EFFECTS OF AMOUNT AND TYPE OF DIETARY FAT ON SERUM LIPIDS, LIPOPROTEINS AND APOLIPROTEINS IN MAN

A Controlled 8-Week Trial

Summary

We have studied whether a low-fat diet is as effective in lowering some risk factors for atherosclerosis as a diet rich in polyunsaturated fat (PUFA). During a 2.5 week control period, 60 volunteers were given a moderate-fat diet (MOD) providing 30% of the daily energy intake (energy %) in the form of fat, one-third of which was PUFA. For the next 5 weeks subjects were divided into 4 groups and received diets providing varying amounts of total fat and of PUFA: for group LO, 20 energy % fat and 3 energy % PUFA; group MOD, 30 energy % fat and 11 energy % PUFA; group HIPUF, 40 energy % fat and 19 energy % PUFA; and group HISAT, 40 energy % fat and 3 energy % PUFA. The diets contained the same amounts of cholesterol, phytosterols, oligosaccharides and other nutrients, known to affect serum lipid levels. All food was prepared daily and weighed out for each individual appropriate to his energy needs. Nutrient intakes were checked by 7-day records and by chemical analysis of double portions.

On diet LO, total serum cholesterol concentration increased by 0.25 mmol/l while HDL cholesterol concentration did not change significantly. The
HDL cholesterol/apoprotein-A₄ ratio fell, and VLDL and LDL triglyceride concentrations were elevated.

On the HIPUF diet, total serum cholesterol concentration was not significantly lower, but HDL cholesterol concentration increased by 0.10 mmol/l. On the HISAT diet, total serum cholesterol concentration went up by 0.38 mmol/l; 0.12 mmol/l of this was due to HDL.

LDL cholesterol/serum apoprotein-B ratios were unaffected by any of the diets.

It was concluded that after 5 weeks, the influence of a low-fat, high-carbohydrate diet on the concentrations of serum lipoproteins was less favourable than that of moderate- or high-fat diets rich in polyunsaturated fatty acids.

**Key words:** Apolipoproteins — Carbohydrates — Dietary fat — HDL cholesterol — Linoleic acid — Serum cholesterol

### Introduction

During the last two decades, prospective epidemiological studies have shown that the risk of cardiovascular disease (CVD) increases with increasing plasma concentrations of total or LDL cholesterol [1] and decreases with increasing HDL cholesterol [2–4]. Plasma HDL cholesterol concentration is reduced in several conditions associated with an increased risk of future CVD namely hypercholesterolemia, hypertriglyceridemia, obesity and diabetes mellitus [5,6]. Subjects with existing clinical atherosclerotic disease also have lower levels of HDL than healthy subjects within the same community [5,7,8].

In order to elucidate the metabolic origin of differences in lipoprotein lipid levels interest has focussed recently on the measurement of the apolipoproteins of LDL and HDL. Apo-B, the main apoprotein of plasma LDL, is substantially increased in the plasma of subjects with hypercholesterolemia, while endogenous hypertriglyceridemia is associated with a mild increase in plasma levels of apo-B [9,10]. In the latter instance the increase in serum apo-B is mainly located in the VLDL fraction.

Apo-A₁, the main apoprotein of plasma HDL, is found to be reduced in survivors of myocardial infarction as compared with controls [11] and the HDL cholesterol/apo-A₁ ratio was also lower in this condition [8]. At the other end of the risk scale, HDL cholesterol/apo-A₁ ratios were higher in a low-risk group of vegetarians than in a control group [12].

Many short-term experiments have shown that on diets in which saturated fat is replaced by polyunsaturated fat the serum cholesterol and triglyceride levels are lowered; in long-term intervention trials a reduction in the incidence of cardiovascular disease was also noted [13,14]. As a result of such studies, diets high in polyunsaturated fat have been advocated for the prevention of CVD, and consumption of vegetable oils in the U.S. has indeed risen considerably during the last decade [15]. There are fewer controlled studies in man on the effect of replacing saturated by polyunsaturated fat on the concentration and composition of separate lipoproteins, while studies on the effect of natural low-fat diets in healthy subjects are quite rare.
We have investigated the effects of a low-fat diet on serum lipids, lipoprotein composition, blood pressure and faecal steroids as compared with a moderate-fat, high-polyunsaturated diet, containing the same amounts of cholesterol and other nutrients that may affect serum lipid levels. In the present paper results of lipoprotein, apo-A\textsubscript{1} and apo-B analyses will be presented.

**Subjects and Methods**

**Selection of subjects**

Thirty-seven male and 23 female university students, aged 18–28 years participated in this study. The subjects were all volunteers who satisfied the following criteria:

- apparently healthy, as judged by a detailed questionnaire;
- serum cholesterol concentration below 5.7 mmol/l;
- serum triglyceride concentration below 1.7 mmol/l;
- diastolic blood pressure below 90 mm Hg;
- percentage of body fat below 23% in males and 30% in females as determined by skin fold measurements.

Only two of the females used hormonal anticonception.

**Experimental design, diets and control of food intake**

During the first 2.5 weeks of the study all subjects consumed a control diet (MOD) which was moderate in fat and relatively high in PUFA (30 energy % total fat, 10 energy % PUFA) in agreement with the recommendations of The Netherlands Nutrition Council. After this period, 4 subgroups were formed which received diets as presented in Fig. 1. The groups were matched for initial serum cholesterol, energy intake and sex. Mean body weights per group were 67.2, 66.6, 64.9 and 66.0 kg for groups LO, MOD, HIPUF and HISAT respectively. Throughout the 8-week period all foodstuffs were weighed out for each person in quantities appropriate to his energy needs, except for 100 kcal/day, which the subjects were free to spend at will. Average energy intake during the control period was 11.1 ± 3.6 MJ (±1 SD) (2643 ± 854 kcal). Actual nutrient intakes were checked by 7-day individual food records using Dutch food composition tables [16], and by double-portion analysis [17] for one imaginary person of average energy intake on each diet. Mean daily intakes on nutrients are given in Table 1. Analysis of double portions revealed a slightly

higher proportion of fat in the total daily energy intake in all groups, but the
differences between groups in fat intake, fatty acid composition and other
nutrients agreed well with the food records. Body weight was recorded weekly.
Energy intake was adjusted when necessary in order to avoid changes in body
weight of more than 2 kg.

The mean change per group in body weight over the 5 weeks of the test
period ranged from $-0.4 \pm 1.1$ to $-0.8 \pm 1.4$ kg.

Stools were collected for 7 days at the end of the control and the test
periods. There were no differences between the groups in intestinal transit time
[18], faecal output and moisture content or frequency of stools in either
period.

**Blood sampling and analysis**

Blood samples were taken after an overnight fast before and during the
experimental period as indicated in Fig. 1. No alcohol was allowed during 24 h
prior to blood sampling. Serum was obtained by low-speed centrifugation.
Serum cholesterol was measured according to Huang et al. [19] using serum
calibrators calibrated as described by Abell et al. [20]. Reproducibility for
blind control sera provided by the Center for Disease Control, Atlanta, GA,
U.S.A., was $\pm 0.9\%$ and accuracy was within $1.4\%$ of the "true" (target) values.
HDL cholesterol was determined after manganese-heparin precipitation of
apo-B containing lipoproteins [21] as previously described [22]. At the end of
the control and the test periods, sera were collected for apolipoprotein-AI and
B determinations and for lipoprotein fractionation by the procedure of Redgrave et al. [23] with several modifications. To visualize the lipoprotein bands after ultracentrifugation, 3 ml serum was mixed with 0.3 ml 0.02% (w/v) Sudan Black (Difco Laboratories) dissolved in dimethylsulphoxide. The background density of the mixture was raised to 1.210 with solid KBr (0.9552 g). On top of the serum a discontinuous density gradient was built up in a centrifuge tube (14×89 mm, 13 ml) with salt solutions of d = 1.063 (4.5 ml) followed by d = 1.006 (4.5 ml). These salt solutions contained EDTA (0.1 mg/ml) and were prepared from NaCl and KBr [24]. Centrifugation was carried out at 20°C and 40 000 rpm (RCF\text{max} = 272,700 \times g) for 16 h and the clearly visible bands of VLDL, LDL and HDL were harvested by tube slicing [25]. Lipoprotein cholesterol concentrations were determined according to Abell et al. [20]. Serum VLDL and LDL triglyceride concentrations were measured as described by Soloni [26].

Apoproteins were measured in whole serum by rocket immunoelectrophoresis [27] (see Fig. 2). Monospecific antisera against human apoprotein-B and apoprotein-A₁ were raised in goats using pure apo-B in LDL (1.040 < d < 1.053 mg/ml) and pure apo-A₁ [28,29] as antigens. Electrophoresis was performed at pH 8.6 using 0.8% agarose (apo-B assay) or 0.8% agarose, 5% dextran T 10 (apo-A₁ assay) in 50 mM diethylbarbiturate buffer as supporting medium for the antisera.

The electrophoresis was performed at 2.5 V/cm for 16 h (apo-B) or at 3.5 V/cm for 10 h (apo-A₁). Serum samples were analysed in three dilutions. For one subject the samples obtained at the start and at the end of the test period were always analysed on one plate in order to minimise the effect of inter-assay variability. Because isolated LDL solutions become turbid during prolonged
preservation, day to day calibration standards of a pooled serum were prepared in four dilutions. The apo-B and apo-A\textsubscript{1} contents in this secondary calibration standard were determined with freshly isolated pure LDL and pure apo-A\textsubscript{1} and redetermined periodically. The protein content in the primary standards was determined by quantitative amino acid analysis. Analytical error was monitored by analysing a sample from a control pool on each plate. The combined within-day and between-day coefficients of variation for this control serum were 7% and 9% for the apo-B and the apo-A\textsubscript{1} assays respectively.

**Statistical evaluation**

The individual values at the beginning and the end of the test period were compared per group, using a paired two-tailed t-test. Each subject thus served as his own control.

**Results**

The time courses of serum total cholesterol, serum total triglycerides and HDL cholesterol are presented in Figs. 3, 4 and 5 respectively.

All groups received the moderate fat, high PUFA MOD diet for the initial 2.5 week control period. By this time the mean serum total cholesterol concentration had decreased significantly by 0.46 mmol/l (Fig. 3), of which 0.06 mmol/l was located in HDL (Fig. 5). Serum total triglycerides had decreased by 0.12 mmol/l (Fig. 4). Although the groups were matched for initial total serum cholesterol there were slight differences in initial values of HDL cholesterol and total serum triglycerides (Figs. 3 and 4). However, neither these initial values nor the changes in these parameters during the control period differed significantly between the groups. When the subjects changed from the MOD diet to the test diets, the concentrations of serum cholesterol remained unchanged in groups MOD and HIPUF and increased significantly in groups LO and HISAT, by 0.25 and 0.38 mmol/l respectively. HDL cholesterol concentration was unchanged in groups LO and MOD, but increased significantly in groups HIPUF and HISAT, by 0.10 and 0.12 mmol/l respectively. Total triglyceride concen-

tration increased significantly in group LO by 0.35 mmol/l and in group MOD by 0.11 mmol/l.

Data for lipoprotein lipids and serum apolipoproteins are presented in Tables 2, 3 and 4 respectively. In all groups HDL cholesterol and serum apo-A₁ concentrations were slightly but not significantly higher for females than for males.

As HDL cholesterol was unchanged in group LO the rise in total serum cholesterol in this group was entirely located in the LDL and VLDL fractions (0.38 and 0.09 mmol/l respectively). This was accompanied by an increase of 118 ± 60 mg/l in serum apo-B concentration, but the LDL/apo-B ratio remained the same (Table 4). Although HDL cholesterol remained constant, HDL composition changed as judged by the HDL cholesterol/apo-A₁ ratio, which decreased significantly (Table 4). VLDL triglycerides increased significantly by 0.14 mmol/l and LDL triglycerides by 0.08 mmol/l (Table 2).

The MOD group, which continued on the control diet during the test period,

The correlation coefficient between LDL cholesterol and serum apo-B was r = 0.87 (n = 60); the correlation coefficient between HDL cholesterol and serum apo-A₁ was r = 0.58. Rather low correlation coefficients between serum apo-A₁ and HDL cholesterol in normolipemics have also been published by other authors [28,46-47].

showed very little change. Although serum total and HDL cholesterol concentration remained unchanged, the HDL cholesterol/apo-A₁ ratio decreased significantly. Total triglycerides increased by 0.11 mmol/l, after an initial decrease of 0.11 mmol/l in the control period (Fig. 4).

Surprisingly, the effects of the HIPUF diet, in which an additional 10 energy % of carbohydrates had been replaced by PUFAs, did not differ greatly from the MOD diet. Total serum cholesterol remained reasonably constant compared with during the control period, but HDL cholesterol increased significantly by 0.10 mmol/l (Fig. 5). There was a minor increase in the HDL cholesterol/apo-A₁ ratio (Table 4). Total triglycerides decreased significantly by 0.13 mmol/l (Fig. 4); this decrease mainly took place in VLDL (0.09 mmol/l).

The high-fat low-PUFA diet caused a significant increase in serum cholesterol concentration. It is noteworthy, however, that of the total increase of 0.38 mmol/l, about 30% was accounted for by HDL. Total serum triglycerides

increased by 0.07 mmol/l, and serum apo-B concentration by 54 mg/l (Table 3).

In all groups, the LDL cholesterol/apo-B ratio remained constant as compared with the control period (Table 4).

Discussion

Participants in this study were well-motivated, normolipidemic students of the Agricultural University. We have repeatedly found [17,30] that the fat and cholesterol consumption in this population is lower than the average intake in this country (Table 1). Thus the change from ‘habitual’ diet to the rigidly controlled MOD diet in the control period of our study mainly involved an increase in the P/S ratio (Table 1). The observed decrease in serum cholesterol and triglycerides is in agreement with earlier studies [31], although the fall in total cholesterol is somewhat larger than expected [31]. This could be due to adaptation to laboratory conditions and to an inaccurate estimation of their habitual fat intake.

At this level of fat intake (30% of energy), our data showed a decrease in HDL cholesterol on the high P/S diet, a result previously described by Shepherd et al. [32] in dietary studies in normo- and hyperlipidemic men. However, as discussed below, we were unable to demonstrate such a change under controlled conditions at a higher fat intake level (40% of energy).

The effects of a change from MOD to LO, HIFUF and HISAT diets on serum lipoproteins were studied under rigidly controlled conditions as was the effect of prolonged consumption of the MOD diet. In the latter (MOD) group no changes in serum total cholesterol, HDL cholesterol and serum apo-B concentrations were observed between 3 and 8 weeks, indicating that these parameters were stabilised already by the end of the control period. However, this was not the case for HDL composition as serum apo-A<sub>1</sub> concentrations rose significantly during the test period.

Changing from the MOD to the LO diet involved a replacement of 8 energy % PUFA by carbohydrates. VLDL increased significantly by this treatment, probably by carbohydrate-induced synthesis [33,34] which may have been reinforced by the decrease in PUFA.

A pertinent finding was the increase in LDL, reflected by the simultaneous rise in LDL cholesterol and serum apo-B concentrations (+17%). Whether the rise in LDL is mediated by an increased conversion of VLDL into LDL [36–38] or by a delayed LDL degradation [39] (the phospholipid moiety of LDL may be more saturated on this carbohydrate-rich diet [35]) is at present not known.

One might speculate that the decreased HDL cholesterol/apo-A<sub>1</sub> ratio in the LO group reflected a shift from the cholesterol-rich HDL<sub>2</sub> fraction to the HDL<sub>3</sub> fraction [42].

Changing from the MOD to the HIFUF diet implied that 8 energy % of carbohydrates were replaced by PUFA. The further increase in dietary linoleic acid did not cause significant changes in LDL and VLDL cholesterol values or serum apo-B. Although this indicates that the HIFUF diet was no more effective in depressing serum LDL levels than the MOD diet, total serum
triglycerides decreased on the HIPUF diet and a significant rise in HDL cholesterol was observed, which was not accompanied by an increase in serum apo-A1 concentration.

On changing from the MOD to the HISAT diet, 8 energy % PUFA plus 8 energy % carbohydrates were both replaced by saturated fat resulting in a significant increase in serum LDL concentrations judged from the proportional change in LDL cholesterol and serum Apo-B concentrations. HDL cholesterol as well as serum apo-A1 concentrations were also significantly increased. At this level of fat intake (40 energy %), no differences in HDL cholesterol and apo-A1 concentrations between the HISAT and the HIPUF diet were present. Lower VLDL and LDL levels on PUFA-rich diets such as MOD and HIPUF, compared with saturated fat-rich diets, such as HISAT, have been reported repeatedly. VLDL synthesis and conversion into LDL may be decreased on high P/S diets [36–38] although a recent report points to increased LDL catabolism [39].

Although different amounts and types of fat in the diet will also affect postprandial chylomicron production [40], it is unlikely that this will lead directly to changes in serum LDL concentrations. Small quantities of LDL can indeed be formed by chylomicron degradation but it can be calculated that the contribution of this pathway to the overall LDL synthesis is very limited.

Potential effects of diet on serum HDL are important since serum HDL cholesterol concentrations have been inversely correlated with risk of cardiovascular disease [2–4]. Recently the effect of a diet rather similar to our MOD diet on serum HDL cholesterol concentrations in hyperlipidemic subjects has been studied by Hjermann et al. [41] and compared with a HISAT type diet. In this intervention study a 20% increase in HDL cholesterol on the MOD-type diet was observed after 4 years. However, it cannot be excluded that this rise was due to the decreases in serum triglyceride concentrations, obesity and cigarette smoking rather than to the diet.

In addition to changes in HDL cholesterol, the average composition of HDL in our experiment was obviously sensitive to diet, although the changes were small.

In order to illuminate the effects of the different diets, we calculated the ratio of the concentration of HDL cholesterol to total cholesterol and of apo-A1 to apo-B (Table 5). If LDL is “atherogenic” and HDL is “anti-athero-

**P < 0.01; significantly different from control period according to paired two-tailed t-test.
genic” then these ratios may have predictive value for atherogenic risks. On the HISAT diet the ratios showed surprisingly little change compared with the MOD diet. The low level of dietary cholesterol may have contributed to this result; there are indications [43] that saturated fat and dietary cholesterol reinforce each other’s effect on serum (LDL) cholesterol levels; the effects of a high saturated fat intake might have been more pronounced if the experiment had been performed at a higher level of cholesterol consumption. The HIPUPF diet showed a trend towards more favourable ratios in contrast to the LO diet where unfavourable changes were observed. However, the latter could in part be due to the relatively short test period of 5 weeks. It is known that after 2–3 months on high carbohydrate diets serum triglyceride concentration will go down again [44]. It is not known if similar long-term changes in HDL cholesterol and apolipoproteins could appear; this should be investigated in long-term dietary studies.
