposed to three different Cu forms (0.1 mg Cu/L) for 24 hours: non-coated and Polyvinylpyrrolidon (PVP) coated Cu_2O NPs, aqueous Cu ($Cu_{(aq)}$) was used as a reference. The size of the synthesized NPs was 8.93±6.9 and 10.68±7.9 nm for non-coated and coated Cu_2O NPs in artificial media, respectively. Bioaccumulation and toxicity (i.e., feeding rate) was tested on *P. antipodarum* exposed to contaminated biofilm for 72 hours. A biofilm concentration of 153.4 and 150.14 μg Cu/g DW biofilm for non-coated and coated NPs, respectively, at the end of the test, was achieved. The feeding rate of *P. antipodarum* was not significantly affected by exposures to any of the Cu treatments. None of the Cu treatments affected the bioaccumulation (body burden) significantly. NPs were also not accumulated significantly compared to $Cu_{(aq)}$. Results suggest that - since NPs (coated or non-coated) are not accumulated to a higher degree than $Cu_{(aq)}$ - released CuNPs will contribute solely to an overall increase in Cu concentration in receiving environments.

MO157

Nanoparticle post-exposure characterization in animal tissues: Enzymes lead the way

S. Makama, Department of Toxicology; I.M. Rietjens, Wageningen University / Division of Toxicology; N.W. van den Brink, Wageningen University / Dept of Toxicology

The production and application of engineered nanomaterials (ENMs) is still increasing and the range of nano-composit consumer products has also multiplied, leading to increased potential for their environmental release. To appropriately characterize the fate, effects and ultimately risks of ENMs in environmental systems, methods are essential to characterize nanoparticles (NPs) in complex biological matrices. Most methods currently used are destructive, with acid destruction for instance additionally dissolving metal NPs. These conventional methods are thus limited in providing information about the effects of size, surface charge, coating, etc. on internal dose levels and fate of ENMs post-exposure. Here we used a combination of enzymatic tissue processing (ETP) followed by ICP-MS, TEM and AF4 to quantify and better characterize AgNP in tissues of the red earthworm *Lumbricus rubellus* after 28 day exposure to nominal concentrations of AgNPs (1.5, 15 and 150) or $AgNO_3$ (1.5 and 15) mg Ag/kg soil. For this, we compared total Ag burdens in ETP-extracted earthworm tissues with Ag levels obtained upon conventional microwave-assisted acid digestion method using routine ICP-MS. Results indicated concentration-dependent total Ag burden of 0.645 ± 0.141, 8.621 ± 0.138 and 15.480 ± 7.61 μg Ag/g (AgNP exposure) and 0.970 ± 0.435 and 8.315 ± 2.470 μg Ag/g ($AgNO_3$ exposure). Total silver in earthworm tissues processed enzymatically revealed comparable concentration-dependent body burdens as those processed via direct microwave-assisted acid digestion, amounting to 1.986 ± 1.822, 3.928 ± 2.275 and 6.641 ± 4.945 μg Ag/g (AgNP exposure) and 2.054 ± 2.132 and 6.968 ± 6.331 μg Ag/g ($AgNO_3$ exposure). TEM images of ETP extracted particles of AgNP exposed earthworms indicated the presence of electron-dense spheres consistent with images made of the AgNPs as-supplied. Further post exposure characterization of ETP-extracted particles using AF4 is underway and will be presented. The present study provides possibilities for improved post-exposure characterization of ENMs in tissues of exposed soil invertebrates. This will enhance the effectiveness of current risk assessment strategies.

MO158

Impact of cerium dioxide nanoparticles on a reconstructed aquatic ecosystem: a mesocosm study

a. bour, ECOLAB UMR CNRS UPS INPT; F. Mouchet, ECOLAB UMR CNRS UPS INPT / ECOTOXICOLOGY AND ENVIRONNEMENTAL HEALTH; L. Verneuil, Ecolab Laboratoire décologie fonctionnelle et environnement; A. Perrault, ECOLAB UMR CNRS UPS INPT; J. Silvestre, ECOLAB UMR CNRS UPS INPT / ECOLAB UMR CNRS UPS INPT; L. GAUTHIER, E. PINELLI, ECOLAB UMR CNRS UPS INPT

The growing interest in cerium dioxide nanoparticles (CeO_2 NPs) for industrial purposes (catalysis, coatings, solar cells, cosmetics…) has led to important volumes of production in the last few years. Environmental release is then expected, but NPs toxicity remains not well known. Ecotoxicological studies on CeO_2 NPs are emerging but are still too few to provide an overview on these particles environmental impact. Furthermore, the complexity of environmental conditions is not taken into account in standard studies, leading to a poor representativeness of NPs toxicity in natural conditions. The aim of the present study is to assess the toxicity of CeO_2 NPs on a simplified aquatic ecosystem using low NPs concentrations, as expected in natural aquatic environments, to provide a better understanding of their toxicity mechanisms. For this purpose, mesocosms comprising a complex primary compartment (bacteria, fungi and algae), and primary (dipteran larvae *Chironomus riparius*) and secondary (amphibian larvae *Pleurodeles waltl.*) consumers were used. This system allows the establishment of trophic relations and simultaneous exposure of the different species, coupled with continuous monitoring of physico-chemical parameters. Mesocosms' contamination consisted in a regular introduction of CeO_2 NPs for four weeks, to get to the final concentration of 1 mg/L of NPs. Toxicity on primary compartment was assessed as bacterial community diversity. Surviving chironomid larvae were counted at the end of the experiment, and growth inhibition was assessed as chronic toxicity endpoint. Mortality, growth inhibition and genotoxicity were assessed on amphibian larvae. No toxicity was observed either on primary compartment or on chironomids, but amphibian larvae were importantly impacted. Indeed, significant genotoxicity, growth inhibition and mortality were observed. Complementary experiments were also realized in order to determine possible mechanisms of toxicity on amphibian larvae. This work has been carried out within the ANR- P2N MESONNET project.

MO159

Effect of silver nanomaterials on microbial diversity in sewage sludge

C. Diaz, Fraunhofer IME; K. Schlich, Fraunhofer IME Institute for Molecular Biology and Applied Ecology; K. Hund-Rinke, Fraunhofer IME / Ecotoxicology

The rising use of silver nanomaterials (AgNM) increases the potential for environmental contamination. AgNM will inevitably reach the wastewater treatment plant (WWTP) were the AgNM adsorb mainly to the sludge. Currently, there is little information available about the effect of AgNM on the microorganisms in a WWTP. This study aimed to evaluate the effects of a spherical AgNM (NM-300K) and a nanorod (NM-302), both from the OECD Sponsorship Program, on the microbial diversity of sewage sludge of a simulated WWTP. A WWTP was simulated (OECD TG 303A) with a denitrification, nitrification and a settling tank. Over 10 days continuously NM-302 at 0.04, 1 and 4 mg/L and a NM-300K at 1 mg/L were dosed into the WWTP. The dissolved organic carbon (DOC) was measured daily in the influent and effluent of the different treatments. The influence of AgNM on the sludge microorganisms was investigated by observing the DOC elimination comparing the different treatments with the control. Additionally the microbial diversity was studied with two fingerprinting methods: polymerase chain reaction-denaturing gradient gel electrophoresis (PCR-DGGE) and automated ribosomal intergenic spacer analysis PCR (ARISA-PCR). Eubacterial primers, for each method, were used to amplify the extracted DNA from sludge. Over the entire experiment no inhibition of DOC elimination by AgNM was detected. Even with continuous addition of 4 mg/L NM-302 for 10 days, the DOC elimination by the microorganisms was not inhibited. The DGGE pattern did not show differences in the bacterial ecological distribution within the different treatments, showing the same predominant groups of bacteria. However when using NM-302 at a concentration of 4 mg/L the intensity of the bands of some predominant bacteria decreased considerably, suggesting that the total population decreased in number. With ARISA-PCR, similar profiling was observed, however some groups of bacteria disappear at higher concentrations of the nanorod NM-302 and with NM-300K, while other groups seems to be favored. The study shows, that the conventional endpoint DOC elimination (OECD TG 303A) gave no evidence of an effect of AgNM on the microorganisms in sludge. A deeper analysis of microbial diversity gave first indications of a possible shift of individual microorganism populations. Further studies, to evaluate in deep the differences observed, must be conducted. The study was financially supported by the EU MARINA Framework 7 project.

MO160

Short-term effects of silver nanoparticles on periphytic communities

C.G. Allue, Eawag / Department of Environmental Toxicology

Periphyton is a mixed microbial community of auto- and heterotrophic organisms embedded in an extracellular polymer matrix. It is involved in ecosystem functions such as primary production and nutrient cycling. Although periphyton has been identified as a probable sink of nanomaterials in aquatic environments, its sensitivity to nanomaterials is unknown. In this study, we assessed the short-term effects of citrate-coated silver nanoparticles (AgNP, 35 nm diameter) and silver ions (Ag^+, dosed as $AgNO_3$) on periphyton through their effects on photosynthesis, respiration, and potential activity of three extracellular enzymes: β-glucosidase (β-GLU), leucine aminopeptidase (LAP) and alkaline phosphatase (AP); which are involved in nutrient acquisition. Glass slides colonized with natural periphyton were placed in microcosms filled with reconstituted freshwater (pH 7.5) and exposed to concentrations ranging from 12.5 to 200 μM AgNP or from 1.25 to 25 μM $AgNO_3$, during 2 hours in the dark at 15 °C. After exposure, the periphytic community was scraped off the slides, suspended, and used in short-term bioassays. Photosynthetic activity was assessed by fluorometry, CO_2 produced during respiration was measured colorimetrically, and potential enzyme activities were assayed with fluorescent substrate analogues. The silver ion ligand sodium 2,3-dimercaptopropanesulfonate (DMPS, 25 µM) was used to assess the contribution of Ag^+ in causing toxic effects. Based on total silver mass, $AgNO_3$ was more toxic than AgNP for both endpoints. The AgNP concentration causing a 50% inhibition (EC_{50}) was 83 μM for photosynthesis and 22 μM for respiration. In the case of $AgNO_3$, EC_{50} values were 3 μM for photosynthesis and 4 μM for respiration. Potential enzymatic activities were also inhibited by both AgNP and $AgNO_3$. β-GLU and LAP activities decreased with increasing concentration of silver. EC_{50} values were 17 μM AgNP and 2 μM $AgNO_3$ for β-GLU, and 23 μM AgNP and 2 μM $AgNO_3$ for LAP. AP activity did not follow a concentration-dependent decrease as the two other enzymes. Based on these values, the toxicity observed could not be solely attributed to the measured fraction of free Ag^+ in the AgNP suspensions (1.5 – 3 %). Experiments with DMPS prevented AgNP toxicity to most endpoints, indicating that the toxic effects were mainly caused by Ag^+. The exception was LAP, which was directly affected by AgNP.

MO161

Ecotoxicity of a novel anti-corrosion engineered nanomaterial in two invasive bivalve species

R. Martins, Department of Biology University of Aveiro / Departamento de Biologia CESAM; C.S. Santos, University of Aveiro / Department of Biology CESAM; R. Freitas, Biology; J. Tedim, Universidade de Aveiro Smallmatek Small Materials and Technologies Lda / Department of Materials and Ceramic Engineering; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; S. Loureiro, Universidade de Aveiro / Biology

Nowadays, corrosion is one of the most relevant problems affecting underwater metallic structures (e.g. ship hulls, oil platforms). To minimize these problems the metallic substrates have been protected with specialized anti-corrosion coatings which contain active compounds, such as corrosion inhibitors. The corrosion inhibitor mercaptobenzothiazole (MBT) is amongst the most widely used in paints, showing high toxicity for organisms and humans. Recently, important insights were given in terms of encapsulation of active compounds, as a result of the banishment or restriction of environmentally harmful compounds (e.g. TBT). The encapsulation is a process used to prevent the interaction of active compounds with paint formulations, to promote their controlled release and to provide protection against the environment. This process may involve "smart" and novel engineered nanomaterials, such as the layered double hydroxides (LDH), also called anionic clays, in which active compounds are encapsulated until the conditions are adequate to be released (e.g. coating degradation, pH changes). When released, active compounds and nanocontainers come available to organisms, but little is known about their fate and toxicity for soft-bottom benthic communities, especially bivalves, despite the eco-friendly labeling of nanocontainers. In this study, two invasive species were selected, one from the marine environment (edible Manila clam *Venerupis philippinarum*) and another from the freshwater environment (Asian clam *Corbicula fluminea*). To assess the potential effects of the anti-corrosion LDHs and the free active compound (MBT), 96h exposures were carried out in both bivalve species. For each species, mortality, clearance rate, survival on air, condition index and biomarkers (LPO, CAT, GST, CBE, ChE and total protein) were assessed.

MO162

Cytotoxicity and immune response of mussel mytilus galloprovincialis after exposure to CdTe QDs and Cd2+

T. Rocha, T. Gomes, University of Algarve / CIMA; C. Cardoso, University of Azores / DOP; J. Letendre, University of Algarve / CIMA; V.S. Sousa, University of Algarve / CENSE; M.R. Teixeira, CENSE and University of Algarve; M.J. Bebianno, University of Algarve / CIMA

Quantum Dots (QDs) are nanocrystals (2 to 9.5 nm in diameter) composed of a semiconductor core and shell that can be modified by the addition of different functional groups. Due to their recognized specificity on cellular targets, strong

fluorescence and resistance to photobleaching, they are used in electronic, nanomedicine, pharmacy and biology. However, these nanoparticles (NPs) can be released into the marine environment, where their toxicological effects and mechanisms of action are unclear. In particular, filter-feeding organisms are target groups for NPs toxicology and the marine bivalve *Mytilus* spp. represent an important model for investigating the toxic effects of NPs in marine invertebrates. Accordingly, the main objective of this study was to analyse the immune response of *Mytilus galloprovincialis* exposed to 10 μg.L^{-1} of CdTe QDs in comparison to their ionic counterpart for 3, 7 and 15 days. Several cytotoxic and genotoxic parameters were analysed, namely density and viability of circulating hemocytes, lysosomal membrane stability (LMS), differential hemocyte counts, micronucleus frequency, frequency of nuclear anomalies and DNA damage (comet assay). This study showed that the accumulation of QDs induces cellular stress and modulates the immune response of mussels *M. galloprovincialis*. Hemocytes lysosomal integrity and cell viability decreased after 3 days of exposure in mussels exposed to both Cd forms, remaining unaltered until the end of exposure. In terms of LMS and density, of significant differences were observed between QDs and Cd^{2+} exposures. On the other hand, the results on differential hemocyte counts and frequency of nuclear anomalies showed different responses on hemocyte types, dependent on the Cd form. After the 15 days of exposure, QDs induced a significant decrease in the percentage of circulating eosinophils and an increase in basophils. In contrast, Cd^{2+} caused a decrease in the proportion of both cell types and increased circulating hyalinocytes. These results indicate that the mechanism of immunotoxicity of QDs may be due to Cd^{2+} dissolution, even though the responses of the types of hemocytes vary according to the form of Cd. Overall, this study showed that *M. galloprovincialis* hemocytes are a suitable model for investigating the effects of NPs in marine invertebrates.

MO163

Multibiomarker assessment of the long term effects of dissolved and nanoparticulate silver (nAg) on zebra mussels: influence of feeding

M. Garaud, Laboratory LIEC CNRS UMR UdL / CNRS UMR; C. Bertrand, N. Brule, LIEC CNRS Université de Lorraine; S. Devin, Universite de Lorraine; V. Felten, LIEC; B. Sohm, LIEC CNRS Université de Lorraine; L. Giamberini, Université de Lorraine CNRS UMR

Incorporation of silver nanoparticles (nAg) in everyday products is expanding quickly, and concerns on their ecological consequences are growing. nAg PEC in surface waters are currently expected to be below the μg/L range. If some studies showed nAg toxicity, even in the low μg/L range on several organisms (including bivalves), solubity issues are forcing us to compare nAg toxicity to dissolved Ag toxicity to try to distinguish specific nAg effects. Feeding is another scarcely studied parameter that could influence Ag toxicity by changing its bioavailability to organisms. The aims of our study were 1) to test nAg effects at low concentrations, 2) to observe an hypothetic modulation of toxicity associated with feeding, and 3) to compare nAg and dissolved Ag toxicity mechanisms. For that, nAg (60 nm, citrate coated) and dissolved silver ($AgNO_3$) effects were assessed on zebra mussels (*Dreissena polymorpha*) following a 14-day exposure to 0.5 and 5 μg/L, with and without lyophilized alga feeding. Mussels were sampled after 7 and 14 days and the haemocyte immunological functions and a wide range of biomarkers in digestive glands were measured (antioxidant and detoxification systems, cellular damages, energetic reserves). Results were synthesized using the Integrated Biomarker Response (IBR) tool. The first results showed a significant toxicity of both dissolved and nanoparticulate Ag on haemocyte immunological parameters. For both sampling times, stress levels as revealed by IBR calculation were consistently higher for unfed mussels. A dose-dependent decrease of cell viability, phagocytosis capacities and ROS production, more pronounced for nAg than for $AgNO_3$, was observed, denoting a potential increase in mussel sensibility to pathogens. On the contrary, the activation of the immune system for fed mussels happened only at day 7, but the stress levels went back to normal after 14 days, resulting from a lowered bioavailability of Ag or a better mussel fitness. As a whole, this work currently suggest that 1) long-term exposure to low concentrations of Ag could inhibit durably mussel immune defenses, 2) feeding decreases Ag toxicity, and 3) at equivalent nominal concentrations, nAg seems to be more toxic than dissolved Ag, suggesting differences in penetration, accumulation and action mechanisms of the two forms in organisms. Those results will be completed by water and internal concentrations of Ag and biomarker measurements into digestive gland.

MO164

Remote effects in charophyte cell of Nitellopsis obtusa after short term exposure to CuO nanosuspensions

L. Manusadzianas, Institute of Botany NatureResearch Centre / Institute of Botany; B. Gylyte, S. JURKONIENE, Nature Research Centre / Institute of Botany; K. SADAUSKAS, Lithuanian University of Educology; R. Vitkus, Nature Research Centre / Institute of Botany

Survival of the cells of macrophytic green algae *Nitellopsis obtusa* exposed to 100 mg/L CuO nanosuspension (< 50nm, Sigma-Aldrich) for at least 5 minutes decreased substantially after 8 days, while the rewash from noticeably toxic concentrations of Cu^{2+} (as $CuSO_4$), after short exposure (up to 6 hours), prevented cell mortality [Manusadzianas et al., 2012]. To explore whether toxicological threshold of exposure to nCuO does exist, the charophyte cells (n=60/treatment) were exposed for periods as short as 5 s to 24 h at sonicated 30 mg/L nCuO, then rewashed in media up to 72 days. Two controls, one with media, another with 30 mg/L nCuO (permanent exposure) were used. For comparison of quantal (mortality probabilities) effects of two single exposure durations the exact Fisher test were used (

MO165

A droplet based microfluidic device for single paramecia cell toxicity testing - a case study with silver nanoparticles

C. Burkart, Technische Universitat Dresden / Institute of Hydrobiology; D. Pfitzner, Technische Universitaet Dresden / Institute of Hydrobiology; R. Illing, Technische Universitaet Dresden Max Bergmann Center of Biomaterials / Institute for Materials Science; L. Baraban, Technische Universitaet Dresden Max Bergmann Center of Biomaterials / Institute for Materials Sciences; G. Cuniberti, Technische Universitaet Dresden Max Bergmann Center of Biomaterials / Institute of Materials Sciences; D. Jungmann, Dresden University of Technology

In microfluidic circuits droplets of analytes which are embedded in an emulsion liquid are infused into fine tubes. This represents a promising technique for non-invasive analysis of single cells or populations. It enables fast analysis of high replicate numbers while operating in very low volumes, down to picolitre range. Here we present a simple method to encapsulate single *Paramecia* cells in a total volume of about 100 nL, supplied with silver nanoparticles and a viability dye, which is transformed to a fluorescent compound by living cells. The aim is to observe the viability of the cells after exposure by measuring the fluorescence of the viability dye in-situ using optical techniques as a toxicological endpoint. Different cell densities and injection rates were tested in order to maximize the efficiency of introducing single cells into droplets, which is challenging because of the mobility of the cells and hence a biased distribution of cells in the liquid. Spectra of every single droplet were recorded and drops were computationally counted and labeled. The number of encapsulated cells was determined based on metabolic activity by this method and results were in accordance with counterchecks with a stereomicroscope. As a result we were able to record cell division of one confined paramecia cell. Microfluidic circuits are predestinated to be used for high sample capacity and for mixture toxicity.

MO166

Transformation and distribution processes governing the fate and behaviour of nanomaterials in the environment: an overview

N.B. Hartmann, Technical University of Denmark DTU / DTU Environment; L.M. Skjolding, DTU / DTU Environment; S.F. Hansen, Technical University of Denmark DTU / DTU Environment; F. Gottschalk; J. Kjolholt, Cowi AS; A. Baun, Technical University of Denmark / Department of Environmental Engineering

To develop a more complete understanding of the potential risks posed by manufactured nanomaterials, it is necessary to further examine their transport and fate in all environmental compartments. At present analytical chemistry methods are limited when it comes to detecting low concentrations of nanomaterials. Furthermore, distinguishing between naturally occurring, anthropogenic and manufactured nanomaterials in an environmental matrix poses additional analytical-chemical challenges. This situation leaves a gap between the present scientific state-of-the-art and the increasing demand for reliable measured or predicted environmental exposure concentrations for environmental risk assessment of ENMs. To fill this gap within a limited time frame modeling appears to be a suitable approach. Chemical fate modeling for nanomaterials is still in its infancy. Informed choices on the basis of available knowledge are needed during model formulation and development to ensure the reliability of predicted environmental concentrations of nanomaterials. A major knowledge gap hampering the further development of such model-based approaches is our current lack of understanding of the interplay between the novel physico-chemical properties, exhibited by many nanomaterials, the properties of the surrounding media/matrix and the underlying processes that determine particle behaviour. Here we identify and summarize key processes governing the fate and behaviour of nanomaterials in the environment. This is done through a critical review of the present state-of-knowledge. We describe the (photo)chemical, physical or biologically mediated transformation of manufactured nanomaterials from their pristine form (as produced or in a product) due to degradation, aggregation, agglomeration, or through association with dissolved, colloidal or particulate matter present in the environment. Specific nanomaterials are used as case studies to illustrate these processes where relevant. Key environmental processes are identified and ranked and key knowledge gaps are identified, feeding into the longer-term goal of improving the existing models for predicted environmental concentrations.

MO167

Number concentration and size distribution of nanoparticle from suspension by transmission electron microscopy

A. Prasad, Georgraphy and Environmental Sciences

Transmission electron microscope (TEM) is the nanoanalytics toolbox and can provide accurate information on nanoparticle (NP) number size distribution, number particle concentration at low concentrations (*ca.* ppt to ppb range) and small sizes (*ca.*< 20 nm) as well as chemical composition. However, the high capabilities of TEM are limited by the traditional sample preparation based on drying a small volume of suspension of NPs on a TEM grid. This method is limited by low recovery of NPs, formation of aggregates during the drying process, and thus, the complete misrepresentation of the NP suspensions under consideration. The present work presents a fully validated sampling technique for TEM that overcomes these shortcomings and allows full recovery and representativeness of the NPs under consideration by forcing the NPs into the TEM grid via ultracentrifugation and strongly attaches the NPs to the TEM grid by surface functionalization of the grid with a positively charged polymer (poly-l-lysine). The high efficiency of the analysis is demonstrated by the uniformity of the NP distribution on the TEM grid (that is low variability between the number of NPs counted on different images on different areas of the grid), the high recovery of the NPs up to 71%) and the good correlation (R>0.95) between the mass and number concentrations. The applicability of the protocol to detect and measure the number concentration of NPs in natural water was demonstrated on natural water spiked with AuNPs at different concentrations. AuNPs were uniformly distributed on the TEM grid (CV< 0.2) and good correlation between number and mass concentrations (R^2~ 0.9) and high recovery (75%-85%) were achieved. Therefore, for the first, we developed and applied a fully validated sampling protocol that enables the use of the full capabilities of microscopy tools to quantitatively and accurately determine the number size distribution and number concentration of NPs at environmentally relevant low concentrations (*i.e.* 0.34-100 ppb). This approach is of high environmental relevance and can be applied widely in environmental nanoscience and nanotoxicology for (i) detection of NPs in environmental systems at low concentrations, (ii) measuring the number concentration dose in nanotoxicological studies, and (iii) accurately measure the number size distribution of NPs, a key requirement for the implementation of the European Commission definition of nanomaterials.

MO168

Transformation and retention of silver nanoparticles through engineered inorganic wastewater treatment media

E.V. Clarke, University of Exeter / College of Engineering Mathematics and Physical Sciences; D.E. Gomez, The University of Exeter / College of Engineering Mathematics and Physical Sciences; C.R. Tyler, Biosciences College of Life and Environmental Sciences

Nanotechnology is an expanding industry with important implications for the global economy. Silver nanoparticles (AgNP) have assumed dominance within this market, with widespread use in industry, medicine and commercial applications. Projections indicate that at least one third of all AgNP containing products have the potential to leach silver into wastewater streams. As such, wastewater treatment plants (WWTP) play a key role in mitigating the impacts of AgNP upon receiving aquatic environments. A concern for WWTP is the potential for AgNP to affect the operation and efficiency of unit processes. Also, the capability of treatment processes to remove nanoparticles from wastewater streams is yet to be fully understood and quantified; this includes inorganic filtration techniques, which to date have not benefited from the same close research scrutiny as their biological counterparts. Using laboratory columns, operated under steady state flow conditions, this investigation aims to evaluate the fate and transport of AgNP through a variety of inorganic filtration substrates. Research will focus upon the physical and chemical interactions of AgNP within the experimental environments. Analysis of AgNP influents and filtered effluent samples has been conducted using transmission electron microscope, energy-dispersive X-ray spectroscopy and inductively coupled plasma optical emission spectrometry in order to characterise the nanoparticles. Preliminary results indicate that AgNP can exhibit varying, yet distinct degrees of mobility and persistence depending upon the filtration media employed. Also, AgNP appears to be less susceptible to ligand interaction than other forms of silver speciation exposed to the same environmental conditions. Column data suggests AgNP mobility in the columns to be closely associated to the surface charge of both the nanoparticles and of the media environment; as such the different capping agents commonly employed in the manufacture of AgNP, such as citrate and PVP, are likely to play an influential role in the mobility and persistence of AgNP through these filtration processes. This work aims to contribute data pertaining to the effects of inorganic treatment techniques and variability of system conditions upon AgNP behaviour and subsequent silver speciation and has the potential to assist future toxicological studies by providing speciation and concentration projections for AgNP at varying stages through a WWTP and into the environment.

MO169

Dispersion stability of CeO2 nanoparticles in different aqueous media and implications for freshwater algae ecotoxicity testing

A. Booth, SINTEF Materials and Chemistry / Environmental Technology; L. Sorensen, SINTEF Materials and Chemistry / Marine Environmental Technology; T.R. Storseth, SINTEF Fisheries and Aquaculture; A. Ahniyaz, A. Fornara, SP Swedish Technical Research Institute / Chemistry Materials and Surfaces

In the present study, an aqueous dispersion of CeO_2 nanoparticles (NPs) was evaluated for its stability in a range of freshwater ecotoxicity media, with and without the presence of natural organic matter (NOM). The potential ecotoxicity of the CeO_2 dispersion was then investigated using the freshwater algae *Pseudokirchneriella subcapitata*. The CeO_2 NPs (10 wt%) were supplied as an aqueous colloidal suspension (pH 8.5) and stabilized with excess anionic polymer stabilizer. Relevant physicochemical properties of the CeO_2 NPs were investigated before use in fate and effects studies. The crystallite size of the particles, determined using transmission electron microscopy, was 3-5 nm with aggregates up to 20 nm observed. Energy-dispersive X-ray spectroscopy indicated trace amounts of Au and Co impurities. HAADF-STEM in Z-contrast mode was used to image the PAA stabiliser present on the surface of the CeO_2 NPs. A Malvern Zetasizer indicated the stock CeO_2 NP dispersion had an average particle size of ~80 nm (dynamic light scattering; DLS) and a zeta potential of -25 mV, indicating the dispersion exhibits good colloidal stability. The stability (zeta potential) and aggregation (DLS) of the CeO_2 NP dispersion was investigated over time following dilution (0.01 and 1 mg/L) into a number of common freshwater ecotoxicity media; moderately hard reconstituted water (general media), TG201 (freshwater algae) and M7 (*Daphnia magna*). Influence of NOM from the Suwannee River (SR-NOM) on dispersion stability was also investigated for each media type. The ecotoxicity of the CeO_2 NPs to the freshwater microalga *Pseudokirchneriella subcapitata* was assessed using a modified version of the ISO algal growth inhibition method. In order to overcome 'shading' of the algal cells when measuring algal growth by fluorescence, the chlorophyll pigments were extracted into ethanol and filtered prior to analysis of absorbance by UV-vis spectroscopy. In order to account for any toxic contribution from the anionic polymer stabilizer present in the stock solution an NMR-based quantification method was established using pure polymer stabilizer. Linear calibration curves (R^2 0.999 from 0.01-100 mg/L) were established and used to determine the free polymer stabilizer concentration in the CeO_2 stock solution. In addition, the concentrations of particulate CeO_2 and dissolved Ce ions were determined by ultracentrifuging diluted aliquots of the stock solution and analysing the supernatant by ICP-MS.

MO170

UV-mediated transformation of C60 fullerene in top soil

A. Carboni, IBED; V. Blanco Montoya, K. Kalbitz, P. de Voogt, J. Parsons, University of Amsterdam / IBED

Owing to their innovative properties, fullerenes are considered as some of the most promising materials in emerging nanotechnology and they are currently applied in several fields such as electronics and household applications as well as cosmetics and organic photovoltaics. The expected increase in production is likely to cause increasing release of such materials into the environment and fullerenes have been suggested to enter the terrestrial ecosystem by direct release (e.g. leaching from fullerenes-containing materials) as well as deposition from the atmosphere and transport through aqueous media. Fullerenes are therefore expected to accumulate in the top soils but their environmental fate and behavior are still largely unknown. Sunlight is likely to play a major role in the transformation of fullerenes and UV-mediated transformation of C60 has already been reported in organic solvents and in aqueous solution. Data are missing, however, concerning the possible degradation of these compounds in soil environment which is expected to act as a sink for the fullerenes in the environment Therefore the aim of the present study was to investigate the degradation of C60 fullerenes in the top soil environment in presence of UV light. Sandy soils differing in texture and organic carbon content were amended with C60 at the concentration of 200 ppb and irradiated with UV light for several weeks. The samples were then extracted at specific time interval with both polar and non-polar solvents and analyzed with HPLC-UV-MS. Non-irradiated soil samples were incubated as controls and C70 fullerene was used as an internal standard for the assessment of the degradation rate. In addition, high-resolution mass spectrometric analysis was applied for the determination of both polar and non-polar transformation products.

MO171

Importance of particle dispersion and ionic environmenton on silver nanoparticle toxicity in the embryonic zebrafish

K. Kim, Seoul National University of Science and Technology / Environmental Engineering; R.L. Tanguay, Oregon State University / Environmental Molecular Toxicology

The mechanism of action of silver nanoparticles (AgNPs) is unclear due to the particles' strong tendency to agglomerate. Preventing agglomeration could offer precise control of the physicochemical properties that drive biological response to AgNPs. In an attempt to control agglomeration, we exposed zebrafish embryos to AgNPs of 20 or 110 nm core size, and polypyrrolidone (PVP) or citrate surface coatings in media of varying ionic strength. AgNPs remained unagglomerated in

62.5 µM CaCl2 (CaCl2) and ultrapure water (UP), but not in standard zebrafish embryo medium (EM). Zebrafish embryos developed normally in the low ionic strength environments of CaCl2 and UP. Exposure of embryos to AgNPs suspended in UP and CaCl2 resulted in higher toxicity than suspensions in EM. 20 nm AgNPs were more toxic than 110 nm AgNPs, and the PVP coating was more toxic than the citrate coating at the same particle core size. The silver tissue burden correlated well with observed toxicity but only for those exposures where the AgNPs remained unagglomerated. Our results demonstrate that size- and surface coating-dependent toxicity is a result of AgNPs remaining unagglomerated, and thus a critical-design consideration for experiments to offer meaningful evaluations of AgNP toxicity

MO172

Particle characteristic dependent effects of titanium dioxide nanoparticles on Daphnia magna and Gammarus fossarum

F. Seitz, Inst for Environmental Sciences / Institute for Environmental Sciences; R.R. MO173

Assessing the toxicity of silver nanoparticles in lentic (static) and lotic (flowing) freshwater environments

C.C. Liddle, Heriot Watt University / School of Life Sciences; A. Cuthberson, Heriot Watt University / School of Built Environment; T.B. Henry, HeriotWatt University / School of Life Sciences; H. Haynes, Heriot Watt University / School of Built Environment; H. Johnston, Heriot Watt University / Life Sciences; T.F. Fernandes, HeriotWatt University / School of Life Sciences

Given the widespread use of silver nanoparticles (Ag NP), their release, whether accidental or intentional, into the environment is inevitable. At this point, Ag NPs threat to freshwater ecosystems is unclear. Current research shows NP toxicity is affected by water chemistry, the presence of organic matter, sediments and other possible influences, such as hydraulics. As such, there is a need to further the understanding of NPs' fate and toxicity in the aquatic environment. This research investigates conditions that affect Ag NP toxicity in lentic & lotic freshwater environments, in an attempt to identify what environmental scenarios may lead to higher hazard, using the Californian blackworm, *Lumbriculus variegatus* as a model organism. Survival, locomotive behaviour, and NP physicochemical characteristics are being assessed of Ag NP (0-30 mg l^{-1};polyvinylpyrrolidone (PVP) coated; 0.02 %wt, nominal size 30-50nm) and silver nitrate ($AgNO_3$;0-240 $\mu g\ l^{-1}$) in both static and turbulent 'environmentally relevant' freshwaters of different chemistries. Results indicate both Ag NP and $AgNO_3$ were acutely toxic to *L. variegatus* in static OECD 225 test water, though the latter was an order of magnitude more toxic (96hr LC50 values of 4.1 mg l^{-1} and 28.2 $\mu g\ l^{-1}$, respectively). There was evidence of locomotive impairment in *L. variegatus*, in static sub-lethal concentrations of Ag NP (3-15 mg l^{-1}) and $AgNO_3$ (20-120 $\mu g\ l^{-1}$), i.e. a 20-60% reduction in successful body reversal (96hrs). Nanoparticle tracking analysis (NTA) of agglomeration/aggregation size (A/A) of Ag NP (5mg l^{-1}) in static OECD 225 medium indicated a median A/A size of 157:116;208nm (median:25;75 percentiles;time=0hrs). The A/A size significantly decreased in low ionic strength (IS) 5%OECD225 medium 68:39;82nm (Man Whitney, P< 0.05). 24hr trials of turbulent flow systems, investigating method suitability, indicated no detrimental impact to *L. variegatus* survival or locomotive behaviour. Ongoing work will continue to investigate flow systems and how 'environmentally relevant' water chemistries, and NP sediment interactions affect the waterborne toxicity of Ag NPs. Results indicate Ag NP to be toxic to freshwater invertebrates in static conditions, however, realistic exposure conditions need to be considered in more detail when assessing environmental risk.

MO174

Response of Chironomus riparius to silver ions and silver nanoparticles

R.S. Lopes, Universidade de Aveiro / Departamento de Biologia CESAM; S. Loureiro, Universidade de Aveiro / Biology

Although nanoparticles (NPs) have always been present in the natural environment and were used throughout human history, it was only in modern times that there was a deep interest in their potential applications. Since it became technologically feasible to mass produce them, there has been an increasing and widespread use of NPs. Their continued use and ubiquity in every day products will surely lead to the increase of their release to the environment, reaching the aquatic medium, with sediments being the ultimate laying basin. Among NPs, silver nanoparticles (Ag-NPs) are one of the most used, notably due to their potential antibacterial properties. This study aims at evaluating the toxic effects of Ag-NPs and their respective ionic form (Ag^+) on the different life stages of the midge *Chironomus riparius* along its life cycle, and estimate how the exposure route affects the toxicity (spiked sediment and spiked water). To assess toxicity, acute, chronic and sub-chronic hatching tests (48 hours, 28 days and 6 days exposures, respectively) were performed, and the effects on survival, reproductive output, growth rate, emergence and hatchability were evaluated. Results showed that Ag^+ is more toxic than Ag-NPs and that the 1st instar larval stage is the most sensitive of the life stages. These assays proved that the exposure route is crucial in assessing the toxicity and bioavailabity of NPs and that the different life stages have different responses and sensitivities to contaminants.

MO175

Influence of nanoparticle shape on Cu bioaccumulation in the deposit feeder, Capitella teleta

L. Dai; G. Banta, Roskilde University / Department of Environmental, Social and Spatial Change; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change; V.E. Forbes, University of Nebraska Lincoln / School of Biological Sciences

There have been few studies of the relationship between nanoparticle shape and bioaccumulation. In the present study, bioaccumulation dynamics was modeled in a deposit feeder, *Capitella teleta*, following exposures to sediment amended with nanosized copper oxide (spheres, rods or platelets) or dissolved Cu ions. After 7 days of exposure, Cu was accumulated in worms with weight-specific body burdens (μg Cu/g dry weight worm) of 13.3 ± 5.5 for controls, 65.5 ± 30.6 for dissolved ions, 57.8 ± 16.4 for spheres, 143.0 ± 43.2 for platelets and 235.4 ± 26.9 for rods. The results indicate that all nanosized CuO particles were bioavailable and bioaccumulated in *C. teleta*. Compared to dissolved ions, CuO rods were more readily accumulated in worms as assessed both from measured body burdens or calculated uptake rate constants. There were no statistically significant differences in bioaccumulation between dissolved Cu and the other CuO particles. However, Cu was accumulated faster and to a higher level for CuO rods than for CuO spheres. Based on Cu mass concentration CuO rods resulted in the highest Cu bioaccumulation in *C. teleta*, whereas CuO spheres had the highest bioaccumulation based on Cu particle number. We further suggest that in order to better understand the effects of nanoparticle shape on bioaccumulation in aquatic organisms, we need to develop easily implementable and affordable methods to characterize NPs in sediment to relate NPs body burden to dose.

MO176

Influence of particle shape and size on bioaccumulation and effects of Copper oxide nanoparticles in two sediment-dwelling worms

A. Thit Jensen, Roskilde University / ENSPAC; T. Ramskov, Roskilde University / Department of Environmental Social and Spatial Change; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change

The use of Copper oxide nanoparticles (CuO NPs) is increasing, thus causing concern about their environmental impacts. Here we examined the toxicity and bioaccumulation (in whole organisms and in five subcellular fractions) of CuO NPs of different size and shape in the sediment-dwelling worms *Nereis diversicolor* and *Lumbriculus variegatus*. In addition, CuO microparticles (CuO_{micro}) and aqueous Cu (Cu_{aq}) were used as references. Worms were exposed to sediment spiked with Cu_{aq}, CuO_{micro} or CuO NPs of different sizes and shapes ($CuO_{6nm\text{-}spheres}$, CuO_{100nm}, $CuO_{spindles}$ and CuO_{rods}) for 10 days (three experiments). In *L. variegatus,* bioaccumulation of either of the Cu forms tested (Cu_{aq} and $CuO_{6nm\text{-}spheres}$) was limited, whereas *N. diversicolor* more efficiently accumulated Cu from the sediment, dependent on Cu form added to the sediment (Cu_{aq}>CuO_{100nm}>CuO_{micro}). In contrast, CuO NP shape had limited effect on Cu bioaccumulation ($CuO_{6nm\text{-}spheres}$, CuO_{rods} and $CuO_{spindles}$) in *N diversicolor*. Neither Cu_{aq} nor CuO_{NP} affected *L. variegatus* (burrowing behaviour, survival). In contrast, Cu affected survival of *N. diversicolor* depended on Cu form (Cu_{aq}>CuO_{micro}, no effect of CuO_{100nm}). Weight-specific growth rate of *N. diversicolor* was affected by exposure to Cu_{aq} and $CuO_{spindles}$, but not by exposure to $CuO_{6nm\text{-}spheres}$ and CuO_{rods}. Distribution of Cu in subcellular fractions of *L. variegatus* differed slightly between the two Cu forms tested ($CuO_{6nm\text{-}spheres}$ and Cu_{aq}). Similarly, the subcellular distribution of Cu in *N. diversicolor* was dependent on Cu form, and distribution of Cu_{aq} was distinctly different from that of the particles tested (CuO_{100nm} and CuO_{micro}). Distribution of Cu_{Aq} differed between the two worms, such that Cu_{Aq} was mainly found in metallothionein-like proteins in *L. variagutus* and in metal rich granules in *N. diversiocolor*. Thus, representing different detoxification mechanisms in the worm species tested. Together these findings indicate that there is a difference in response between the two worm species and between Cu_{aq} and particulate CuO (both nano- and micrometer-sized). Generally, Cu_{aq} was found more bioavailable and toxic than CuO particles, especially for *N. diversicolor*. However, more studies on differences among species and effects of metal form, particle size and shape are needed. Only then can we ensure that we are able to assess the risk of NPs adequately and use nanotechnology wisely.

MO177

Factors triggering the combined toxicity of nanosized titanium dioxide and heavy metals

R.R. Rosenfeldt, Uniersity of KoblenzLandau Institute for Environmental Sciences / Institute for Environmental Sciences

As an ingredient in many consumer products (e.g. paints and sunscreens) titanium dioxide nanoparticles ($nTiO_2$) may enter aquatic ecosystems *via* wastewater treatment plant effluents, where they probably co-occure with other stressors, such as heavy metals. The adsorption of free ions onto $nTiO_2$ surfaces may reduce heavy metal toxicity in some cases, due to their removal from the water phase. However, agglomerates of $nTiO_2$ – together with the adsorbed metal ions – may actively be ingested by filter feeding organisms, such as *Daphnia magna*, enhancing the overall toxicity. In this context, the present study investigated shifts in copper (Cu) toxicity in presence versus absence of $nTiO_2$ after an interaction period (=aging) under different conditions. Thus, the influence of ionic strength and pH on the combined toxicity of $nTiO_2$ and Cu was assessed during 72-h acute toxicity test using *D. magna*. Briefly, the presence of $nTiO_2$ reduced Cu toxicity of the mixture aged in pure deionized water to an extent comparable to an unaged mixture of both stressors. The same was observed for an aging in test medium at pH 6. Contrary, 72-h aging in test medium at pH 8 lead to a 70% enhanced Cu toxicity following 48 h of exposure in presence compared to absence of $nTiO_2$. The supplemental analytics suggest, that the test organisms finally ingest numerous $nTiO_2$ agglomerates together with high amounts of absorbed Cu ions. Hence, nanonoparticle agglomerates may contribute meaningfully to the uptake and effects of other chemical stressors, while the environmental conditions during aging determin whether the toxicity of the mixture is increased or decreased by the $nTiO_2$.

MO178

A comparison of the acute and chronic toxicity of three silver nanoparticles and AgNO3 to Daphnia magna: implications for regulation and wide-level screening

K.B. Paul, HeriotWatt University / School of Life Sciences; F.R. Khan, Roskilde University / ENSPAC; L. Ellis, University of Birmingham; V. Stone, Heriot Watt University; T.F. Fernandes, HeriotWatt University / School of Life Sciences

Silver nanoparticles (Ag NPs) are of growing interest due to their use in a wide range of applications. Currently Ag NP production accounts for over 30% of NP technology output. Questions have therefore been raised regarding environmental risks following Ag NP release. This study assessed how different Ag NP surface coatings and characteristics can affect toxicity. Polyhedral Ag NPs with mean core diameters of ~10 nm with three different coatings (ie. PVP, PEG and citrate) were used, in parallel with $AgNO_3$. The biological effects of the 3 Ag NPs and $AgNO_3$ were assessed using *Daphnia magna* in 48-hour static non-renewal OECD 202 immobility tests. LC_{50} were 0.9 μg/ L for $AgNO_3$ and between ~5-25 μgL^{-1} for the Ag NPs. 21-day *D. magna* reproduction studies followed OECD 211 protocol. Effects here were shown on moulting, reproduction and growth at concentrations from 0.3 μgL^{-1} for $AgNO_3$ and ~1-4 μgL^{-1} for the Ag NPs. Toxicity rank varied for each exposure type, acute and chronic exposure toxicity ranks were PVP-Ag NP > Cit-Ag NP > PEG-Ag NP and Cit-Ag NPs > PVP-Ag NPs > PEG-Ag NPs, respectively. Chronic sub-lethal effects between $AgNO_3$ and Ag NPs differed regardless of concentration as toxicities displayed for the different endpoints varied. Exposure to Ag NPs resulted in significatnly smaller *D. magna* length, before reducing offspring number; no effects were observed on total moults over 21 days, however $AgNO_3$ exposures showed a significant reduction in offspring before length and significant reduction in *D. magna* moults. Results obtained suggest potential different modes of action for acute and chronic effects, and for $AgNO_3$ and Ag NPs. Therefore extrapolation of acute data sets to chronic modelling or regulations may be ill-advised. The data also implies Ag^+ release from Ag NPs cannot fully explain their toxicity and using adapted Ag^+ toxicity models for Ag NP impact assessment may have inherent shortcomings. The authors acknowledge funding from NERC and contributions from other partners in this project.

MO179

Characterizing nanoparticle exposure and effects in the epibenthic crustacean, Hyalella azteca

J.M. Lazorchak, US EPA / Office of Research and Development; H.C. Poynton, University Of Massachusetts Boston / Molecular Indicators Research; J.M. Unrine, University of Kentucky; H. Haring, The McConnell Group

Manufacturednanoparticles (NPs) are expected to make their way into the aquatic environment where sedimentation of particles will likely occur, putting benthic organisms at particular risk. Therefore, organisms such as *Hyalella azteca*, an epibenthic crustacean which forages at the sediment surface, is likely to have a high potential exposure compared with water column organisms such as *Daphnia magna*. In general, *H. azteca* is more sensitive to NPs compared with *D. magna*; however, NP toxicity is particle specific. *H. azteca* is highly susceptible to Zinc Oxide (ZnO) NP exposure, with ZnO NPs demonstrating greater potency compared with the corresponding metal ion, Zn^{2+}. Silver (Ag) NPs act differently, with a lower potency compared to Ag ions. Our ongoing studies are comparing the toxicity of these particles to *H. azteca* in different sediment types and characterizing their transformation in these sediments. Preliminary results suggest that the presence of a substrate, including sand, decreases the toxicity of nanoparticles. These studies will help us better understand the susceptibility of benthic organisms to nanomaterials in realistic exposure scenarios. The views expressed in this presentation are those of the authors and do not represent those of U.S.EPA.

MO180

The effects of abiotic factors on the toxicity of nanoparticles to zebrafish (Danio rerio) larvae

B. Shaw, School of Biological Sciences; K. Tatsi; J. Fox, Plymouth University; R. Handy, University of Plymouth / School of Biomedical and Biological Sciences

It is well established that water chemistry can influence the bioavailability and subsequent toxicity of contaminants. To enable the development of exposure models for nanoparticles (NPs) it is essential that the effects of these abiotic factors are established. Larval zebrafish (*D. rerio*) were used to assess the effects of water hardness (as Ca), pH, $NaCl^-$ and humic acid (HA) on the toxicity of TiO_2 NPs (anatase, 8 nm and P25 rutile/anatase, 21 nm), Ag NPs (15 nm) and multi-walled carbon nanotubes (MWCNT), supplied as part of the E.C. FP7 MARINA project, along with appropriate controls. Larvae were exposed in a semi-static design using bespoke exposure chambers that enabled dispersion of the NPs whilst ensuring animal health. Changes to water chemistry did not affect the toxicity of any TiO_2 material (survival generally >90 % throughout) with limited effect upon MWCNT (small decreases in survival with >Ca and HA). However, increased water hardness (150 mg Ca l^{-1}, added as $CaCl_2$) resulted in increased mortality (>80 %) which was not seen in $AgNO_3$ exposed larvae ($P < 0.05$). Subsequent experiments with $Ca(NO_3)_2$ confirmed that toxicity was related to Ca and not the Cl^- (again >80 % mortality). Larvae exposed to the Ag NPs at high Ca became noticeably lethargic with reduced swimming compared to controls. Increased $NaCl^-$ concentration resulted in increased survival with no significant differences between the two forms of Ag (ANOVA, $P > 0.05$). At 1 mmol l^{-1} $NaCl^-$ mortality was 68 and 60 % in Ag NP and $AgNO_3$ exposed larvae respectively, decreasing to 30 and 25 % in the presence of 10 mmol l^{-1} $NaCl^-$. Following exposure at pH 6, 7 or 8 there were no significant differences in acute toxicity between Ag NPs and $AgNO_3$ (ANOVA, $P > 0.05$), though both experienced increased mortality at pH 6 and 8 compared to pH 7 (ANOVA, $P < 0.05$). Increased concentrations of HA were seen to increase mortality in Ag NP exposed larvae (40 and 60 % at 1 and 10 mg l^{-1} HA respectively, ANOVA, $P < 0.05$), but was somewhat protective to $AgNO_3$ exposed animals. The general consensus is that there will likely be increased NP aggregation with increased HA, which could result in reduced exposure and thus toxicity. However, this was not seen here and further work is required to understand this effect. Whilst TiO_2 NPs and MWCNT were generally not affected by changes to water chemistry, significant effects were seen following exposure to Ag NPs.

Human exposure to emerging contaminants: monitoring and modeling (P)

Evaluation of Lead Contamination in a Shooting Range in Qatar

I. Goktepe, Qatar University / Biological and Environmental Sciences; H. Khalaf Al Mohammed , Qatar University / Department of Biological and Environmental Sciences; M. Amr, Qatar University / Central Laboratory Unit

Recreational shooting in indoor and outdoor firing ranges is becoming popular in Qatar where several natural factors, such as high salinity and low organic matter content can accelerate lead (Pb) pellet weathering and; thus, potentially contaminate the environment. However, little information is available as to the impacts of Pb pellets on the environment. Therefore, there is a need to determine Pb contamination levels at shooting ranges in Qatar. In this study, the concentrations of Pb in soils and dust collected from indoor, semi-outdoor, and outdoor ranges were evaluated. Lead was extracted from soil and dust samples using open acid digestion method, then its concentrations were determined using an ICP-MS. A baseline data on the health status of shooters was carried out using a 12-questions survey questionnaire. Results showed that maximum concentration of Pb in soil samples collected from outdoor ranges at 76 m was 148,557 ppb. When the Pb concentrations in dust samples collected from semi-outdoor ranges were compared between the shooting line and target line, it was found that the Pb levels were significantly higher ($p<0.05$) at the target site. The dust samples collected from 25 m indoor range contained relatively higher concentrations of Pb than those of 50 m indoor range results. Overall, the concentrations of Pb were determined to be significantly ($p<0.05$) higher in indoor ranges than those of outdoor and semi-outdoor ranges. These results indicate that there is a clear need for improving the situation in indoor ranges by using lead-free ammunition or by better ventilation. Based on the survey data, it was estimated that 25% and 15% of participants suffer from anemia and reduction in their mental capacity, respectively, based on self-report. This could be related to the recreational exposure to Pb, however, the cause and effect can only be established through controlled clinical studies.

MO182

Mass concentration and elemental composition of traffic-related particulate matters in Doha, Qatar

I. Goktepe, Qatar University / Biological and Environmental Sciences; H. AlMazrooey, Qatar University / Department of Biological and Environmental Sciences; M. Amr, Qatar University / Central Laboratory Unit

Particles generated from vehicle exhausts negatively impact public health since they can deeply penetrate the respiratory tract carrying considerable amounts of toxins including trace metals and hydrocarbons on their surfaces. In a recent report published by the Qatar Statistics Authority, it was reported that the annual PM10 readings were five times that of the set limit (50 µg/m3). Since there is a direct correlation between particulate matters (PMs) and their adverse health effects on humans, there is an urgent need to monitor the levels of PMs generated by vehicles and identify their elemental composition to determine their potential health effects on Qatari population. The aim of this study was to determine the levels of traffic-related PMs and their elemental compositions in Doha, Qatar during February and March 2013. The PM2.5 and PM10 concentrations were measured using DPS monitors. The elemental composition of PM samples was determined by an ICP-MS. During the study period, it was determined that there is a direct relationship between the concentrations of elements detected in PM samples and the number of cars passed through sample collection sites. The environmental factors, such as temperature, humidity, and wind speed did not influence the concentrations of PMs. The levels of Pb, Ni, and Cr which are known carcinogenic metals were reported to be between 200 and 900 ppb, indicating a possible public health hazard. The presence of high concentrations of Al, Mg, Na, Fe, and Zn referred to the origin of PM to be mainly crustal material, sea salt, and fossil fuel combustion. The results obtained in this study might be helpful in establishing new air quality standards to protect the public health and the environment in Qatar.

MO183

The Nutritional-Toxicological Conflict Associated with Antarctic Krill Oil Dietary Supplements vs. Fish Oil Alternatives

S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program SOPOPP; P.D. Nichols, Commonwealth Scientific and Industrial Research Organisation CSIRO / Marine and Atmospheric Research; M. Schlabach, Norwegian Institute for Air Research

Fish are a nutrient-dense food source. The role of marine-derived, long-chain (LC) (≥C20) Omega-3 (ω3) fatty acids, in particular docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), in the promotion of health is well established. Accordingly a host of international agencies recommend consumption of fish at least twice a week. Modern diets in developed nations are however characterised by severe LC ω3 deficiency, reflecting low seafood intake. In fact, it must be considered that meeting health targets for seafood intake is not economically, nor ecologically attainable for large fractions of the global population. In the absence of sufficient high quality, affordable seafood sources, dietary supplements are pitched to play a role of increasing strategic importance. A new nutriceutical oil derived from Antarctic krill *(Euphausia superba)*, has recently been launched on the seafood-oil market. Marketing is based on three key promotional statements, namely; the improved bioavailability of krill oil ω3, the sustainability of krill fisheries and, finally, that krill are free of toxins and pollutants. Persistent Organic Pollutants (POPs) are ubiquitous, toxic and bioaccumulative contaminants and the vast majority of human exposure to POPs occurs via seafood consumption. In the case of fish oil dietary supplements, the situation is even more acute. Legacy POPs are lipophilic and accumulate in the lipid reserves of animals. When the lipid fractions of fish oils are selectively isolated and concentrated for administration as dietary supplements or complementary medicines, the fish oil micronutrient:POP burden conflict is exacerbated. Here we evaluated the nutritional quality and the contaminant burdens of Antarctic krill oil versus nine other fish oil dietary supplements readily available on the Australian market. All products adhered reasonably well to manufacturer DHA and EPA specifications and no products, at the maximum recommended dose, came close to fulfilling the contaminant tolerable daily intake (TDI) values assigned by international regulatory authorities. Contaminant profiles of Antarctic krill oil were distinct from other products, although not consistently lower. These results provide much needed quantitative data for a rapidly expanding new product in the fish oil market sector and in particular for the krill fishing industry.

MO184

Effects of cooking on the subcellular partitioning of Cd in cooked rice

B. Chen, H. Lai, C. Liu, MingDao University

Rice and rice products are staple foods in Asia. Rice grains may accumulate excess cadmium (Cd) when exposed to Cd-contaminated soil. Therefore, it is necessary to assess and manage the health risks of populations exposed to Cd through rice products consumption. In this study, two varieties of paddy rice were hydroponic cultivated in the Cd contained solutions to investigate their uptake and subcellular distribution of Cd. In addition, the subcellular partitioning of Cd in cooked rice under different cooking treatments was also examined. Experimental results showed that approximately 92-99% of the accumulated Cd was bounded to the cell wall and vacuole in the shoot and root of rice plants. The subcellular partition of Cd in cooked rice was significantly affected by different cooking treatments (boiled, steamed, and stir-fried). Generally, the proportion of Cd concentration in cell wall debris was increased with increasing heating duration and temperature of cooked rice. Results of the present study can be used to refine the exposure assessment in human health risk assessments.

MO185

Screening chemicals in commerce in the Nordic countries using multimedia fate and bioaccumulation models

I.S. Krogseth, Norwegian Institute for Air Research; K. Breivik, Norwegian Inst for Air Research; J.A. Arnot, ARC Arnot Research Consulting / Department of Physical Environmental Science; F. Wania, University of Toronto at Scarborough / Department of Physical Environmental Sciences

Increasingly, quantitative structure property relationships and/or environmental multimedia models are used to screen chemicals in commerce for substances that are potentially of concern for human health and the environment. These efforts have largely focused on hazard-related properties such as persistence, bioaccumulation, and long-range transport potential. This is partly because risk-based evaluations are often considerably limited by highly uncertain emission estimates, which render predicted concentrations and hence also chemical rankings uncertain. The availability of detailed information on the usage of hundreds of chemicals in commerce in Norway, Sweden, Finland, and Denmark for the years 2000-2007 through the SPIN (Substances in Preparations in Nordic Countries) database may allow for emission estimates with increased confidence within a Nordic context. Concentrations in the environment and in humans were calculated by inputting emissions, obtained by a combination of SPIN data and a high-throughput estimation method, into a dynamic integrated environmental fate and food chain bioaccumulation model (CoZMoMAN) specifically parameterized for the Nordic region. The chemical ranking based on those concentrations was then compared with those derived with a steady-state screening level risk assessment model (RAIDAR), parameterized for an evaluative environment and food-chain. This allowed us to investigate the impact of a steady-state assumption and a region-specific parameterization on the chemical ranking results.

MO186

Tox-Box: Developing a Test Battery for Toxicological Assessment of Anthropogenic Micropollutants in Drinking-water – A first Evaluation

A. Eckhardt, Federal Environment Agency / Drinking Water and Swimming Pool Water Toxicology; T. Grummt, R. Heinze, Federal Environment Agency / Toxicology of Drinking Water and Swimming Pool Water; R. Junek, Federal Environment Agency Germany / Drinking Water and Swimming Pool Water Toxicology

The joint project Tox-Box (BMBF 02WRS1282A) aims at evaluating anthropogenic (micro-)pollutants in terms of possible genotoxic, neurotoxic and endocrine disruptive effects. To establish a guideline value when limited data is available, the UBA developed a theoretical concept called “Health related indicator value (HRIV)”. This is the foundation of Tox-Box, which will define a test battery that provides in vitro data for turning a theoretical concept into a practical one. The tests used in Tox-Box will thus be aimed at creating in vitro data to allow the evaluation of the endpoints addressed in the HRIV concept. In the first part of the project single substances are tested in different test schemes, specific for the endpoints genotoxicity, neurotoxicity and endocrine disruption. Once these test schemes are established, substances having different effects on the endpoints tested can be distinguished. Based on the results, HRIV values for drinking water can be derived. The sub-project “In-vitro testing of neurotoxicity” tested 20 chemicals in a three-tiered approach. A first set of experiments employs the comparison of cytotoxic effects in cancer cell lines which had their origin in different organs, i.e. liver, blood or nervous system, to give a 1st hint towards possible neurotoxicity. Tier 2 uses a more thorough approach, when mitochondrial membrane potential, apoptosis, formation of reactive oxygen species and GSH content are tested. When the assumed neurotoxicity is substantiated, the 3rd rd tier is applied. Here the cytotoxic effects on primary astrocytes, activity of a neuron specific enzyme and neurite outgrowth are scrutinized. First experiments with acrylamide as a positive control indicate that primary cells are much more susceptible to this agent than the neuroblastoma cell line SH-SY5Y, which is used in the 1st and 2nd tier. Moreover, investigations in liver cancer and neuroblastoma cells clearly show a stronger acrylamide effect on the latter. So far our results indicate, that of the 20 substances tested, 7 have a neurotoxic potential. Among these is dichlorvos, which is a known inhibitor of acetyl cholinesterase, a neural transmitter. Dichlorvos was used as proof of principle. We are currently running the tests of the compounds selected for tier 3. Our results regarding dichlorvos were confirmed in the Tox-Box sub-project “In-vivo testing of neurotoxicity” which performed similar experiments in zebra fish (*Danio rerio*).

MO187

How to produce drinking water from surface water of the Three Gorges Reservoir in China according to the German drinking water directive?

A. Wolf, IWW Water Centre / Water Resources Management; A. Bergmann, IWW Water Centre / Department of Water Ressources Management; H. lutze, University DuisburgEssen / Institute of Instrumental Analytical Chemistry; I. Schreiter, F. Zaun, Technische Universitat Darmstadt / Institute for Applied Geosciences; X. Gao, Chongqing University / Faculty of Urban Construction and Environmental Engineering; L. Landwehrkamp, R. Hobby, University DuisburgEssen / Institute for Energy and Environmental Process Technology; Y. Bi, Chinese Academy of Sciences / Institute of Hydrobiology; H. Chen, University of Waterloo; R. Wilken, IWW Water Centre / Department of Water Resources Management; T.C. Schmidt, University DuisburgEssen / Institute of Instrumental Analytical Chemistry; C. Schueth, Technische Universitat Darmstadt / Institute for Applied Geosciences

The impoundment of the Three Gorges Reservoir (TGR) in China is widely blamed and investigated for its impact on the ecosystem and water quality [1-3]. Water quality in the Yangtze river and its tributaries is therefore of major concern, as in the catchment area of the TGR surface water is commonly used as the raw water source for public water supply [4]. Additionally, it is considered for the provision of fresh water for the dryer northern part of China, as part of the south-north water diversion project [5]. Samples from surface water, tap water, and waste water treatment plant effluents in the TGR area were shown to contain mainly herbicides, trihalomethanes, and pharmaceuticals, respectively, in concentrations above the limit values given by German water directives [6]. In this study, therefore, the adsorption of the main pollutants clopyralid, picloram, chloroform, and bromoform in TGR surface water was studied on the three powdered activated carbons AquaSorb® BP2, AquaSorb® CP1, and ColorSorb® G9 (Jacobi) and the chelating resin AMBERLITE™ IRA743 (Rohm and Haas Industrial Processes).
Additionally, oxidation experiments with ozone and hydroxyl radicals were performed for herbicides (atrazine, clopyralid, and picloram), an antibiotic (sulfamethoxazole), and bromide. The results indicate a good adsorption behavior and wide range of oxidation of the analyzed compounds until a limitation by toxic by-products. Hence, the application of an activated carbon filter in drinking water treatment is a useful treatment step and an oxidation with ozone and hydroxyl radicals possible. This study is part of a Sino-German joint research project supported by the Federal Ministry of Education and Research (Germany) [7].

Challenges for building a safety net for biocidal products: a Korean case

J. Kwon, Korea University / Division of Environmental Science and Ecological Engineering; J. Lee, NeoEnBiz Co / Institute of Environmental Protection and Safety; H. Oh, Sogang University / Department of Chemistry; S. Lee, Korea Institute of Toxicology / Ecotoxicology research team

Biocides are used in massive amount worldwidely for a variety of purposes. Due to their inherent activities on living creatures, the safe management of them is required for human and the environmental health. Unlike strictly regulated and managed pesticides, biocidal products still remains in a dead zone in terms of the safe management of chemicals in many places of the world. As a result of the uncontrolled safefy management of biocidal products, it was reported in 2011 that unidentified fatal lung disease found in Korea is suspected to have been caused by chemical disinfectants used with household humidifiers. The suspected active ingredients were found to be cationic synthetic oligomers that had been put in the water tanks of humidifiers for the prevention of germs, mold, and/or algae proliferation. Although, it is not very difficult to predict that this use of reactive cationic oligomers will end up nano-sized aerosols in the indoor environment, even a screening-level assessment was not been attempted. Immediately after this tragedic case, the Korean government has been trying to build a safety net for the regulation of biocidal products. However, the lack of information how and how much biocidal active ingredients are currently used in various products is now revealed to be a bottle-neck in the law-making process. The existing chemical regulations in the country are based mostly on the potential hazard of priority chemicals with high toxicity and production volume, but not on the use and the consequent risks of chemicals. Therefore, it is now immediately needed that the use of the biocides should be incorporated to a new chemical management framework. Due to the limited resources and time for building a safety net for biocides, a smart, prudent approach is needed. Herein, we propose both top-down and bottom-up approaches. In a top-down approach, the active ingredients that are used in a large quantity and already evaluated with respect to their chemical safety, the safety evaluation should be re-made by the governmental authorities for the specific uses of the activie ingredient. In the bottom-up approach, those who intend to sale biocidal products in the market should be enforced to register new biocidal products and the safety evaluation should be made for the specific uses. With both approaches, we expect that unexpected fatal accident due to the mis-use of biocidal active ingredients will be minimized in the future.

MO189

The HEALS approach to health and environment-wide associations

D.A. Sarigiannis, denisengauthgr / Chemical Engineering; I. Annesi-Maesano, University of Paris Marie Curie / Medical School; J. Cherrie, Institute of Occupational Medicine; J. Bartzis, University of Western Macedonia / Department of Mechanical Engineering; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering

1. Introduction The exposome represents the totality of exposures from conception onwards, simultaneously identifying, characterizing and quantifying the exogenous and endogenous exposures and modifiable risk factors that predispose to and predict diseases throughout a person’s life span. Unraveling the exposome implies that both environmental exposures and genetic variation are reliably measured simultaneously. **2. Materials and methods** The HEALS (Health and Environment-wide Associations based on Large population Surveys) approach brings together and organizes environmental, socio-economic, exposure, biomarker and health effect data; in addition, it includes all the procedures and computational sequences necessary for applying advanced bioinformatics coupling advanced data mining, biological and exposure modeling so as to ensure that environmental exposure-health associations are studied comprehensively. The overall approach will be verified in a series of population studies across Europe, tackling various levels of environmental exposure, age windows and gender differentiation of exposure, and socio-economic and genetic variability. The HEALS approach will be refined on the basis of **pre-existing population data** and then it will be applied in a **pilot environment and health examination survey** covering eighteen EU Member States. **3. Results and discussion** Exposome studies will require new tools to address the complexity of emerging environmental health issues. Critical for success will be the ability to bring together existing geospatial, environmental, health and socioeconomic data, and to collect new high resolution data using novel environmental micro-sensors, remote sensing or other community and omics/systems biology based approaches approaches to describe the exposome for e.g. endocrine disruption-related syndromes and sex-related changes (menopause), neurodegenerative or respiratory diseases. Focus will be on susceptibility windows during growth (including pregnancy) and development, and on the unequal distribution of the burden of epigenetically active food and environment-related disease to vulnerable populations such as the young, elderly, socio-economic disadvantaged, gender and ethnic minorities. **4. Conclusions** The lessons learned will be translated into scientific advice towards the development of **protocols** and **guidelines** for the setting up of a European environment and health examination survey.

The German Environmental Specimen Bank – Long-term Monitoring of Human Exposure and Exposure Factors

D. Lermen, Fraunhofer IBMT Institute for Biomedical Egineering; A. Conrad, German Federal Environment Agency UBA; M. Bartel-Steinbach, H. von Briesen, Fraunhofer IBMT Institute for Biomedical Egineering; C. Schroeter-Kermani, German Federal Environment Agency UBA; T. Goeen, Institute and Outpatient Clinic of Occupational Social and Environmental Medicine IPASUM; M. Kolossa-Gehring, German Federal Environment Agency UBA

The German Environmental Specimen Bank (ESB) is an important part of the German health-related environmental monitoring program. It is coordinated by the Federal Environment Agency (UBA) and monitors time trends in human exposures and changes in exposure relevant factors. The ESB collects, stores, and analyzes human samples since the 1980s. As a new member of the ESB, since 2012 Fraunhofer IBMT acquires blood, plasma and urine samples of approx. 600 young adults annually using a biological safety level 2 mobile laboratory. Several health-relevant pollutants and physiological parameters are quantified in these samples by initial real time monitoring. Besides, each volunteer fills in an extensive questionnaire on exposure factors and exposure relevant behaviors. Additional cryopreservation of samples allows for rapid access to samples collected over decades for retrospective analyses and trend evaluation. Results are evaluated and reported to the UBA annually. Emerging pollutants like plasticizers and synthetic compounds are currently discussed to have a diverse range of impacts on human health. Especially diethylhexylphthalate (DEHP) is still used in a wide variety of consumer and industrial products. Hence, human exposure to DEHP is omnipresent. Health related effects of DEHP are discussed to range from endocrine disruption, reproductive dysfunction to diabetes and cancer. Latest results of the German ESB document the success of regulatory efforts to reduce human exposure to phthalates like DEHP. In contrast, same data indicate an increase of other plasticizers (e.g., DINP) used to replace those classified as reproductive toxicants. Hence, within the German health-related environmental monitoring the ESB serves as an early-warning system regarding changes in human pollutant burden patterns

and exposure affecting characteristics of the population. Therefore, the continuously generated ESB data are vital for priority setting in population-representative human biomonitoring studies as well as maintaining up-to-dateness of German exposure factors as an important basis to generate exposure models for the general population. Moreover, the ESB is a highly flexible tool for assessing the success of policy measures aiming at reducing the human exposure to contaminants. Keywords: phthalates, human biomonitoring, mobile laboratory, environmental specimen bank

MO191

Detection of Aflatoxin M1 concentrations in human milk samples in Novi Sad, Serbia

M. Vojinovic MIloradov; I. Mihajlovic; S. Kocic Tanackov, University of Novi Sad Faculty of Technology Serbia; J. Radonic, Faculty of Technical Sciences; m.M. turk sekulic, Department of Environmental Engineering and Occupational Safety and Health; Z. Grujic, University of Novi Sad Faculty of Medicine; M. Skrinjar, University of Novi Sad Faculty of Technology Serbia

Aflatoxins, extracellular toxic metabolites produced by some fungal species from genus Aspergillus (A. flavus, A. parasiticus), are inducing aflatoxicoses, which are having toxic, immunosuppressive, theratogenic and cancerogenic effect. AM1 (i.e. milk toxin) is produced by human and animal metabolism in the liver, after eating food or feed contaminated with aflatoxin B1. During development of fetus, prenatal, it absorbs certain amount of toxins from mother organism. After birth, infant is through milk exposed to aflatoxin M1. AM1 in human milk samples was determined in Turkey, Egypt, Sudan, Kenya, Jordan, Iran and other countries; however there are no results on this topic for the region of East Europe and also for Serbia. After detection of AM1 in cow milk in Croatia and Serbia, urgent need is arisen to detect AM1 in human milk, to estimate status of whole environmental and health of newborns. Samples of colostrum were collected on Gynecological and obstetrical clinic of Faculty of Medicine in Novi Sad. Qualitative and quantitative determination of AM1 concentration level in human milk have been done with imuno-enzymatic tests kits, Imunolab Aflatoxin M1 (NOACK). Concentration of AM1 was determined photometric on 450nm on ELISA rider (Multiscan EX, Thermo Electron Corporation). Method sensitivity was lower than 10 pg/ml. A total of 33 samples (25 colostrum samples, 5 human milk samples and 3 commercial milk formulas) of whole milk were analyzed. Aflatoxin M1 residues were detected in 56% of colostrum samples. None of 3 commercial milk formulas contained AM1. In all human milk samples from mothers who breastfeeding babies 3 to 7 months older, AM1 was detected with the mean value of 247±176 pg/ml. Obtained concentrations levels of AM1 in samples show prenatal exposure of fetus, mothers and contamination of food products by aflatoxins. Monitoring results also give concentration profiles of AM1 in correlation of demographic parameters, such as mother's age, number of pregnancies and child births, occupation, body weight of newborn. Application of results gives special possibility to assess risk of fetus exposure and as well newborns on this mycotoxin, and also the first screening is of extraordinary importance to evaluate conditions of environmental contamination in Serbia. Acknowledgement: The research has been supported by Provincial Secretariat for Science and Technological Development of AP Vojvodina (114-451-3989/2013-03).

MO192

Body burden of POPs of Serbia residents, based on human milk and umbilical cord blood

m.M. turk sekulic, Department of Environmental Engineering and Occupational Safety and Health; Z. Grujic, University of Novi Sad Faculty of Medicine; S. Jankovic, Institute of Meat Hygiene and Technology; M. Vojinovic MIloradov; M. Prica, University of Novi Sad Faculty of Technical Sciences / Department of Graphic Engineering and Design; I. Mihajlovic; J. Radonic, Faculty of Technical Sciences

This initiated study is one of the very few investigating the body burdens of POPs in residents of Serbia. POPs pose a danger to the ecosystems and human health as they are bioaccumulative, resist, cycle in the environment over long periods, and can be transported over long distances. Especially susceptible might be the fetus, which is exposed in utero, and newborn breast-fed infant, since both are exposed to relatively high levels of POPs during a critical period of organ growth and development. Destruction during the NATO operation in former Yugoslavia caused the emission of POPs into the environment. No systematic and regular human biomonitoring of POPs has been performed in the West Balkan Countries till now. This study was carried out in collaborations with 5 Serbian national and research institutions. In order to gather reliable and comparable data, participants were encouraged to adhere as closely to WHO protocol as possible. In this study umbilical cord blood samples of healthy pregnant women aged between 20 and 42 years at the time they gave birth and human milk samples from the same women following delivery were collected during February 2013 from 100 participants living in Vojvodina. All samples were analyzed for their content of DDT, DDE, DDD, dioxin-like (PCB 118) and indicator (28, 52, 101, 138 153, 180) PCB congeners. Measurements were performed using GC ECD VARIAN CP-3380. Concentrations of PCBs and OCPs were in the range of 3-91 ng/$g_{lipid\ base}$ (med: 13, arith mean±stdev: 18.67±15.59), or 2-307 ng/$g_{lipid\ base}$ (med: 75.6, arith mean±stdev: 81.36±69.28), for the human milk, respectively. In all umbilical cord blood samples levels of analyzed POPs were under the LOD (< 0.5 ng/g, lipid adjusted). The four congeners (118, 138, 153, 180) contribute the main share to total body burden of PCBs. Higher chlorinated PCBs were found in up to 10-fold higher concentrations in human milk in relation to the lower congeners, while the levels of hexaCB were 3-4-fold higher than the levels of heptaCB. The body burden of POPs increases with age and decreases over the total nursing period. Women who had lived outside highly industrialized areas showed lower concentrations of PCBs. Birth weights didn't influence of POPs concentrations on human milk burden. New information on mother-child transfer by human milk and umbilical cord blood of POPs is needed, since it controls incentive of breastfeeding, indispensable way for health infant's development and growth.

MO193

Concentrations of phthalates metabolites in breast milk of Korea, 2011-2012: Current contamination, exposure amount, and risk assessment

S. Kim, Seoul National University / School of Public Health; S. Kim, Seoul National University; J. Park, SOON CHUN HYANG UNIVERSITY / College of Natural Sciences; G. Choi, Soonchunhyang University Hospital / Department of Environmental Health Sciences; J. Lee, Soonchunhyang University Hospital; H. Kim, Korea University Hospital; S. Kim, S. Choi, Hallym University Medical Center / Department of Obstetrics and Gynecology; S. Kim, Jeju National University; H. Moon, Hanyang University / Marine Sciences and Convergent Technology; K. Choi, Seoul National University / School of Public Health

Phthalates have been used in a variety of consumer products and have been associated with endocrine disruption and developmental effects in many experimental and epidemiological studies. However, very limited information is available on phthalate exposure among infants through breast milk feeding. In order to understand the levels of phthalate exposure among breastfed infants, 132 breast milk samples were collected from breast feeding mothers in four cities of Korea in 2011-2012. Six phthalate metabolites, i.e. mono-isobutyl phthalate (MiBP), mono-n-butyl phthalate (MnBP), mono(2-ethyl-hexyl) phthalate (MEHP), mono(2-ethyl-5-oxo-hexyl) phthalate (5-oxo-MEHP), mono(2-ethyl-5-hydroxyhexyl) phthalate (5-OH-MEHP), and monoethyl phthalate (MEP) were analyzed. MEP and MEHP were detected in 100 % of breast milk with median value of 0.35 and 2.47 μg/L, respectively. MiBP and MnBP were also detected > 94% of breast milk samples. However, the secondary metabolites of DEHP (5-oxo-MEHP and 5-OH-MEHP) were less frequently detected. The levels of metabolites among Korean mothers are far lower compared to those reported elsewhere. Demographic or seasonal characteristics could not explain the variations of the phthalate metabolites in breast milks, suggesting that exposure sources of phthalates vary among individuals. Median and 95th percentile daily phthalate intake through breast feeding was estimated at 0.35 μg/kg body weight (bw) and 2.22 μg/kg bw, respectively, for MEHP, 0.24 μg/kg bw and 3.09 μg/kg bw for MnBP, for an exclusively breast-fed infants (3 months old). The estimated phthalate metabolites intakes corresponds to only about 2% (median) to 51% (maximum) of reference dose of parent compounds.

MO194

Non-targeted screening of mercapturic acids in human urine – comparison of different LC-MS approaches

R. Bloch, Helmholtz Centre for Environmental Research GmbH / UFZ; M. Plassmann, Department of EffectDirected Analysis; W. Brack, M. Krauss, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis

Glutathione conjugation is an important detoxification pathway in the human body to eliminate reactive electrophiles formed by metabolisation of internal biomolecules or pollutants taken up from diet or atmosphere. Among other pathways gluthathione conjugates are subsequently converted to mercapturic acids and renally excreted. Thus, they can be used as biomarkers to assess the electrophilic burden of the human body reflecting both the internal and external chemical environment. This study aimed at developing and comparing two analytical approaches to detect mercapturic acids in urine in a non-targeted fashion. Both methods are based on the fact that all mercapturic acids show a common neutral loss during mass spectrometric fragmentation. Using LC-MS techniques, two different neutral loss scan methods were developed. An in source fragmentation scan was performed on a high resolution ion trap-Orbitrap mass spectrometer followed by a software-based search for the exact neutral loss mass difference. A QTrap mass spectrometer in constant neutral loss scan mode at unit resolution was used for a rather fast screening method. For the evaluation of both methods, a small set of spiked and native urine samples was analyzed. Both methods were compared regarding sensitivity and selectivity, their potential for structure elucidation of the unknown mercapturic acids and the capability to enhance sample throughput.

MO195

PFAS concentrations in cat serum and association to thyroxin levels

J. Weiss; M. Bohlen, IVM institute for environmental studies; J. Norrgran, Stockholm University / Materials and Environmental Chemistry; B. Jones, Swedish University of Agricultural Sciences; M. Lamoree,

An analytical method was developed and applied for the analysis of fifteen per- and polyfluoroalkyl substances (PFASs) in blood serum. The method is fast, demands a small sample volume (50 μl) and was successfully validated regarding recovery, accuracy and repeatability. The method consists of a methanol precipitation and an online SPE clean up of the whole sample. Chemical analyses were carried out using HPLC-MS/MS measurements with multiple reaction monitoring. Internal standard recoveries varied among PFASs (39–84%) and median recovery were 60%. This is on the low end, and probably related to the loss of sample material due to induced protein precipitation during sample preparation. Here it is regarded sufficient for accurate level concentrations. The accuracy was 55–110% for the PFASs and the method repeatability standard deviation was 1–7%. The limits of detection (LODs) were between 3 and 50 pg/mL depending on the congener. The method was applied to serum samples (n=30) from cats in Swedish households sampled between 2010 and 2011, within the framework of the recently started project MiSSE (Mixture Assessment of EDCs, Formas 210-2012-131, www.mmk.su.se/misse/). The project aims to use cats as models for indoor exposure to dust related endocrine disruptors, also relevant for humans and especially toddlers. The cats were suspected or known to have feline hyperthyroidism, a disorder also common in humans, hence the thyroxine (T_4) have been measured and reported. Some cats were treated with thiamazole orally. The PFAS profile was dominated by PFOS (median 2.8 ng/g fw), followed by PFOA (median 1.5 ng/g fw). The concentrations were slightly lower or similar to human levels, except the long-chain PFASs (C9-14) which were elevated. The T_4 levels and PFASs serum concentrations in corresponding samples were tested for linear correlation. A negative linear correlation between T_4 levels and long-chain (>C9) PFASs in cat serum could be observed. The cause for this is not yet fully understood. It can be an expression of the higher metabolism correlating to higher T_4 levels. The determined binding affinity of PFAS to the T4-transport protein transthyretin did not correlate to the concentration of the long-chained PFASs. No correlation between shorter chain length and T_4 could be observed.

MO196

Total intake estimates of PBDEs derived from PBDE biomonitoring data sets from the Australian population

T.C. Gyalpo; L. Toms, Queensland University of Technology; J. Mueller, Entox / National Research Centre for Environmental Toxicology Entox; M. Scheringer, ETH Zuerich / Institute for Chemical and Bioengineering; K. Hungerbuehler, ETH Zurich / Institute for Chemical and Bioengineering

In Australia, polybrominated diphenyl ethers (PBDEs) have been measured in large-scale biomonitoring studies in 2-year intervals since 2002/3. Since the technical mixtures of penta-BDE and octa-BDE were banned by the Stockholm Convention on Persistent Organic Pollutants only in 2004, the biomonitoring data has been collected simultaneously with the ban. Here we use a population pharmacokinetic model to back-calculate PBDE intake by the Australian population from these biomonitoring data. When solved in a forward way, the pharmacokinetic model calculates the PBDE body burden of individuals born in different years on the basis of PBDE intake data and intrinsic elimination half-lives of individual PBDE congeners. Here we use the model in a backward calculation that adjusts the PBDE intake in such a way that the body burden calculated by the model is as close as possible to the PBDE biomonitoring data; the elimination half-lives of the PBDEs have to be provided as model input parameters. We investigate the most common PBDE congeners (i.e. BDE-47, -99, -100, -153); as model input we use four cross-sectional biomonitoring studies conducted in 2002/3, 2004/5, 2006/7, and 2008/9 in Australia and the intrinsic elimination half-lives of 1.4, 0.8, 1.8, and 7.4 years for BDE-47, -99, -100, and -153, respectively. The back-calculation of the intakes resulted in an adult intake of BDE-47, -99, -100, and -153 of 3.0, 2.0, 0.6, and 0.4 ng/kg/d, respectively. These estimated intake rates are about a factor of 10 higher than what is expected when the intake is calculated in a bottom-up exposure assessment, i.e. derived from PBDE concentrations found in indoor media (dust and indoor air) and diet, multiplied by the default contact rates. As has also been shown for the US population, to explain the measured body burdens, the PBDE exposure has to be much higher in Australia than what is calculated in bottom-up exposure assessments.
