Aan mijn ouders en schoonouders
Voor Gerardien, Jarl en Robert

Voorwoord

Bij het voltooiën van dit proefschrift maak ik graag van de gelegenheid gebruik om allen, die hierin op enigerlei wijze een bijdrage geleverd hebben, mijn welgemeende dank te betuigen.

De basis voor dit proefschrift werd al gelegd tijdens het laatste gesprek over mijn aanstelling bij de vakgroep Fysische en Kolloïd-chemie van de Landbouwhogeschool. Mijn promotor, Prof. Dr. J. Lyklema, stelde tijdens dit gesprek voor om diëlectisch onderzoek aan latices te gaan verrichten. Hans, jouw belangstelling voor dit soort onderzoek, niet alleen als promotor, is met name in de periode waarin de verslaglegging plaats vond, stimulerend en van zeer veel waarde geweest. Voor de grote mate van vrijheid, die je mij niet alleen bij het onderzoek, maar ook bij mijn onderwijstaken liet, ben ik je zeer erkentelijk.

In het beginstadium van het onderzoek zijn de gesprekken met Joop Wisse, onder wiens leiding ik mijn na-kandidaatsstudie verricht heb, van veel nut geweest.

De vele proefmetingen zijn verricht samen met John Blom, die verder aan het ontwerp van de meetcel de belangrijkste bijdrage geleverd heeft. Het resultaat van deze samenwerking is de basis voor hoofdstuk twee geworden.

Ronald Wegh gaf adviezen op electronisch terrein en Simon Maasland construeerde de meetcel.

De veelzijdige bijdragen van Anton Korteweg in de realisatie van de meetopstelling, metingen en berekeningen is van essentieel belang geweest. Anton, jouw betrokkenheid bij het onderzoek bleek uit de accurate en inventieve inbreng gedurende de vele maanden waarin we op prettige wijze samengewerkt hebben. Met je vrouw, Ina, zorgde je er bovendien in eensgezinde samenwerking voor dat de meetresultaten via een terminal in het computergeheugen opgeslagen werden.

Theo Reesinck vervaardigde de eerste versies van de computer-programma's, terwijl Jan Scheutjens in het eindstadium een aandeel gehad heeft in de totstandkoming van de programma's.

De samenwerking met Joost Mertens, die ontstond uit gesprekken, waarin we ons afvroegen welke metingen zinvol zouden kunnen zijn op grond van de bestaande theoriën, heeft in belangrijke mate bijgedragen tot de realisatie van hoofdstuk vijf.

Herman van Leeuwen is zo bereidwillig geweest om het manuscript kritisch door te nemen.

Gert Buurman en Simon Maasland dank ik voor de snelle en accurate wijze waarop het tekenwerk en het fotografische werk verricht zijn.

I am grateful to John Ralston (Melbourne, Australia) and Colin Young (Bristol, United Kingdom) who corrected the english text during their stays at the Department of Physical and Colloid Chemistry of the Agricultural University.

Clare van Dijk ben ik zeer erkentelijk voor het ontwerpen van de lay-out en het zodanig accuraat typen van het manuscript, dat versienigvuldigen van het proefschrift via een off-set procedure verwezenlijkt kon worden. Mevr. E.P.A. de Vries-Forrer verzorgde een gedeelte van het typewerk.

Dat de realisatie van dit proefschrift mijn ouders voldoening schenkt, moge blijken uit de wens, die mijn vader in het voorwoord van zijn proefschrift uitte en die ik hier in aangepaste vorm overneem: „Voor mijn twee zonen moge dit boekje een geschenk zijn, dat ook hen later aanspore tot wetenschappelijke studie”.

Tenslotte, wat zou de waarde van dit proefschrift voor mij zijn, zonder de daadwerkelijke en morele steun van jou, Gerardien.

Alhoewel het beschreven onderzoek fundamenteel van aard is, hoop ik dat op den duur een praktische toepassing gedeeltelijk terug te voeren is op de inhoud van dit proefschrift.

j	imaginary unit
L	low terminal
L_b	lead inductance
L_c	inductance, due to the part of the cell not localized between the electrodes and due to the coaxial cables connecting the cell with the terminals of the bridge.
m	parameter defined by equation (5-16)
n	constant
n_i	number of particles
N	number of colloid particles per m^3
N_o	number of charges per m^3
r^2	correlation factor
R	gas constant
R_c	resistance, due to the part of the cell not localized between the electrodes and due to the coaxial cables connecting the cell with the terminals of the bridge.

t	time
T	absolute temperature
V	applied voltage
V_d	minimum detectable voltage
W	parameter defined by equation (5-33) or (5-36)
Y	admittance
Y_d	total admittance of the phase sensitive detectors
$Y_{e.s}$	external admittance standards
$Y_{i.s}$	internal admittance standards
Y_{st}	sum of external and internal admittance standards
Y_x	unknown admittance
z	charge number
z_i	valency of ion species i
z_+	charge number of a positive ion
z_-	charge number of a negative ion
Z	impedance
Z_e	electrode polarization impedance
Z_w	Warburg impedance
α	Cole-Cole distribution parameter
β	parameter defined by equation (5-34) or (5-37)
δ	phase angle, loss angle
δ_s	loss angle for a solution in the cell
ϵ	permittivity
ϵ_d	relative permittivity of the diffuse double layer
ϵ_r	relative permittivity
ϵ_s	permittivity at high frequencies
ϵ_w	relative permittivity of water
ϵ_0	absolute permittivity of free space
ϵ_1	relative permittivity of the dispersed medium
ϵ_∞	permittivity at high frequencies

ϵ'	real part of ϵ
ϵ''	imaginary part of ϵ
$\Delta\epsilon_{st}$	static dielectric increment
ζ	electrokinetic potential
η_w	viscosity of water
κ^{-1}	thickness of the diffuse double layer
κ_1^σ	surface conductivity (section 5.2.1 only)
$\kappa_{1\sigma}$	surface conductivity due to a d.c. current
$\kappa_{2\sigma}$	surface conductivity due to a bound charge current
Λ	molar conductivity of the electrolyte solution
Λ_+	molar conductivity of a positive ion
Λ_-	molar conductivity of a negative ion
μ	complex dipole moment
μ_0	static dipole moment
ν	frequency of the applied field
π	ratio between circumference and diameter of a circle
σ	conductivity
σ_b	conductivity of the bulk electrolyte
σ_d	conductivity of the diffuse double layer
σ_{dc}	d.c. value of the conductivity
σ_w	parameter defined by equation (5-31)
σ_o	surface charge density
σ_1	conductivity of the dispersed medium
τ	most probable relaxation time
ϕ	volume fraction of the latex sample
ψ_d	potential of the diffuse part of the double layer
ω	angular frequency
ω_{cr}	critical frequency

1. INTRODUCTION

1.1. Purpose of this study

The main aim of this investigation is to provide better experimental evidence which can be used to test theories of dielectric phenomena in colloid dispersions*. In particular, our results may be used to establish the limits of applicability of theories developed for dilute systems. It appeared possible to improve the calculation of the permittivity of suspended particles from the permittivity and the composition of the mixture by taking into account polarization at the charged phase boundary (O'Konski, 1955,1960; Lijklema, 1957).

Recent theoretical contributions, especially those of Dukhin and coworkers (e.g. 1969,1970,1971,1974) are very comprehensive. These authors gained insight into the mechanism by which concentration polarization of the double layer around colloid particles leads to the very strong low-frequency dielectric dispersion. Their analysis involves some of the principles of irreversible thermodynamics. Ion flux equations were used to calculate potentials in the perturbed double layers.

Dukhin et al. initially considered systems which, when subjected to a constant electric field, resulted in the formation of a stationary state of the charge distributions around the particles. Equations are obtained for the polarized diffuse double layer. These equations are used for the interpretation of electrokinetic measurements (Derjaguin and Dukhin, 1974).

As a next case, Dukhin et al. treated systems to which an alternating electric field was applied. In this case, the interfacial po-

* It is noted that the word "dispersion" is used with two distinct meanings, viz. in indicating the state of matter ("colloid dispersion") and in indicating frequency dependency ("dielectric dispersion"). We shall insert the words "colloid" or "dielectric" in those cases where confusion may arise.

larization created leads to an alternating polarization field, which is out of phase with the applied field. This corresponds to a relaxation effect of the conductance, from which the increase of the permittivity is calculated. Its value depends on some parameters characterizing the double layer under static conditions and on the diffusion coefficients of the ions. The theory enables calculation of ionic mobilities in the boundary layer to be made along with the ψ_d -potential in the double layer when the experimental data are obtained from dielectric measurements (Dukhin, 1970). Here, ψ_d is the potential of the diffuse part of the double layer. In both treatments the polarization of the double layer is the central theme. Reliable measurements are needed to test these theories.

The behaviour of the double layer under dynamic conditions is also crucial in developing a better understanding of electrokinetic phenomena, particularly as embodied in the retardation formulae relating mobilities to electrokinetic potentials in electrophoresis.

Our results may further be used to adapt the DLVO theory treating the stability of lyophobic colloids (Derjaguin and Landau, 1939; Verwey and Overbeek, 1948). In this theory, the repulsion between two colloid particles is attributed to the overlap of the diffuse part of the double layers around the colloid particles. An essential assumption of this theory is that during interaction the double layers are taken to be always in equilibrium. However, the possibility that the double layers, or part of them, relax on a time scale longer than the encounter time of two particles must be investigated. Hence it is not known to what extent the DLVO-theory applies under highly dynamic conditions. Our results may provide some insight into this matter.

The measurement of dielectric relaxation spectra is finding ever wider applications in research into both the processes of structure formation and to changes in structure under external influences. Consequently, this method of investigation is important for several as-

pects of colloid science. For instance, the size and shape of colloid particles are reflected in the dielectric dispersion.

These examples clearly illustrate the potential use of dielectric studies in colloid systems. However, in literature very few attempts to apply this method have been reported. The reason for this is that there are considerable difficulties involved. We shall now show what the main difficulties are and indicate some likely procedures to overcome them.

1.2. Outline of the experimental difficulties involved in connection with the theory

In order to apply the theories mentioned above, dilute colloid systems are required, in which the thickness of the double layer around the particles is very small compared with the linear dimension of the particles. This condition is expressed as (Dukhin and Shilov, 1974):

$$\kappa a \gg 1 \quad (1-1)$$

As will be seen in section 1.3 only spherical particles will be used. In this case, a is the particle radius and κ^{-1} is the thickness of the diffuse double layer. κ is defined by the relation (e.g. Kruyt, 1952):

$$\kappa^2 = (\sum_i c_i z_i^2 F^2) / \epsilon RT \quad (1-2)$$

where c_i and z_i are the bulk concentrations and the valency, respectively, of ionic species i . F is the Faraday constant, ϵ the permittivity, R the gas constant and T the absolute temperature.

A second prerequisite, closely related to the first, is that κa is the same for all particles, i.e. the system should be homodisperse.

In practice it is difficult to meet condition (1-1), because both

an increase of a and an increase of κ give rise to experimental problems:

- 1) Increasing a leads to a shift of the relaxation spectrum to lower frequencies (Schwarz, 1962). However, measurement on aqueous solutions in the lower frequency range leads to an unacceptable influence of electrode polarization (Oncley, 1942; Mandel, 1956, 1965; Schwan, 1963). This effect is due to concentration gradients of ions present in the solution. The polarization can be described in terms of an impedance Z_e , localized at the electrodes and independent of the distance d between the electrodes of the measuring cell. Impedances containing the measured conductance G and capacitance C , can be plotted as a function of d . From the slopes of the straight lines obtained, the dielectric quantities can then be calculated. In doing so, Z_e is eliminated (Fricke and Curtis, 1937). As Z_e increases with decreasing frequency, it is necessary to measure above a certain frequency to obtain sufficiently accurate measurements. In practice, the lowest frequency that may be applied to attain a certain accuracy is dependent on:
 - a) the quality of the measuring system;
 - b) the dimensions of the measuring cell;
 - c) the nature of the surface of the electrodes in the cell;
 - d) the amount and nature of the electrolyte present in the solution under investigation.

Consequently, due to the experimental restrictions, there are serious restraints on the increase of a .

- 2) From equation (1-2) it follows that an increase in κ is obtained by increasing the amount of indifferent electrolyte in the solution, also implying that the conductivity of the whole solution is increased. However, the very existence of a certain minimum resolution of all bridges, which are to be used for the measurements, imposes a restriction on the maximally tolerable value of

the conductance G . Difficulties arise when, at low frequencies, the conductive currents through the solution become larger than the capacitive ones. The relationship between G and C of the solution is given by the expression for the loss tangent δ :

$$\operatorname{tg} \delta = G/\omega C \quad (1-3)$$

in which ω is the angular frequency of the applied electric field. Therefore, the above condition can also be formulated such that $\operatorname{tg} \delta$ should remain below a certain limit. Fortunately, if ka increases, the dielectric increment increases also, leading to a decrease of $\operatorname{tg} \delta$.

In the above, it was mentioned that the minimum value of ω at which measurements can be performed is determined by a . Therefore, according to equation (1-3), the maximum amount of electrolyte in the solution is also restricted by a .

Consequently $ka \gg 1$ leads to the condition $\operatorname{tg} \delta \gg 1$, so that the two imposed restrictions are incompatible. In practice, some compromise must be sought for.

Moreover, other problems also play a part, e.g.:

- a) deviations from the ideal behaviour of the measuring cell, leading to stray capacitances;
- b) non-ideality of the conductance standards used, leading to capacitance errors;
- c) drift of the conductivity of the solution during the time required to perform the measurements at different frequencies.

In our study we used two transformer ratio arm bridges to be able to cover the frequency range from about 100 Hz up to a few MHz. By using this type of bridge in combination with a three-terminal cell, shunt impedances from the terminals to earth are eliminated (Calvert and Mildwater, 1963; Rosen, Bignall, Wisse and Van der Drift, 1969). The measuring cell was especially designed for the experiments

with the chosen colloid system (see section 1.3] with our bridges. Moreover, a conductance box was constructed to enlarge the conductance range of one of the bridges.

With the equipment used, up to about 1 mol/m^3 of a simple electrolyte (e.g. KCl) may be present in the dilute colloid systems used.

1.3. Choice of the subject to be investigated

This choice of the colloid system was limited by several restrictions:

- 1) In connection with the theoretical analysis it is very convenient to choose a system with spherical particles.
- 2) In order to find the most favourable radius of the particles (see section 1.2] it should be possible to vary the particle size.
- 3] A heterodisperse system leads to a very broad distribution of relaxation times. Therefore, the use of a monodisperse system is mandatory.
- 4) The system has to be stable in the colloid-chemical sense during the time of the measurements. The frequency spectrum has to be determined at several electrolyte concentrations. Considering the various extrapolations and standardizations which are necessary, this leads to a stability requirement of several weeks.
- 5) In order to check theoretical predictions, the surface should be non-porous and the surface charge or surface potential must be known.
- 6) It is desirable to be able to vary the surface charge density of the particles in connection with solving colloid-chemical problems.
- 7] Reasonable standard procedures should be available for characterizing the system (especially the particle size and the surface charge).

Monodisperse aqueous polystyrene latices, prepared according to a method described by Furusawa, Norde and Lyklema (1972), were found to be very suitable, because they meet all of the conditions mentioned

above. Such lattices were used throughout our measurements.

Fortunately, much work has been performed during the last few years in characterizing these colloid systems (Furusawa, Norde and Lyklema, 1972; Goodwin, Hearn, Ho and Ottewill, 1973,1974; Small, 1974; Stone-Masui and Watillon, 1975; Norde, 1976; Takano, 1978; Bijsterbosch, 1978).

In summary, this thesis will describe progress in measuring the dielectric relaxation behaviour of colloids by simultaneously improving experimental techniques and using well-characterized model colloids.

2. EXPERIMENTAL EQUIPMENT AND MEASURING TECHNIQUE

2.1. Introduction

Several experimental set-ups have been developed to perform measurements on aqueous solutions. Cole and Gross (1949) designed a transformer bridge for measurements at frequencies up to 10 MHz. Schwan and Sittel (1953), Mandel and Jung (1952) and Van der Touw (1975a, 1975b) have built or modified Schering bridges for the frequency range 10 Hz up to a few hundred kHz. In the early sixties, bridges became commercially available.

Young and Grant (1968) used the less accurate Wayne Kerr B221 bridge, which covers the frequency range 10 Hz - 120 kHz. De Backer and Watillon (1966, 1973) performed measurements with two Wayne Kerr bridges (B221 and B601). South and Grant (1970, 1972) and Williams and James (1973, 1976) have successfully employed a Wayne Kerr B201 bridge (0.1 - 5 MHz). Rosen, Bignall, Wisse and Van der Drift (1969) used a thoroughly calibrated Hatfield bridge, type LE/300A, for the frequency range 0.1 - 10 MHz. A part of the corresponding calibration work has been performed by the present author (Wisse et al., 1968).

The principles of four-terminal measurements are already known for many years (Ferris, 1963). Such measurements have been done with aqueous solutions by Berberian and Cole (1968, 1969), Hayakawa, Kanda, Sakamoto and Wada (1975) and Zwolle (1978). Problems concerning the electronic part of the design are still difficult to overcome. Fortunately, a very suitable measuring system became commercially available recently from the General Radio Company, i.e. the GR1621 system.

2.2. Choice of the measurement equipment

For frequencies below 10 MHz the reliability obtained for the permittivity and dielectric loss of aqueous solutions is inevitably limited by technical difficulties in bridge measurements and cell design. We shall now describe the set-up in some detail.

2.2.1. Bridge requirements

Transformer ratio arm bridges were chosen because:

- 1) the potential across a transformer arm in series with the unknown is balanced in amplitude and phase with a similar potential from the standard admittance. The same standard components can be used for measurements over a wide range of admittances;
- 2) bridges with inductive ratio arms do not require a Wagner earth arrangement. The associated inconvenience of double balancing is thereby avoided (Calvert, Cornelius, Griffiths and Stock, 1958);
- 3) transformer ratio arm bridges are particularly suitable for three-terminal measurements: residual impedance effects, due to resistances and shunt capacitances of the circuit elements and their leads, are minimized (Cole and Gross, 1949; Middelhoek, 1967; and Bordewijk, 1968). Only self-inductances play a part. However, as will be seen in section 2.7, the remaining self-inductances can be eliminated by performing measurements at different electrode separations.

A solution in the cell can be represented electrically by an admittance:

$$Y = G + j\omega C \quad (2-1)$$

with $j = \sqrt{-1}$. The determination of Y involves the balancing of two currents in different parts of the circuits of the bridge, one of them flowing through the unknown admittance:

$$I = YV = (G + j\omega C) V \quad (2-2)$$

with I = electric current and V = applied voltage. In the mathematical representation this can be conceived as a current flowing through G in phase with V and a current flowing through C in quadrature with V (see fig. 2-1). The phase angle δ defined as the loss angle and the loss tangent is given by equation (1-3). For large values of $\tan \delta$, an

Figure (2-1): Argand diagram of the complex current.

accurate determination of both C and G demands extremely accurate balancing of the current, especially at low ω values. Therefore, in practice a limit of the highest value of $\tan \delta$ will be met, depending on the quality of the measuring system: special attention has to be paid to the resolution when a choice is made for a measuring system.

2.2.2. Problems involved in designing the cell

In the case of dielectric measurements on aqueous solutions, corrections must be made essentially for three possible errors, which in part are characteristic for the aqueous solution case:

- 1) a contribution due to lead impedances;
- 2) deviations from ideality of the cell, resulting in a residual capacitance;
- 3) a contribution by electrode polarization.

Ad 1): At high frequencies, deviations due to the occurrence of inductances in the leads play a part. Attention must be paid to the quality and length of the leads, connecting the cell with the bridge and leads between the bridge and external standards, if any.

Ad 2): Residual capacitances arise if part of the electric field lines pass out of the liquid (stray capacitances). Therefore, it is important that such stray fields should be strictly controlled during the experiment. In the cells used, field lines which did not pass

through the liquid to be tested were bound to travel through a layer of teflon (cell wall) either between the electrodes or from the electrodes into the third terminal.

Ad 3): Several methods are applicable to correct for the effects of electrode polarization:

- a) Techniques to reduce the influence of electrode polarization on the measured quantities.

The enlargement of the electrode surfaces by applying platinum black electrodes or sandblasted electrodes especially has to be mentioned (Schwan, 1963, 1966; Takashima, 1964). A disadvantage of platinum black electrodes is that they are easily damaged. The use of platinized electrodes is not sufficient to eliminate the polarization effect completely.

- b) Frequency variation method.

Oncley (1942) plotted the measured capacitance C_x against $G_x^2 \nu^{-(2-n)}$ in which G_x is the measured conductance and n is assumed to be a constant over the entire frequency range used. A straight line is obtained, yielding the capacitance C_s of the solution as intercept. However, C_s has to be constant and hence dielectric dispersion is not allowed to occur in the frequency range used. From preliminary measurements on polystyrene lattices we found that the frequency range should be chosen below 1 kHz to apply the frequency variation method, because relaxation occurs above 1 kHz. Below 1 kHz unfavourably large $\tan \delta$ -values are encountered and, consequently, large capacitance errors are met. Therefore we did not apply the frequency variation method.

- c) Substitution method.

This method is based on the subtraction of capacitive increments observed at a simple electrolyte solution from the corresponding increment of the unknown solution (Schwan, 1963). Both solutions must have the same conductance. The measurements have to be made under the same experimental conditions (in particular, the current

density must be equal and the same pair of electrodes must be used). Furthermore, it has to be assumed that the polarization contribution is the same in both cases. However, some investigators (Moser, Squire and O'Konski, 1966; Wisse, 1970) observed differences in behaviour of the electrode polarization and magnitude of polarization errors between the solutions to be tested and the electrolyte solutions.

- d) Method in which a variable electrode distance is involved.

Fricke and Curtis (see section 1.2) proposed this method, whereas Mandel (1956,1965), Rosen (1966,1969), Young and Grant (1968) and Van der Touw (1971a,b, 1975c) further considered and applied this technique. The method starts from the assumption that the electrode polarization capacitance C_e is independent of the distance d . This was proven to be correct experimentally by Mandel (1956). Furthermore, it appeared to be a reasonable assumption that C_e remains constant during the time needed to perform measurements at a restricted number of electrode separations. The time during which C_e remains constant depends on the solution under investigation (see section 2.7.2). A disadvantage of this method is that it is very time-consuming because all measurements have to be repeated at various d -values.

From the investigations described above, where use has been made of the variable electrode distance method, it is established that this method is the most promising one. Therefore, in our investigations the method involving a variable electrode distance was chosen in combination with the use of sandblasted platinum electrodes.

2.2.3. *Instrumentation used*

For the frequency range from 70 Hz to 100 kHz, a General Radio 1621 Precision Capacitance Measurement System was applied (see section 2.3). In the frequency range from 100 Hz to 5 MHz a Wayne Kerr B201

bridge in conjunction with a Wayne Kerr SR268L source and detector was used (see section 2.5). Both bridges directly measure the parameters C_m and G_m in parallel configuration. The applied frequency was measured with a Venner digital counter TSA6634A/2. With the help of a Tektronix 5103N oscilloscope system the voltage across the electrodes of the cell was controlled and kept below 100 mV (r.m.s. value) to avoid electrolysis in the aqueous solutions.

A three-terminal cell was developed for measurements of protein solutions in the frequency range above 100 kHz (Rosen et al., 1969; Wisse et al, 1969). We used this cell* as a test cell in establishing the demands for a more appropriate cell. Hence all final measurements were performed using a three-terminal cell designed in cooperation with Blom (see section 2.6). In all the measurements, the cell was thermostatted with a Calora Ultra thermostat NB-33 (accuracy $\pm 0.05^\circ\text{C}$). The measurements were performed with the solution in the cell kept under a nitrogen atmosphere.

During the measurements, preliminary computations were made with a Hewlett Packard HP97 programmable printing calculator to judge the significance of the results. Final results were obtained by calculations with a DEC-10 computer.

2.3. The General Radio 1621 Precision Capacitance Measurement System

2.3.1. *General features*

The 1621 is an assembly of three integrated instruments. Both the very sensitive GR1238 detector and the GR1316 highly stable oscillator are developed especially for use in combination with the GR1616 bridge, resulting in a measuring system with high sensitivity and allowing easy manipulation.

Eight of the twelve internal capacitance standards of the bridge

* This cell was constructed by Mr. G. Selier and Mr. T.A.C. van Vliet, Mechanical Workshop, Department of Chemistry, University of Leiden.

are enclosed in a thermally insulated compartment with a thermal time constant of six hours to reduce the effects of ambient temperature changes. Metal film resistors in T-networks with small phase angles are used to balance the conductance. Standards not in use are disconnected to reduce shunt capacitances across the detector input. The detector has a 130 dB gain and contains three meters to increase the rate of balancing: one displays the magnitude of the voltage, and the two others show a simultaneous display of the in-phase and quadrature component of the voltage. The effect of input-signal irregularities can be reduced by means of a tunable filter, line-rejection filter (band width 3%) and selectable time constants in the phase-sensitive detector circuits. The 1316 contains a Wien-bridge oscillator and two reference outputs, for use in precise balances of conductance and capacitance.

With this system it is in principle possible to resolve unbalances as small as 0.1 aF and 0.1 fS. Detection of such small unbalances is aided by ratio-transformer voltage capabilities up to 160 Volts at 1 kHz. However, because a voltage of only 100 mV was applied to the cell to avoid electrolysis, the detection was not as sharp as possible but was still satisfactory for our purposes (see section 2.3.2). Furthermore, at high $\tan \delta$, only the predominant admittance can be measured accurately (see section 2.2.1). The high accuracy of C is lost when a high G has to be balanced, because G standards always contain some stray capacitance.

It was considered worthwhile to pay much attention to the General Radio system used. As the application of this General Radio system to aqueous solutions has not yet been given in the literature, we decided to analyse the performance under these conditions in some detail.

Fig. (2-2) gives the fundamental bridge network.

2.3.2. Sensitivity of the system

The unknowns C_x and G_x can be determined with an accuracy which

Figure (2-2): Simplified circuit diagram of the GR1621 measuring system. D = GR1328 detector. H = high terminal. L = low terminal. O = GR1316 oscillator. $Y_{e.s.}$ = external standards. $Y_{i.s.}$ = internal standards. Y_x = unknown admittance.

depends on the sensitivity of the detector. In our special case the bridge has to measure extremely large capacitances and conductances. The accuracy, as calculated by the General Radio Company (1974a,b), based on the detector sensitivity, does not apply to the conditions of our studies, because of the high $\tan \delta$ values involved. Therefore, it was found necessary to determine the attainable detector sensitivity independently.

When the bridge is balanced:

$$Y_x = Y_{st} \quad (2-3)$$

Y_x is the unknown admittance and Y_{st} is the sum of the internal and external standards (see fig. 2-3). The amplitude of the minimum de-

Figure (2-3): Elementary diagram of the balanced bridge. p.s.d. = the two phase sensitive detectors of the GR1238. Y_{st} = sum of the internal and external standard admittances. Y_x = unknown admittance. ΔY_x = minimum detectable change of Y_x .

tectible voltage V_d across the two phase sensitive detectors of the GR1238 is equal to:

$$V_d = V_{CA} = V_i + jV_q \quad (2-4)$$

Application of Kirchhoff's laws gives:

$$I_{BA} = (Y_x + \Delta Y_x) V_{BA} = (Y_x + \Delta Y_x) (V + V_i + jV_q) \quad (2-5)$$

and

$$I_{AD} = I_{BA} - I_{AC} = Y_{st} V_{AD} = Y_{st} (V - V_i - jV_q) \quad (2-6)$$

in which ΔY_x is the minimum detectable change of Y_x . Let Y_d be the total admittance of the phase sensitive detectors, then

$$I_{AC} = Y_d V_{AC} = -Y_d (V_i + jV_q) \quad (2-7)$$

Combining equations (2-5), (2-6) and (2-7) results into:

$$\Delta Y_x = Y_{st} \frac{V - V_i - jV_q}{V + V_i + jV_q} - Y_d \frac{V_i + jV_q}{V + V_i + jV_q} - Y_x \quad (2-8)$$

V_i and V_q decrease gradually from about 130 nV at 10 Hz to 40 nV at 500 Hz ($V_i = V_q = 70$ nV at 120 Hz; $V_i = V_q = 55$ nV at 220 Hz) and $V_i = V_q = 40$ nV for frequencies above 500 Hz (General Radio Company, 1974b). The applied voltage is 100 mV. Therefore,

$$V \gg V_i \quad \text{and} \quad V \gg V_q \quad (2-9)$$

Combining equations (2-3), (2-8) and (2-9) gives:

$$\Delta Y_x \approx -Y_x \frac{V_q^2 + 2jVV_q}{V^2} - Y_d \frac{V_i + jV_q}{V} \quad (2-10)$$

With $Y_x = G_x + j\omega C_x$, $\Delta Y_x = \Delta G_x + j\omega \Delta C_x$ and $Y_d = G_d + j\omega C_d$ equation (2-10) can be written as:

$$\Delta G_x \approx G_x \frac{V_q^2}{V^2} - \omega V_q \frac{2C_x + C_d}{V} + G_d \frac{V_i}{V} \quad (2-11)$$

and

$$\Delta C_x \approx C_x \frac{V_q^2}{V^2} + \frac{V_q}{V} \frac{2G_x + G_d}{\omega V} + C_d \frac{V_i}{V} \quad (2-12)$$

Using the detector specifications $C_d = 20$ pF and $G_d = 1$ nS (General Radio Company, 1974b) ΔG_x and ΔC_x have been calculated for some representative experimental conditions (see table 2-1).

As may be deduced from the experimental data, both ΔG_x and ΔC_x are always mainly determined by the second term in the equations (2-11) and (2-12) respectively. Therefore, ΔG_x increases with increasing ωC_x , whereas ΔC_x decreases with increasing ω , because in the

frequency range covered G_x is independent of ω to within 1%. The possible increase or decrease of ωC_x with increasing ω depends on the amount of electrolyte present in the solution and on the extent of electrode polarization. This becomes clear when $\Delta G_x(\omega)$ for H_2O and 1.000 mol/m^3 KCl or the polystyrene latex are compared. The dependences of ΔG_x and ΔC_x on ω , as predicted by the equations (2-11) and (2-12), are always experimentally obeyed in transformer bridge measurements on pure water or poorly conducting solutions.

Only at frequencies below 1 kHz and at d-values below about 7 mm, ΔC_x becomes insufficient if polystyrene latices with about 1.5 mol/m^3 of a simple electrolyte are measured. However, as will be seen in chapter 4, measurements below 700 Hz are less interesting with our equipment, due to the occurrence of an other relaxation mechanism below 1 kHz.

The lowest decade which is needed in the conductance measurements is 1 - 10 nS. Therefore, the minimally detectable ΔG_x is sufficiently low for our measurements.

Based on preliminary measurements, similar to those described here, the sensitivity of the GR1621 system was found to be sufficient to perform measurements on polystyrene dispersions with a maximum of about 1.5 mol/m^3 simple electrolyte present.

2.3.3. Accuracy

The most important reason for the limitation of the accuracy at frequencies above 10 kHz is the presence of a leakage reactance in the ratio transformer. The difficulty in determining the residual parameters of the numerous switch combinations renders impracticable the detailed calculation of errors for correction of most measurements. The uncertainties are given by (Homan, 1968):

$$C_{\text{error}} = -\omega^2 C_{hs} C_{ls} L_{sg} \quad (2-13)$$

and

$$G_{\text{error}} = - \omega^2 C_{\text{hs}} C_{\text{ls}} R_{\text{sg}} \quad (2-14)$$

with C_{hs} = shunt capacitance from the high terminal side to ground; C_{ls} = shunt capacitance from the low terminal side to ground. Patch cord contributions have to be included in C_{hs} and C_{ls} . L_{sg} and R_{sg} are, respectively, the resistance and inductance of the path from a virtual common point in the shield surrounding the unknown admittance to the ground point in the heart of the bridge. Equations (2-13) and (2-14) do not contain d . Therefore, the permittivity ϵ and conductivity σ of the measured solutions are independent of C_{error} and G_{error} (see section 2.7).

In addition, the elimination of Z_e will introduce errors. As may be seen from table (2-1), values up to about 90 nF for the capacitance of polystyrene solutions may be found. The calculated permittivities at the frequencies mentioned are about ten times the permittivity of water. The corresponding capacitances amount only 0.9 nF, being only 1% of C_x . Several measurements have to be performed at one frequency to eliminate Z_e . Advantage was taken of this necessity by using the same measurements to calculate standard deviations of ϵ and σ .

Although the resistors for the external conductance box (see section 2.4) were carefully selected, systematic errors will be inevitably present. The accuracy of the resistors is better than 0.1%. The accuracy in σ will be influenced also by the extent to which it will be possible to correct for the time drift in σ (see section 2.7.2).

In combination with the results given in section 2.3.2 it is clear that:

- 1) the final accuracy of ϵ in the frequency range of the GR1621 system will depend more on C_e than on the quality of the measuring system;
- 2) the final accuracy in σ does not depend on the quality of the measuring system, but on the quality of the conductance box and on the

time drift in σ ;

- 3) in addition to errors always present (e.g. due to the non-ideality of the cell) the standard deviations are a measure of the reproducibility.

2.4. The conductance box^{*}

The GR1616 has the disadvantage of a conductance range which is too limited for our purposes. Therefore an extra conductance box was constructed, to be used in conjunction with the bridge. This box, with a conductance G_b , ranging from 10 μ S to 9 mS, is connected to the external standard terminals of the bridge (see fig. 2-2).

The 100 k Ω standard of the bridge, in combination with the terminal selector and the external multiplier, has been used to select by comparison sets of low inductance metal film resistors of 100 k Ω , 10 k Ω and 1 k Ω (Draloric Electronic GmbH, SMA 0207). This type of resistor is very stable (temperature coefficient: 50 ppm/K; constant conductance value and almost constant reactance value up to 100 kHz). The selected resistors were placed parallel in the box. The resistors were connected to the terminals of the box by three sets of push-button switches (Oreor CTN1008). The same switches were used to earth the resistors not in use.

A problem in the construction is the occurrence of lead inductances L_b , leading to changes in C_x by an amount $L_b G_b^2$. To reduce this effect L_b was kept low by applying short coaxial cables and by placing the decade with the highest G_b closest to the terminals. Although the products $L_b G_b^2$ were kept as low as possible, it was found necessary to calibrate the deviations C_b in the capacitance readings of the bridge. This was performed by comparing the various settings of the

* Developed in cooperation with J. Blom, A.J. Korteweg and R.A.J. Wegh, Laboratory for Physical and Colloid Chemistry, Agricultural University, Wageningen, The Netherlands.

conductance box, connected to the external standard terminals of the bridge, with additional selected resistors of the same type and values connected to the unknown terminals of the bridge. To obtain reproducible results, the additional resistors were soldered on two parallel brass plates, fixed in a small shielded box. The capacitance of the empty small box was measured directly with the bridge. The obtained corrections ΔC on C_x , including the residual capacitance of the conductance box, are used for all the calculations. ΔC values are listed in appendix A. The values appeared to be independent of the frequency up to at least 80 kHz.

2.5. The Wayne kerr B201 and SR268L measuring system

The B201 is meant to be used for the frequency range 100 kHz to 5 MHz. Calvert (Wayne Kerr monograph no. 1) described the principles of this bridge. Bordewijk (1968) used a B201 to investigate the dielectric behaviour of alcohols. South and Grant (1970,1972) and Williams and James (1973,1976) used this type of bridge for measurements on aqueous solutions.

A simplified circuit diagram of the measuring system is shown in fig. (2-4). Tappings on the two bridge transformers are connected to decade controls. Thereby it is possible to perform measurements with an accuracy of 0.1% for capacitances from 1 pF to 1 nF and an accuracy of 0.5% for conductances from 1 μ S to 0.1 S. The accuracy for both C and G decreases above 1 MHz proportionally to the square of the frequency. Therefore almost all measurements were performed below 1 MHz.

The source level and gain control of the bridge were preset to their maximum values, because the attenuators on the SR268L generator and detector were used to reduce the time required for balancing. The balance point is displayed on a magnitude null-meter.

Because only a small contribution of C_e exists for $\nu > 100$ kHz, $C_x < 0.2$ nF for the measurements with the B201. Therefore this bridge is used for measurements of usual C_x values. Already much attention

Fig. (2-4). Simplified diagram of the Wayne Kerr measuring system. D = SR268L detector. O = SR268L generator. Y_{st} = standard admittance. Y_x = unknown admittance.

has been paid in literature to the B201 (see section 2.1). Hence it was not considered necessary to repeat the analysis of the merits and demerits of this bridge.

As with the GR1621 system, the standard deviations of ϵ and σ are calculated from the different measurements at one frequency.

2.6. The measuring cell*

2.6.1. *General description*

An important prerequisite in the construction of the cell is the

* Designed and constructed in cooperation with J. Blom, A.J. Korteweg and S. Maasland, Laboratory for Physical and Colloid Chemistry, Agricultural University, Wageningen, The Netherlands.

necessity of a variable distance d between the two plane parallel electrodes (see section 2.2.2). Cells with this option have been described by Mandel and Jenard (1958), Schwan and Maczuk (1960), Broadhurst and Bur (1965), Young and Grant (1967,1968), Rosen et al. (1969) and Van der Touw, Selier and Mandel (1975c).

The essential features of the cell are given in fig.(2-5). The electrodes have a diameter of 25 mm and are made of platinum to ensure ideal polarization as well as possible (Grahame, 1946,1947,1954). The total surface area of the electrodes was increased by sandblasting. Accordingly, the influence of Z_e is reduced as described by Schwan (1963,1966,1968). In a theoretical analysis, Scheider (1975) associated the frequency dependence of Z_e with surface roughness. The fixed bottom electrode (32) is connected to the high terminal of the bridge. The upper electrode (31) and the shield (15) are connected to the low terminal. The other metal parts, including the guard-ring (27) are earthed. The upper electrode, the glass tube (9) containing the coaxial cable (5) and the plateau (8) can move together upwards and downwards. This plateau is moved manually. The fine setting is achieved by a set-screw (2). The associated displacement is registered by a Compag 523 GL 10 micrometer gauge (1). The inner diameter of the cylindric sample holder (18) is 26 mm. In the top plate (12) of the sample compartment there are three openings: two (11) for the inlet and outlet of nitrogen gas and one (10) for the introduction of electrolyte with an Agla syringe micrometer.

For $d > 10$ mm stray fields have been found to play a part. Currents from the lower electrode passing through the solution and the teflon cell wall (14) to the shield are purely capacitive. The potential drop in the solution is almost completely determined by G_x and d , because in our measurements usually $G_x > \omega C_x$. This was verified by Blom (1979), performing measurements on a 1.000 mol/m^3 KCl solution. During these measurements the upper electrode was connected to earth, the shield to the low terminal and the bottom electrode to

the high terminal of the bridge. With this method the stray capacitance was obtained from the bridge readings, because the potentials of the electrodes and the shield are the same as in the normal measurements. It appears that the stray capacitance is independent of the frequency with our cell.

2.6.2. *Equivalent circuit of the cell*

It is generally accepted that the total impedance of connecting leads and the cell filled with a conducting liquid may be represented by the equivalent circuit as shown in fig.(2-6) (e.g. Mandel, 1965; Young and Grant, 1968; Van der Touw et al., 1971a). It is convenient to write the impedance Z of the circuit without C_r :

$$Z = \frac{1}{G_s + j\omega C_s} + \frac{1}{G_e + j\omega C_e} + R_c + j\omega L_c \quad (2-15)$$

Y_x is the admittance of the completed circuit:

$$Y_x = \frac{1}{Z} + j\omega C_r \quad (2-16)$$

In electrode kinetic studies it has been argued that the position of C_s is somewhat different, i.e. parallel with the combination C_e, G_e^{-1} . However, it has been shown that for measurements in the frequency range below 10 MHz this is of no importance (Van Leeuwen, 1978).

2.7. Calculation of the permittivity and conductivity

In this part the techniques involved in obtaining the permittivity ϵ and the conductivity σ of the solution under investigation will be described.

2.7.1. *Mathematical formulation*

Y_x is measured with both bridges as a parallel capacitance C_x and conductance G_x . Due to the use of the conductance box as an external standard, C_x must be corrected with ΔC (see section 2.4). We define:

Figure (2-6). Equivalent circuit of the cell.

C_e = electrode polarization capacitance. G_e = electrode polarization conductance. C_s = capacitance of the bulk of the solution in the cell. C_r = residual capacitance, depending on the construction of the cell. L_c and R_c : inductance, respectively resistance due to the part of the cell not localized between the electrodes and due to the coaxial cables connecting the cell with the terminals of the bridge. G_s = conductance of the bulk of the solution in the cell.

$$C_y = C_x - \Delta C \quad (2-17)$$

With (2-16) the relation between the measured quantities and the components of the equivalent circuit becomes:

$$G_x + j\omega C_y = \frac{1}{Z} + j\omega C_r \quad (2-18)$$

Combining (2-15) and (2-18):

$$G_x + j\omega C_y - j\omega C_r = \frac{1}{G_s + j\omega C_s} + \frac{1}{G_e + j\omega C_e} + R_c + j\omega L_c \quad (2-19)$$

After separation of the real and imaginary parts of (2-19):

$$\frac{G_x}{G_x^2 + \omega^2 (C_y - C_r)^2} = \frac{G_s}{G_s^2 + \omega^2 C_s^2} + \frac{G_e}{G_e^2 + \omega^2 C_e^2} + R_c \quad (2-20)$$

and:

(2-21)

$$\frac{C_y}{G_x^2 + \omega^2 (C_y - C_r)^2} = \frac{C_s}{G_s^2 + \omega^2 C_s^2} + \frac{C_e}{G_e^2 + \omega^2 C_e^2} + L_c + \frac{C_r}{G^2 + \omega^2 (C_y - C_r)^2}$$

For aqueous solutions at frequencies below a few MHz,

$$R_c \ll \frac{G_s}{G_s^2 + \omega^2 C_s^2} \quad (2-22)$$

Therefore, under these conditions, R_c may be neglected.

C_r depends on the nature of the solution in the cell and on d , which makes it impossible to determine C_r exactly in advance. Furthermore, ωC_r has to be compared with ωC_s and G_s to decide whether it is allowed to neglect C_r in equation (2-21). For $d < 25$ mm it was shown by measurements on a 1.00 mol/m³ KCl solution that $C_r < 0.4$ pF (see also Blom, 1979). The smallest value of C_s is about 17 pF. Particularly for large values of $G_s/\omega C_s = \tan \delta_s$, found at low frequencies, the influence of C_r is negligible in the left hand term of the equations (2-20) and (2-21). As a first approximation, the equations (2-20) and (2-21) can then be simplified to:

$$\frac{G_x}{G_x^2 + \omega^2 C_y^2} = \frac{G_s}{G_s^2 + \omega^2 C_s^2} + \frac{G_e}{G_e^2 + \omega^2 C_e^2} \quad (2-23)$$

and

$$\frac{C_y}{G_x^2 + \omega^2 C_y^2} = \frac{C_s}{G_s^2 + \omega^2 C_s^2} + \frac{C_e}{G_e^2 + \omega^2 C_e^2} + \frac{C_r}{G_x^2 + \omega^2 C_y^2} + L_c \quad (2-24)$$

Use will be made of the well-known expressions for an ideal condensor:

$$C_s = \frac{\epsilon A}{d} \quad (2-25)$$

and an ideal conductance:

$$G_s = \frac{\sigma A}{d} \quad (2-26)$$

with:

$$\epsilon = \epsilon_0 \epsilon_r \quad (2-27)$$

ϵ_0 = absolute permittivity of free space, ϵ_r = relative permittivity, and σ = electrical conductivity. A is the area of a cross-section of the cell, parallel to the electrode surfaces ($A = 543 \text{ mm}^2$). After introduction of the equations (2-25) and (2-26) in (2-23) and (2-24):

$$\frac{G_x}{G_x^2 + \omega^2 C_y^2} = \frac{\sigma}{\sigma^2 + \omega^2 \epsilon^2} \cdot \frac{d}{A} + \frac{G_e}{G_e^2 + \omega^2 C_e^2} + O(d^2) \quad (2-28)$$

and

$$\frac{C_y}{G_x^2 + \omega^2 C_y^2} = \frac{\epsilon}{\sigma^2 + \omega^2 \epsilon^2} \cdot \frac{d}{A} + \frac{C_e}{G_e^2 + \omega^2 C_e^2} + L_c + O(d^2) \quad (2-29)$$

The left hand side terms of equations (2-28) and (2-29) are plotted against d/A . From the intercepts σ , $\Delta\sigma$, ϵ and $\Delta\epsilon$ are calculated, using a linear regression procedure. The terms $O(d^2)$ indicate quantities on the order of d^2 and are due to the non-ideality of the cell (Rosen et al., 1969). The term $C_r/(G_x^2 + \omega^2 C_y^2)$, depending on d^2 , is the main part of $O(d^2)$ in equation (2-29). Deviations in the geometry of the cell and deviations in the determination of d also lead to terms incorporated in $O(d^2)$. As C_r increases with increasing d , d was kept as small as possible for each frequency in the calculation of ϵ , to minimize the influence of $O(d^2)$. Especially for the measurements with the B201 bridge the number of d values and the range of d values may be restricted. The frequency at which C_e becomes negligible depends on the nature of the solution in the cell (Schwan, 1963); e.g. for 1.000 mol/m^3 KCl solution it was calculated that measurements with $4 \leq d \leq 12.5 \text{ mm}$ were sufficient to obtain reliable results for ϵ at $\nu > 70 \text{ kHz}$. In the calculation of σ for the same solution measurements with $4 \leq d \leq 22.5$ were used, because C_r is absent in equation (2-27).

In determining the range of d values to be taken, use was made of the correlation factors from the linear regression calculations.

2.7.2. Drifts of the conductivity and capacitance with time

The time dependence of the conductivity, $d\sigma/dt$, is a difficulty

in the dielectric measurements of aqueous solutions. Takashima (1963) reported a time drift for measurements on protein solutions, and Pethybridge and Spiers (1975) made a similar observation in their study of aqueous solutions in Pyrex glass cells.

In our measurements, about eight hours are needed to obtain the data for a complete description of the dielectric behaviour at a particular electrolyte concentration. Therefore the conductivity drift is a complication in our study as well. It was necessary to repeat a chosen frequency a few times during a measuring cycle to establish $d\sigma/dt$. These values were subsequently used to correct σ for this drift.

In section 2.2.2 it was indicated that C_e is independent of d . Therefore it was assumed that C_e , in particular, was constant during the time needed to measure G_x and C_x at the different d values. However, it appears that some drift in C_x occurs usually within a few hours. This drift is probably connected with a change in C_e , due to the adsorption of particles from the solution on the electrodes (Tamamuchi and Takahashi, 1974). Therefore it is not surprising that dC_x/dt is somewhat larger for latices than for simple electrolyte solutions.

2.8. Measuring procedure

The influence of dC_x/dt was kept negligible as compared with the overall accuracy by:

- 1) observing a waiting time of at least 24 hours, after a new solution was introduced into the cell;
- 2) measuring C_x and G_x at one frequency at all selected d values before a new frequency was taken;
- 3) mixing of the solution in the cell was performed by moving the upper electrode up and down. In the case of a new solution this was done thirty times before measurements were started. In addition, this mixing procedure was carried out five times every half

hour as a further prevention of drift in C_x ;

- 4) the measurements at one frequency were performed without interruption.

dC_x/dt was checked by repeating after each d-variation cycle the measurement at the first d value.

2.9. Experimental verification of the procedure

2.9.1. *Introduction*

To check the experimental set-up and the basic equations used to calculate σ and ϵ , test measurements were performed. To measure a system with varying σ and constant ϵ , pure water and KCl solutions were used for these measurements. In the frequency range of the bridges used, ϵ of aqueous solutions with less than 10 mol/m^3 KCl is negligibly different from ϵ of pure water (Rosen, Bignall, Wisse and Van der Drift, 1969).

It is generally accepted in the literature that bridge measurements on aqueous solutions have reached an acceptable degree of reliability (for references, see section 2.1). Therefore only a limited number of test measurements have been performed.

The dielectric loss ϵ'' is calculated as:

$$\epsilon'' = \frac{\sigma - \sigma_{dc}}{\epsilon_0 \omega} \quad (2-30)$$

σ_{dc} , the d.c. value of the conductivity, is subtracted from σ . Therefore σ is a less critical parameter and hence it was found unnecessary to prepare water and KCl solutions of extremely high purity.

2.9.2. *Representative results*

The results collected in tables (2-2), (2-3) and (2-4) are calculated with the use of equations given in section 2.7, in particular with the equations (2-28) and (2-29).

The expected value for ϵ is 78.4 at 25.0°C (Handbook of Chemist-

ry and Physics, 1976-1977). In the three tables r^2 is the coefficient of determination (correlation factor) indicating the quality of the fit, achieved by the linear regression. r_G^2 stems from equation (2-28) and r_C^2 from equation (2-29). Two d-ranges are given in the tables, one for the calculation of ϵ and one for the calculation of σ . Finally, use is made of:

$$\operatorname{tg} \delta_s = \frac{\sigma}{\omega \epsilon_0 \epsilon_r} \quad (2-31)$$

with $\epsilon_0 = 8.854 \text{ pF/m}$.

2.9.3. Conclusion

The result on water and the KCl solutions show that reliable results are obtained especially when $\operatorname{tg} \delta_s >$ about 5 and when $\operatorname{tg} \delta_s <$ about 2000.

From extra measurements, necessary to determine $d\sigma/dt$, it followed that the results are reproducible to a high extent; e.g. the following values for ϵ are obtained: 76.6 and 76.1 (1.000 mol/m^3 KCl; 9.972 kHz), 82.1 (2 \times) and 81.9 (0.500 mol/m^3 KCl; 993 Hz) and 87.5 (3 \times) (H_2O ; 993 Hz). This reproducibility is even better than expected from the data in tables (2-2), (2-3) and (2-4).

Comparing the values of $\Delta\epsilon$ and $\Delta\sigma$ in the tables of section 2.9.2 with the content of section 2.7 it is clear that other errors must be present as well. These errors are probably due to the occurrence of the time drift in σ and the neglect of C_r and $O(d^2)$ terms in the calculations.

In the case of the polystyrene dispersions used, ϵ is strongly dependent on the electrolyte concentrations. A further treatment of this system will be given in chapter 4. At this point it may be concluded that the accuracy obtained is sufficient to serve the purpose of the present study as described in section 1.1.

3. MATERIALS

3.1. Chemicals

All chemicals used were of "pro analyse" quality, except for lithium chloride, being of "purum" quality. The water used was always doubly distilled and saturated with nitrogen.

3.2. Preparation and characterization of the polystyrene latices

The latices were prepared by the method of Furusawa, Norde and Lyklema (1972) to obtain particles with surfaces uncontaminated by emulsifiers. This method is based on a procedure described by Kotera, Furusawa and Takeda (1970). A detailed description of the method of preparation and characterization has been given by Norde (1976). Our only modification in the preparation of latices with high surface charge consisted of a change in the amount of distilled styrene used. Like Bijsterbosch (1978), we reduced the amount of styrene to obtain smaller particles. Instead of the amount of 20 ml (Norde, 1976), we used 8.5 ml distilled styrene to prepare latex A, 6.2 ml to prepare latex B and 4.2 ml to prepare latex C.

All measurements were performed on ion-exchanged latex samples.

3.2.1. *Determination of the particle size of the latices*

A Philips EM 300 electron microscope was used to determine mean values for the particle radius a . At least 150 particles of each sample were measured. The number average radius is:

$$a_{10} = \frac{\sum_i n_i a_i}{\sum_i n_i} \quad (3-1)$$

where n_i is the number of particles with radius a_i . The uniformity ratio can be written as a_{32}/a_{10} , where

$$a_{32} = \frac{\sum_i n_i a_i^3}{\sum_i n_i a_i^2} \quad (3-2)$$

The two parameters a_{10} and a_{32} were calculated for the lattices used.

An example of an electron micrograph is given in figure (3-1).

Figure (3-1): Electron micrograph of a latex sample.

3.2.2. *Determination of the surface charge of the lattices*

The surface charge density σ_0 was determined by conductometric titration. The experimental set-up used was the same as for the dielectric measurements, i.e. the General Radio GR 1621 system and the sample cell described in section 2.6. The frequency used was 1 kHz. In chapter 5 the results for latex A are used for comparison with theory. Therefore latex A was taken as an example of a titration curve

(see fig. 3-2). The shape of this curve is comparable to the shape of the curve given in the publication of Furusawa, Norde and Lyklema (1972): only one distinct kink is present, due to the titratable sulphate groups.

All relevant information on the latices used in the dielectric measurements is collected in table (4-1).

Figure (3-2): Conductivity σ as a function of added volume 22.1 mol/m³ KOH for 55 cm³ of undiluted sample latex A.

4. RESULTS OF THE MEASUREMENTS ON LATICES

4.1. General

To obtain latices with K^+ or Li^+ as the counterions as completely as possible, the ion exchanged samples were titrated with KOH or LiOH respectively to the equivalence point of the sulphate groups. The dielectric investigations were performed with these samples. In this way the conductivity and permittivity were determined as a function of added KCl, LiCl or HCl.

In order to describe the dielectric properties of the measured latices as completely as possible, all the results of the measurements, corrected for drift in conductivity, are given in tables containing ϵ , $\Delta\epsilon$, σ and $\Delta\sigma$ (see Appendix B).

TABLE (4-1). Survey of the ion-exchanged latices used in dielectric investigations.

a_{10} = number average radius; a_{32}/a_{10} = uniformity ratio;
 σ_o = surface charge density; ϕ = volume fraction of the latex sample.

sample	A ₁	A ₂	A ₃	B ₁	C ₁	C ₂	C ₃
a ₁₀ (nm)	222			193	152		
a ₃₂ /a ₁₀	1.001			1.002	1.002		
σ_o (mC/m ²)	16.1	18.6	18.6	21.0	15.4	17.6	17.6
ϕ	0.022	0.021	0.022	0.033	0.016	0.016	0.016
electrolyte	KCl	HCl	LiCl	KCl	KCl	HCl	LiCl

4.2. Graphical representations used

In view of the use of the experimental results in chapter 5, the data will be presented in three types of figures: ϵ' versus $\log \omega$

graphs, ϵ'' versus ϵ' graphs (so-called Cole-Cole plots; Cole and Cole, 1941) and $\Delta\epsilon_{st}$ versus c_b graphs. Here c_b is the concentration of electrolyte added to the latex samples and $\Delta\epsilon_{st}$ is the static dielectric increment. To obtain values for $\Delta\epsilon_{st}$ both the ϵ' versus $\log \omega$ graphs and the Cole-Cole plots were used. Cole and Cole (1941) introduced a parameter α in the original Debye equation (Debye, 1929) to account for a distribution of relaxation times. The modified equation is written as follows:

$$\epsilon' - j\epsilon'' = \epsilon_{\infty} + \frac{\epsilon_s - \epsilon_{\infty}}{1 + (j\omega\tau)^{1-\alpha}} \quad (4-1)$$

with ϵ_s = permittivity at low frequencies, ϵ_{∞} = permittivity at high frequencies, α = Cole-Cole distribution parameter ($0 < \alpha < 1$), and τ = most probable relaxation time. Further,

$$\Delta\epsilon_{st} = \epsilon_s - \epsilon_{\infty} \quad (4-2)$$

The diagram of the imaginary part ϵ'' of the complex permittivity plotted against its real part ϵ' gives a circular arc. The intersections of the arc with the ϵ' -axis correspond to ϵ_s and ϵ_{∞} . Dielectric behaviour conforms to the circular arc rule (equation 4-1) if the system obeys a certain distribution of relaxation times around the most probable relaxation time τ , corresponding to the frequency where $\epsilon'' = \epsilon''_{\max}$. This distribution of relaxation times is characterized by the empirical constant α .

To obtain the best estimates of dispersion parameters, a computer analysis has to be carried out. However, as will be shown in chapter 5, a large discrepancy between theories of dielectric dispersion and experiments is found for dilute latex dispersions. Therefore, it was not considered opportune to perform a detailed statistical analysis of the experimental data by computer to obtain more accurate results.

The values of $\Delta\epsilon_{st}$ as a function of c_b are our most important results in the comparison with theories.

4.3.1. Dielectric measurements on latex A_1

Latex A_1 , with the almost symmetrical electrolyte KCl, was chosen for comparison with theory. Therefore the results are given both as plots of ϵ' against $\log v$ and as Cole-Cole plots for the different KCl concentrations used, and as a plot of $\Delta\epsilon_{st}$ versus c_b (see fig. 4-1 up to fig. 4-9). In table (4-2) the resulting most probable relaxation times are given, obtained from the Cole-Cole plots.

TABLE (4-2). The relaxation times (latex A_1) as a function of c_b .

4.3.2. Dielectric measurements on latices B_1 and C_1

These experimental results with KCl as added electrolyte are also given to indicate that comparable results are obtained for latices with another surface charge density and another particle radius (figures 4-10 to 4-17). In order to restrict the amount of figures, only a few Cole-Cole plots are given (figures 4-12 to 4-15). In figures (4-16) and (4-17) the results for $\Delta\epsilon_{st}$ are given.

Figure (4-10): Latex B_1 : ϵ' versus $\log \nu$ at different KCl concentrations c_b (mol/m³): 0.000 (○); 0.226 (□); 0.457 (*); 0.729 (▽); 0.984 (◇); 1.502 (Δ).

Figure (4-17): Latex C_1 : $\Delta\epsilon_{st}$ versus the KCl concentration c_b .

4.3.3. Dielectric measurements on the remaining latices

As will be shown in chapter 5, up to now no satisfactory theory exists to explain the results for experiments on colloidal systems to which a symmetrical electrolyte is added. Therefore, experiments on latices with electrolytes having different diffusion coefficients for anion and cation cannot be explained at the current stage of development of the theory. For possible use in the future, the remaining results are also listed in appendix B. In order to give an overall impression of the experiments with HCl and LiCl as the added electrolyte, plots of ϵ' against $\log v$ are given for the latices A_2 , A_3 , C_2 and C_3 in the figures (4-18) to (4-21).

Figure (4-18): Latex A₂: ϵ' versus $\log \nu$ at different HCl concentrations c_D (mol/m³): 0.000 (o); 0.137 (\square); 0.272 (*); 0.412 (Δ); 0.493 (\bullet).

5. COMPARISON OF EXPERIMENTAL RESULTS AND THEORIES *

5.1. Introduction

In this chapter the experimental results are compared with some existing theories. It must be noted that the latter are based on Maxwell's theory (1873). Part of his article 314 states: "In order that the action of the spherical particles may not produce effects depending on their interference, their radii must be small compared with their distances, and therefore ϕ must be a small fraction". Therefore ϕ has to be small to avoid interaction between the particles.

The theory of dielectric dispersion must at least explain the values found for two important parameters, $\Delta\epsilon_{st}$ and τ . In sections 5.2 and 5.3 $\Delta\epsilon_{st}$ is considered. The most important fact to be explained here is the strong increase of $\Delta\epsilon_{st}$ with electrolyte concentration c_b (see figures 4-9, 4-16 and 4-17). In section 5.4 the relaxation time is considered.

For comparison of the various theoretical calculations the experimental data from measurements on latex A_1 are used. The pertinent data are given in table (5-1). As may be seen from figure (4-5), at a KCl concentration $c_b = 0.644 \text{ mol/m}^3$, a static dielectric increment $\Delta\epsilon_{st} = 530$ is found experimentally. At this particular KCl concentration calculations with the different theories are performed.

5.2. Comparison with the existing theories on $\Delta\epsilon_{st}$

5.2.1. *Theory of De Backer*

De Backer (1966) applies a three-phase heterogeneous Maxwell-Wagner approach to the problem of double layer relaxation (Maxwell, 1873; Wagner, 1914). De Backer considers the particle and its double

* This chapter has been written in cooperation with Mr. P.J.A.M. Mertens, Laboratory for Physical and Colloid Chemistry, Agricultural University, Wageningen, The Netherlands.

TABLE (5-1). Data used in the calculations

relative permittivity of polystyrene (25.0 °C)	: $\epsilon_1 = 2.55$
conductivity of polystyrene	: $\sigma_1 = 0.00 \text{ mS/m}$
volume fraction of latex A_1	: $\phi = 0.022$
mean particle radius of latex A_1	: $a = 222 \text{ nm}$
surface charge density of particles of latex A_1	: $\sigma_o = 16.1 \text{ mC/m}^2$
relative permittivity of water (25.0 °C)	: $\epsilon_w = 78.36$
viscosity of water (25.0 °C)	: $\eta_w = 0.890 \text{ mNs/m}^2$
temperature at which measurements are performed:	298.2 K
molar conductivity of K^+ ion (25.0 °C)	: $\Lambda_+ = 7.45 \text{ mS m}^2/\text{mol}$
molar conductivity of Cl^- ion (25.0 °C)	: $\Lambda_- = 7.55 \text{ mS m}^2/\text{mol}$
diffusion coefficient of K^+ ion (25.0 °C)	: $D_+ = 1984 \text{ } \mu\text{m}^2/\text{s}$
diffusion coefficient of Cl^- ion (25.0 °C)	: $D_- = 2011 \text{ } \mu\text{m}^2/\text{s}$

layer as two separate phases having different permittivities and conductivities. A first Maxwell-Wagner treatment leads to the formulation of the permittivity and the conductivity of an equivalent spherical particle having homogenous dielectric properties. Next, this particle is thought of as embedded in the bulk electrolyte. To the resulting two-phase heterogeneous system the Maxwell-Wagner treatment is applied again. The final expression contains three sets of dielectric properties: those from the particle, from its double layer and from the bulk electrolyte. According to De Backer the static dielectric increment is given by:

$$\Delta\epsilon_{st} = \frac{9\phi(1-\phi)(\epsilon_w\sigma_h - \epsilon_h\sigma_b)^2}{\{\epsilon_h + 2\epsilon_w - \phi(\epsilon_h - \epsilon_w)\}[\sigma_h + 2\sigma_b - \phi(\sigma_h - \sigma_b)]^2} \quad (5-1)$$

with:

$$\epsilon_h = \epsilon_1 + \frac{2\epsilon_d}{ka} \quad (5-2)$$

and

$$\sigma_h = \sigma_1 + \frac{2\sigma_d}{\kappa a} \quad (5-3)$$

ϵ_1 = relative permittivity of the dispersed medium

σ_1 = conductivity of the dispersed medium

ϵ_d = relative permittivity of the diffuse double layer

σ_d = conductivity of the diffuse double layer

κ^{-1} = thickness of the diffuse double layer

σ_b = conductivity of the bulk electrolyte

σ_d depends on the surface conductivity κ_1^σ of the latex particles:

$$\sigma_d = \sigma_b + \kappa \kappa_1^\sigma \quad (5-4)$$

κ_1^σ is calculated with the use of the equation:

$$\kappa_1^\sigma = \frac{FD_c \sigma_o}{RT} \quad (5-5)$$

with D_c = diffusion coefficient of the counterion.

The equations (5-1), (5-2) and (5-3) are valid for spherical particles with the assumptions (De Backer, 1966):

$$\sigma_d > \sigma_1 \quad (5-6)$$

$$\kappa a > 1 \quad (5-7)$$

$$\epsilon_d = \epsilon_w \quad (5-8)$$

The conductivity σ_b of a 0.644 mol/m³ KCl solution at 25.0 °C is 9.96 mS/m. The calculation is performed with:

$$\sigma_b = \Lambda c_b \quad (5-9)$$

and the Nernst-Einstein equation for a symmetrical electrolyte:

$$\Lambda = \frac{zF^2(D_+ + D_-)}{RT} \quad (5-10)$$

Λ is the molar conductivity of the electrolyte solution and z is the charge number. κ^{-1} is obtained with equation (1-2): $\kappa^{-1} = 120 \text{ nm}$. From the data given it follows that the assumption (5-6) is correct. Because $\kappa a = 18$, the assumption (5-7) is also obeyed. Using data given in a publication by Lyklema and Overbeek (1961) concerning the permittivity in the double layer, it appears that for the σ_b value used equation (5-8) is realistic. However, substitution of these data in the above equations leads to $\Delta\epsilon_{st} = 0.81$ which is far below our experimental value $\Delta\epsilon_{st} = 530$.

5.2.2. Theory of Schwarz

Schwarz (1962) examined the low frequency dielectric behaviour of colloid dispersions with the aid of a model employing a frequency dependent surface conductivity. With this model the particle polarization from tangential electromigration and diffusion fluxes of what he terms "bound ions" was calculated. This approach leads to a Debye-like relaxation process with a static dielectric increment:

$$\Delta\epsilon_{st} = \frac{9\phi a \sigma_o F}{4(1 + 0.5\phi)^2 \epsilon_o RT} \quad (5-11)$$

Substitution of the appropriate values leads to $\Delta\epsilon_{st} = 761$ for the experimental conditions as given in table (5-1).

Apart from the fact that this increment is too high, the main drawback of the Schwarz approach is that the dielectric increment is independent of the electrolyte concentration, whereas a strong increase with the electrolyte concentration is found experimentally (see figure 4-9).

According to Dukhin and Shilov (1974) equation (5-11) has to be

corrected for the occurrence of radial fluxes partly compensating the tangential electromigration fluxes. The corrected formula reads for

$$z_+ = z_- = 1:$$

$$\Delta\epsilon_{st} = \frac{9\phi a \sigma_o F}{4(1+0.5\phi)^2 \epsilon_o RT(1+2\kappa_o c_b^{-1} F^{-1})} \quad (5-12)$$

Substitution of $\kappa = 83.3 \mu\text{m}^{-1}$ and $c_b = 0.644 \text{ mol/m}^3$ gives $\Delta\epsilon_{st} = 17.6$ which again is far below the actual value. The alleged importance of radial fluxes is precisely the argument used by Dukhin and Shilov to reject Schwarz's approach and hence design a better theory.

5.2.3. Theory of Schurr

Schurr (1964) introduces the concept of two different values of the surface conductivity: κ_1^σ and κ_2^σ . A distinction is made between a bound charge current, leading to κ_2^σ , and a true or d.c. current, which persists in accordance with Ohm's law in the steady state. The true current leads to the surface conductivity κ_1^σ , as given in equation (5-5). In this treatment, Schurr makes use of both the theory of O'Konski (1955, 1960) and that of Schwarz (1962). Schurr gives an expression for the complex conductivity of the colloid particle. This expression has to be used to calculate $\Delta\epsilon_{st}$, performed by us through substitution of the expression of Schurr into the formulae of the Maxwell-Wagner theory for the complex dielectric increment (Maxwell, 1873; Wagner, 1914). With $\kappa a > 1$:

$$\Delta\epsilon_{st} = \frac{9\phi a \sigma_o F \sigma_b^2}{\epsilon_o RT \{ \sigma_b (2+\phi) + 2\kappa_2^\sigma a^{-1} (1-\phi) \}^2} \quad (5-13)$$

We calculated κ_2^σ with the Bikerman formula for a symmetrical electrolyte (Bikerman, 1935):

$$\kappa_2^\sigma = \frac{2F^2 c_b D (1+3m)}{RT\kappa} \{ \exp(\frac{1}{2} F \psi_d / (RT)) + \exp(-\frac{1}{2} F \psi_d / (RT)) - 2 \} \quad (5-14)$$

with $D = D_+ = D_-$, and: (5-15)

$$m = \frac{2\epsilon_o \epsilon_w R^2 T^2}{3F^2 D \eta_w} \quad (5-16)$$

Assuming that specific adsorption is absent, ψ_d is calculated from the surface charge density with the formula:

$$\sinh \left(\frac{F\psi_d}{2RT} \right) = \frac{\sigma_o}{2(2\epsilon_o \epsilon_w c_b RT)^{1/2}} \quad (5-17)$$

which stems from Gouy-Chapman theory (Kruyt, 1952). κ is calculated with equation (1-2). Substitution of the data given in table (5-1) leads to: $\kappa = 83.3 \mu m^{-1}$

$$m = 0.172$$

$$\psi_d = 123 \text{ mV}$$

$$\kappa_2^\sigma = 1.59 \text{ nS}$$

With equation (5-13) $\Delta\epsilon_{st} = 265$ is calculated. However, compared with the experimental $\Delta\epsilon_{st} = 530$, this value is too low.

This theory predicts $\Delta\epsilon_{st}$ to depend on c_b (see equations (5-9) and (5-13)). Hence, for $\phi \ll 1$, equation (5-13) may be written as:

$$\Delta\epsilon_{st} = \text{constant} \times f(c_b, \psi_d) \quad (5-18)$$

with:

$$\text{constant} = \frac{9\phi a \sigma_o F}{\epsilon_o RT} \quad (5-19)$$

and:

$$f(c_b, \psi_d) = \frac{\sigma_b^2}{(2\sigma_b + 2\kappa_2^\sigma a^{-1})^2} \quad (5-20)$$

We calculated the dependence of $\Delta\epsilon_{st}$ on c_b with these equations. The results are given in table (5-2) and figure (5-2). For the data used the constant given in equation (5-19) is equal to 3111. This is the

maximum for $\Delta\epsilon_{st}$, reached when $\kappa_2^\sigma a^{-1}$ is negligibly small compared with σ_b . In the experimentally accessible range of c_b given in table (5-2), the influence of κ_2^σ remains considerable. This influence is

TABLE (5-2). Dependence of $\Delta\epsilon_{st}$ on c_b , calculated with equation (5-18)

c_b (mol/m ³)	σ_b (mS/m)	ψ_d (mV)	κ_2^σ (nS)	$\Delta\epsilon_{st}$	$f(c_b, \psi_d)$	$\kappa_2^\sigma a^{-1}$ (mS/m)	$J(\kappa_2^\sigma)$ (%)
0.20	3.00	153	1.73	62	0.019	7.78	72
0.30	4.50	142	1.67	111	0.035	7.50	62
0.40	6.00	135	1.65	160	0.050	7.41	55
0.60	9.00	125	1.60	241	0.077	7.23	45
0.80	12.00	117	1.53	314	0.101	6.91	37
1.00	15.00	112	1.52	366	0.118	6.85	31
1.50	22.50	102	1.45	464	0.150	6.53	22
2.00	30.00	95	1.39	526	0.171	6.28	17

given in the table as the ratio

$$J(\kappa_2^\sigma) = \frac{\kappa_2^\sigma a^{-1}}{(\sigma_b + \kappa_2^\sigma a^{-1})} \quad (5-21)$$

To compare the theories of Schwarz and Schurr with each other, equation (5-13) is rewritten as:

$$\Delta\epsilon_{st} = \frac{9\phi a \sigma_o F \sigma_b^2}{4\sigma_b^2 (1 + 0.5\phi)^2 (1+x)^2 \epsilon_o RT} \quad (5-22)$$

indicating that for $x \ll 1$ equations (5-11) and (5-13) become identical. The magnitude of $(1+x)$ follows from the equations (5-13), (5-22):

$$(1+x) = \left[1 + \frac{\kappa_2^\sigma (1-\phi)}{a\sigma_b (1 + 0.5\phi)} \right] \quad (5-23)$$

$x \ll 1$ corresponds with:

$$\sigma_b \gg \frac{\kappa_2^\sigma (1-\phi)}{a(1+0.5\phi)} \quad (5.24)$$

For $\phi \ll 1$ formula (5-24) reduces to:

$$\sigma_b \gg \kappa_2^\sigma / a \quad (5.25)$$

The theoretical calculations by Schwarz are based on experimental results (polystyrene latices; electrolyte: KCl) of Schwan, Schwarz, Maczuk and Pauly (1962) : $\phi = 0.22$; $a = 585$ nm; $\sigma_b = 0.07$ S/m and $\sigma_o = 32$ mC/m². In addition, we calculated κ_2^σ by use of the equations (1-2), (5-9), (5-10), (5-14) and (5-17): $\kappa_2^\sigma = 1.38$ nS. Using these values, it is concluded that the condition given as formula (5-24) is very well satisfied. From this it is understood that the theory of Schwarz is in rather good agreement with the experimental results of Schwan et al., although in this theory $\Delta\epsilon_{st}$ is independent of c_b . However, our experiments are not comparable with the experiments of Schwan et al., because ϕ and σ_b are lower in our case. Therefore, in our experiments condition (5-24) is not satisfied and hence it is not surprising that Schwarz's theory does not apply to our data.

5.2.4. Theory of Einolf and Carstensen

Einolf and Carstensen (1971) apply the Schurr model to porous particles containing both the "surface charge" and the counterions. Therefore, the counterions are also present inside the particles. Assuming that the polystyrene particles are porous in this sense, the calculation has to be performed now with N_o charges per m³:

$$N_o = \frac{3\sigma_o}{ea} \quad (5-26)$$

If, in addition to the theory of Einolf and Carstensen, the approximations $\kappa a > 1$ and $\epsilon_1 < \Delta\epsilon_1$ are used, the following expression is ob-

tained:

$$\Delta\epsilon_{st} = \frac{9}{4} \phi \Delta\epsilon_1 \quad (5-27)$$

with $\Delta\epsilon_1$ = static dielectric increment of the permittivity of the colloid particle due to the double layer polarization. In the theory of Schwarz (1962), $\Delta\epsilon_1$ depends on σ_o . In the treatment of Einolf and Carstensen $\Delta\epsilon_1$ depends on δ_o , being essentially a function of $N_o^{1/2}$, leading to $\Delta\epsilon_1 = 1878$ and $\Delta\epsilon_{st} = 93$. Compared with the low value of 265, calculated with the theory of Schurr (1964), the supposed porosity of the polystyrene particles leads to a further decrease of $\Delta\epsilon_{st}$. This could be expected because in the case of porosity an extra depolarizing mechanism exists, namely the diffusion of the counterions through the colloid particles.

5.2.5. Theory of Ballario, Bonincontro and Cametti

Ballario, Bonincontro and Cametti (1976) follow the approach of Schurr but their theory specifically applies to systems of low electrolyte concentrations. Their treatment results in an expression for $\Delta\epsilon_{st}$ consisting of two contributions; one from double layer polarization and one from the Maxwell-Wagner effect:

$$\Delta\epsilon_{st} = \frac{9\phi\{\sigma_b^2(2+\phi)2\tau\kappa_1^\sigma a^{-1}\epsilon_o^{-1} + (1-\phi)\epsilon_w(2\kappa_1^\sigma a^{-1})^2\}}{(2+\phi)\{\sigma_b(2+\phi) + 2(1-\phi)\kappa_2^\sigma a^{-1}\}}^2 + \frac{9\phi(1-\phi)\{2\epsilon_w a^{-1}(\kappa_1^\sigma + \kappa_2^\sigma)\}^2}{\epsilon_w(2+\phi)\{\sigma_b(2+\phi) + 2a^{-1}(\kappa_1^\sigma + \kappa_2^\sigma)(1-\phi)\}}^2 \quad (5-28)$$

with κ_1^σ = d.c. surface conductivity, κ_2^σ = surface conductivity of bound ions, as before, and:

$$\tau = \frac{a^2 F \sigma_o}{2RT\kappa_1^\sigma} \quad (5-29)$$

On the right hand side of equation (5-28) the first term is the double layer polarization contribution and the second term is due to

the Maxwell-Wagner effect. We calculated κ_1^σ with equation (5-5) and κ_2^σ with the Bikerman formula (eq. 5-14). Substitution of the given data and $c_b = 0.644 \text{ mol/m}^3$ leads to:

$$\kappa_1^\sigma = 1.25 \text{ nS}$$

$$\tau = 12.4 \text{ } \mu\text{s}$$

$$m = 0.172$$

$$\psi_d = 123 \text{ mV}$$

$$\kappa_2^\sigma = 1.59 \text{ nS}$$

Because $\phi \ll 1$ in our experiments, equation (5-28) can be approximated by:

$$\Delta\epsilon_{st} = \frac{9\phi\sigma_b^2\tau\kappa_1^\sigma}{2a\epsilon_o(\sigma_b + \kappa_2^\sigma a^{-1})^2} + \frac{9\phi\epsilon_w(\kappa_1^\sigma)^2}{2(a\sigma_b + \kappa_2^\sigma)^2} + \frac{9\phi\epsilon_w(\kappa_1^\sigma + \kappa_2^\sigma)^2}{2(a\sigma_b + \kappa_1^\sigma + \kappa_2^\sigma)^2} \quad (5-30)$$

In this equation the third term of the right hand side is again the Maxwell-Wagner contribution. The second and third terms on the right hand side of equation (5-30) contribute only 1.2% to $\Delta\epsilon_{st}$. With the use of equation (5-29) τ may be eliminated from equation (5-22).

Thereby, for $\phi \ll 1$ the first term on the right hand side of equation (5-30) becomes equal to equation (5-13). Therefore, it is not surprising that, compared with the result of section 5.2.3, the theory of Ballario et al. gives almost the same $\Delta\epsilon_{st}$, viz. 266. It must be concluded that this theory is no improvement compared with the theory of Schurr.

5.2.6. Theory of Shilov and Dukhin

A major difference from Schwarz's approach (1962) occurs in the theory proposed by Shilov and Dukhin (1970a, 1970b) and Dukhin and Shilov (1974). This theory includes diffusion phenomena, which take place between the bulk and the diffuse double layer as secondary effects following the primary effect of electromigration due to the applied field. Tangential electromigration is compensated for by radial diffusion. The application of an alternating electric field leads to

the establishment of three kinds of ion fluxes:

- a. electromigration fluxes due to the applied field
- b. diffusion fluxes due to the polarization field
- c. convection fluxes due to electroosmosis.

Using flux equations from irreversible thermodynamics, the authors proceeded to calculate the stationary state of the "perturbed" double layer which can be expressed as an asymmetric potential distribution or, alternatively, as an asymmetric concentration distribution. Shilov and Dukhin obtained mathematical expressions by which the perturbed potential distribution can be expressed in terms of the original Poisson-Boltzmann distribution, characterized by the parameters ψ_d and ka . In dielectric measurements an alternating polarization field is obtained which lags in phase behind the applied field (see also section 1.1). The imaginary part of the complex conductance can formally be related to the real part of the complex permittivity. The latter quantity decreases with increasing frequency. The static dielectric increment is found by extrapolating to zero frequency and depends on the double layer parameters ψ_d and ka and on the diffusion constants of anion and cation.

Since the effect of dielectric dispersion amplification is associated with the imaginary part of the dipole moment of the particle, the theory of strong low-frequency dielectric dispersion should be based on the theory of double layer polarization in an alternating field. However, Overbeek (1941) calculated the dielectric increment by solving the problem of polarization in a constant electric field. Although correct allowance is made for all the factors affecting the static polarization of the diffuse double layer, the theory of Overbeek does not yield the effect of strong low-frequency dispersion, because the system described is conducting. Relaxation has to be considered as an increase of the conductivity with increasing frequency, which formally can be related to a decrease of the permittivity with increasing frequency.

The perturbation of the double layer lags in phase behind the applied alternating field. The result is a perturbed double layer, the composition of which is a function of time, described as a polarization field $\phi(r, \theta, \omega)$. This field is equivalent to the field of an alternating dipole moment μ , located in the centre of the spherical particle. Because the polarization field can be expressed in terms of the original Poisson-Boltzmann distribution, as stated before, the dipole moment depends on the double layer parameters ψ_d and ka . Moreover, μ is complex due to the phase difference with the applied alternating field. Working with this model, Shilov and Dukhin had to introduce some approximations into the double layer concept. This is necessary because it is impossible to give analytical solutions for the spherically symmetrical Poisson-Boltzmann differential equation. The double layer polarization theory needs such an explicit solution for the potential distribution $\psi(r)$ in order to solve the flux equations. Dukhin and Shilov applied the solution for a flat surface to any angle θ . This of course means that the result can only be valid for $ka \gg 1$ (see section 1.2). The final result of this theory is given as equations III.103, 104 and 108 in the work of Dukhin and Shilov (1974). In these equations the parameter ζ occurs, due to the theoretical accommodation of the electroosmosis phenomenon. ζ is the electrokinetic potential, an important parameter in colloid chemistry (see e.g. Kruyt, 1952). The picture is that behind the shear plane no convective liquid movement occurs, whereas electromigration and diffusion are taking place from the distance $r=a$ onward.

A very remarkable feature of these dispersion equations is that double layer polarization does not exhibit a Debye-like relaxation behaviour. Double layer polarization according to Dukhin and Shilov can formally be described as the behaviour of a circuit consisting of a resistance R , a Warburg impedance Z_w and a capacitance C in series (see figure 5-1).

Figure (5-1): The electrical equivalent circuit for the model of Dukhin and Shilov for double layer polarization.

Z_w is given by (Vetter, 1961)* :

$$Z_w = (1-j)\sigma_w \omega^{-1/2} \quad (5-31)$$

The parallel capacitance C_p of the equivalent circuit shown in figure (5-1) is given by:

$$C_p(\omega) = C \frac{1+W}{(1+W)^2 + W^2(1+\beta W)^2} \quad (5-32)$$

with:

$$W = \sigma_w C \omega^{1/2} \quad (5-33)$$

and

$$\beta = \frac{R}{C \sigma_w^2} \quad (5-34)$$

Equation (III,103) from Dukhin and Shilov (1974) can be represented by analogy with equation (5-32) as:

$$\Delta \epsilon'(\omega) = \Delta \epsilon_{st} \frac{1+W}{(1+W)^2 + W^2(1+\beta W)^2} \quad (5-35)$$

* In electrochemistry Z_w is used in the representation of the diffusional impedance of an electrochemical cell. Then, σ_w is inversely proportional to the square root of the diffusion coefficients and the concentrations of the electro-active species.

with:

$$W^2 = \frac{\omega a^2}{2D_e} \quad (5-36)$$

$$\beta = A_2 A_1^{-1} \quad (5-37)$$

$$D_e = \frac{2D_+ D_-}{D_+ + D_-} \quad \text{for } z_+ = z_- \quad (5-38)$$

A_1 and A_2 are complicated factors, depending on ψ_d , κa , D_e and the quantity m , given in equation (5-16). Using the formulas (5-33) and (5-36), it is found that σ_w depends on $D_e^{-1/2}$ (see footnote on page 75). Using the set of about twenty equations needed to calculate A_1 and A_2 (see Dukhin and Shilov, 1974) and the data from the preceding sections of this chapter, we find $\Delta\epsilon_{st} = 154$ for this theory. It is shown that the theory of Dukhin and Shilov is also unable to explain the experimental results. Furthermore, we calculated that even at infinitely high surface charge $\Delta\epsilon_{st}$ attains a maximum value of 377 at 0.644 mol/m^3 KCl.

Moreover, another prediction of the theory of Dukhin and Shilov, i.e. the occurrence of a maximum in the static dielectric increment as a function of the electrolyte concentration (or κa) is not corroborated by experimental results. Table (5-3) shows results calculated with the known set of data and equation III,104 (Dukhin and Shilov, 1974), reading:

$$\Delta\epsilon_{st} = \frac{9}{4} \phi \epsilon_r (\kappa a)^2 (A_1 a_2 - A_2 a_1) A_1^{-2} \quad (5-39)$$

a_1 and a_2 are again complicated factors, depending on ψ_d , κa , D_e and m . The experimental and theoretical results are compared in figure (5-2). Thereby, κ is calculated with equation (1-2) and ψ_d with equation (5-17). In the theoretical calculations the maximum value of $\Delta\epsilon_{st}$ is caused by an increase of κa with increasing c_b , resulting in an increase of $\Delta\epsilon_{st}$ together with a decrease of ψ_d at constant σ_0 and increasing c_b , resulting in a decrease in $\Delta\epsilon_{st}$.

Figure (5-2): Dependence of $\Delta\epsilon_{st}$ on c_b , with: O: experimental results on latex A₁ (from fig.4-9); *: results according to the theory of Schurr; □: results according to the theory of Dukhin and Shilov.

5.2.7. Survey of results

In Table (5-4) the results for $\Delta\epsilon_{st}$ by various workers are shown together for convenience.

It must be concluded that there is no theory as yet which can explain the increment $\Delta\epsilon_{st}$ obtained from our experiments. Moreover, the increase of $\Delta\epsilon_{st}$ with increasing electrolyte concentration, c_b , for our experiments on polystyrene latices with low volume fraction ϕ (see fig.5-2) is not explained theoretically. The Dukhin-Shilov approach is, up to now, the most elaborate and comprehensive treatment of the double layer polarization problem. However, it must be noted that the diffusion-determined frequency dependence of the permittivity in this theory is not corroborated by the experimental, almost Debye-like, Cole-Cole plots. Considering a homodispersed colloid system and taking $\beta = 1$ the maximum value of the dielectric loss ϵ''_{\max} only amounts to $0.277 \Delta\epsilon_{st}$. The expression for ϵ''_{\max} is obtained by substituting equation (5-39) and $\beta = 1$ in equation III.108 (Dukhin and Shilov, 1974), resulting in

$$\epsilon''(\omega) = \Delta\epsilon_{st} \frac{W}{(1+W) + W^2(1+W)} \quad (5-40)$$

The maximum value of $\epsilon''(\omega)$, ϵ''_{\max} , is calculated with equation (5-40) and is found to occur at $W = 0.66$. Experimentally an ϵ''_{\max} value of nearly $0.5 \Delta\epsilon_{st}$ is found for our nearly homodispersed latices. For a single Debye relaxation process $\epsilon''_{\max} = 0.5 \Delta\epsilon_{st}$ (see e.g. Böttcher and Bordewijk, 1978). Therefore, the experimentally determined frequency dependence exhibits an almost normal Debye-like function instead of the diffusion-like function of Dukhin and Shilov.

From the criticism of Dukhin and Shilov (1974) of the theories of O'Konski (1955, 1960) and Schwarz (1962) in particular, it appears that it is necessary to introduce in the theoretical treatment the diffusion processes of ion exchange between the bulk and the diffuse double layer. Although the model of Schurr (1964) is an improvement,

the diffusion fluxes of ions in the diffuse double layer are disregarded by Schurr. The diffusion processes have to be considered as a consequence of the electromigration due to the applied electric field. Therefore, the tangential electromigration along the colloid particles results in a radial diffusion process. As a consequence, it is artificial to consider the two surface conductivities κ_1^σ and κ_2^σ as two independent quantities as Schurr and Ballario et al. (1976) have done. The treatment of Dukhin and Shilov is based on the above considerations. The concept of diffusion processes of ions in the double layer is best elaborated in the theory of Schurr and the theory of Dukhin and Shilov.

Comparison of our experimental results on latex A_1 with our results on other latices (see chapter 4) shows that the chosen results on latex A_1 are characteristic of the dielectric behaviour of polystyrene latices at low volume fractions ϕ . Therefore it may be taken as a general conclusion that Schurr's theory leads to a better agreement with experiment than that proposed by Dukhin and Shilov as is shown by:

1. $\Delta\epsilon_{st} \text{ (experimental)} > \Delta\epsilon_{st} \text{ (Schurr)} > \Delta\epsilon_{st} \text{ (Dukhin and Shilov)}$;
2. the theory of Schurr does not predict a maximum for $\Delta\epsilon_{st}$ against c_b ;
3. experimentally a Debye-like behaviour is found. This is more in concordance with Schurr's theory than with that of Dukhin and Shilov.

However, theoretically the theory of Dukhin and Shilov must be considered as the best one up to now, because Schurr disregards the diffusion fluxes of ions in the diffuse part of the double layer. Unfortunately, Dukhin and Shilov's theory is very complicated, and our comparison of experiment and theory has shown that at least for our results a discrepancy exists between experiment and theory. It was therefore thought appropriate to attempt to obtain a better agreement between experiment and theory. The approach is described in section 5.3.

5.3. Comparison with a theory based on the parameter M_e

5.3.1. *Introduction of the parameter M_e*

None of the theories conforms with the demands that the dielectric increment should increase strongly with the electrolyte concentration c_b . Bearing the experimental results in mind, we postulated a Debye-like complex dipole moment, characterized by a dimensionless parameter M_e . Instead of the very complicated expression for the complex dipole moment μ (Dukhin and Shilov, 1974, equation III.101), which is a function of both σ_0 (via ψ_d) and c_b (via κa), the following simple expression is assumed:

$$\mu = - \frac{6\pi\epsilon_0 E a^3 M_e}{(1 + j\omega\tau)} \quad (5-41)$$

in which E is the applied electric field strength. In this equation, M_e determines the value of μ through the influence of the properties of the double layer. The particular advantages of this parameter M_e is that the unwieldy factors A_1 and A_2 used by Dukhin and Shilov are not longer needed. As has already been mentioned in section 5.2.6 A_1 and A_2 are calculated through a set of about twenty equations. The appearance of all these equations makes it difficult to trace the influence of the colloid-chemical parameters ψ_d and κa on $\Delta\epsilon_{st}$. Therefore, we are not able to determine why the expression for $\Delta\epsilon_{st}$ given as equation (5-39) is not in accordance with our experimental results.

Equation (5-41) will now be used to obtain an expression for $\Delta\epsilon_{st}$ in which M_e occurs. Equation (5-41) is substituted next in equation II.38 (Dukhin and Shilov, 1974), giving the complex dielectric increment as:

$$\Delta(\epsilon' - j\epsilon'') = \frac{j3\pi N a^3 (\kappa a)^2 \epsilon_w A(D_+, D_-) M_e (1 - j\omega\tau)}{W^2 (1 + \omega^2 \tau^2)} \quad (5-42)$$

with N = number of colloid particles per m^3 , and for $z_+ = z_- = 1$:

$$A(D_+, D_-) = \frac{D_+ + D_-}{2 D_e} \quad (5-43)$$

To obtain equation (5-42) we have assumed, like Dukhin and Shilov, that $ka \gg 1$, implying that

$$\frac{\omega \tau A(D_+, D_-)(ka)^2}{4 D_e W^2} \gg 1 \quad (5-44)$$

With equations (1-2), (5-36) and (5-43), this is transformed as:

$$\frac{\tau \sigma_b}{\epsilon_o \epsilon_w} \gg 1 \quad (5-45)$$

Because $\omega_{cr} \tau = 1$ (see e.g. Böttcher and Bordewijk, 1978), using equation (2-31), formula (5-45) is expressed as:

$$(\text{tg } \delta_s)_{\omega=\omega_{cr}} \gg 1 \quad (5-46)$$

In practice this means that the continuous medium should possess an appreciable conductance over the whole frequency range in which relaxation occurs. This condition is fulfilled with our experiments (see also section 2.2.1). More generally, formula (5-46) is expressed as $\text{tg } \delta \gg 1$ (compare with section 1.2).

Introducing equations (1-2), (5-36), (5-43) and

$$\phi = \frac{4}{3} \pi N a^3 \quad (5-47)$$

the real part of the dielectric increment from equation (5-42) is given as

$$\Delta \epsilon' = \frac{9 \phi F^2 c_b M_e (D_+ + D_-) \tau}{2 \epsilon_o R T (1 + \omega^2 \tau^2)} \quad (5-48)$$

Using the Nernst-Einstein equation (5-10) with $z=1$ and the definition of $\Delta \epsilon_{st}$, already given as equation (4-2), the static dielectric increment is given by:

$$\Delta \epsilon_{st} = \frac{9 \phi \Lambda \tau M_e c_b}{2 \epsilon_o} \quad (5-49)$$

If the factor M_e is independent of the electrolyte concentration c_b , equation (5-49) predicts an increment varying linearly with c_b . Furthermore, according to equation (5-49), the slope of the straight line

$\Delta \epsilon_{st}$ against c_b depends on the molar conductivity Λ of the electrolyte used.

From the experimental results on latex A₁ (see figure 4-9), a slope of about 620 m³/mol is calculated. From table (4-2) $\tau = 23 \mu s$ is taken as a mean value. With additional data given in table (5-1), M_e is calculated as 0.31 from experiment.

In the sections 5.3.2. and 5.3.3., two theories on the static dipole moment μ_o of spherical particles surrounded by a diffuse double layer are used to derive an expression for M_e . The expression for μ_o follows from equation (5-41):

$$\mu_o = -6\pi\epsilon_o E a^3 M_e. \quad (5-50)$$

5.3.2. Theory of Dukhin and Shilov

The expression for μ_o (Dukhin and Shilov, 1974, eq. III.71), disregarding electroosmotic effects, reads:

$$\mu_o = - \frac{24\pi\epsilon_o E a^3 \sinh^2 \{F\psi_d / (4RT)\}}{\kappa a + 8 \sinh^2 \{F\psi_d / (4RT)\}} \quad (5-51)$$

The disregard of electroosmotic effects leads only to a correction of about 3% in equation (5-51). ψ_d is 150-100 mV (see table 5-6). Therefore, the next approximation may be applied:

$$\sinh \left(\frac{F\psi_d}{2RT} \right) = 2 \sinh^2 \left(\frac{F\psi_d}{4RT} \right) \quad (5-52)$$

Combining equations (1-2), (5-17), (5-50), (5-51) and (5-52), the following expression for M_e can be derived:

$$M_e = \frac{\sigma_o}{2\sigma_o + 2aF c_b} \quad (5-53)$$

With data from table (5-1) M_e and $\Delta \epsilon_{st}$ are calculated for the concentration series 0.2 - 2.0 mol/m³ (see table 5-5). Use is made of equations (5-53), (5-49), table (5-1), and of $\tau = 23 \mu s$ (from table (4-2)).

TABLE (5-5). Calculated values for M_e and $\Delta\epsilon_{st}$ with equations (5-53) and (5-49)

c_b (mol/m ³)	M_e	$\Delta\epsilon_{st}$
0.2	0.39	301
0.4	0.33	497
0.6	0.28	635
0.8	0.24	738
1.0	0.21	817
1.5	0.17	953
2.0	0.14	1040

5.3.3. Theory of Overbeek

The expression of Overbeek (1941) for the static dipole moment reads:

$$\mu_o = - \frac{4\pi\epsilon_o EB}{\kappa^3} \quad (5-54)$$

where B is a very complicated function of ψ_d and κa (see Overbeek, 1941, eq.84'). However, this expression for B can be approximated for $\kappa a \gg 1$, $\psi_d = \zeta$, $z_+ = z_-$ and $D_+ = D_-$ by:

$$2B = (\kappa a)^3 \frac{1 - \frac{(1+3m)(F\psi_d)^2}{2\kappa a(RT)^2}}{1 + \frac{(1+3m)(F\psi_d)^2}{4\kappa a(RT)^2}} \quad (5-55)$$

In the range of c_b values under consideration this expression is correct within 5-10%. The expression for m is given by eq. (5-16). Now the following expression for M_e can be obtained by using the equations (5-50), (5-54) and (5-55):

TABLE (5-6). Calculated values for M_e and $\Delta\epsilon_{st}$ with equations (5-56) and (5-49)

c_b (mol/m ³)	κa	ψ_d (mV)	M_e	$\Delta\epsilon_{st}$
0.20	10.3	153	- 0.23	- 177
0.30	12.6	142	- 0.15	- 166
0.40	14.6	135	- 0.08	- 128
0.60	17.9	125	- 0.0003	- 1
0.80	20.6	117	+ 0.05	+ 164
1.00	23.1	112	+ 0.10	+ 365
1.50	28.3	102	+ 0.16	+ 909
2.00	32.7	95	+ 0.20	+1495

$$M_e = \frac{1}{3} \frac{1 - \frac{(1+3m)(F\psi_d)^2}{2\kappa a(RT)^2}}{1 + \frac{(1+3m)(F\psi_d)^2}{4\kappa a(RT)^2}} \quad (5-56)$$

In an analogous way as in section 5.3.2., M_e and $\Delta\epsilon_{st}$ are calculated (see table 5-6).

5.3.4. Concluding remarks

It is clear that the treatments of sections 5.3.2. and 5.3.3. predict values for M_e which are dependent on the electrolyte concentration. Furthermore, in section 5.3.3. negative results for $\Delta\epsilon_{st}$ are obtained at low c_b . This may only partly be due to the approximations used. However, let us reason the other way around, i.e. accept the theory and accept $M_e = 0.31$ as obtained from the experiments (fig. 4-9). It is then possible to calculate the consequences for the surface charge, as shown in table (5-7). Thereby ψ_d (Dukhin) is calcu-

TABLE (5-7). Calculated values for ψ_d and σ_o for the case that M_e is independent from c_b ($M_e = 0.31$)

c_b (mol/m ³)	κa	ψ_d (Dukhin) (mV)	ψ_d (Overbeek) (mV)	σ_o (Dukhin) (mC/m ²)	σ_o (Overbeek) (mC/m ²)
0.20	10.3	110	21	3.1	0.31
0.30	12.6	120	23	5.7	0.52
0.40	14.6	128	25	8.9	0.75
0.60	17.9	138	27	16	1.2
0.80	20.6	145	29	25	1.8
1.00	23.1	151	31	35	2.4
1.50	28.3	161	34	64	4.0
2.00	32.7	169	37	100	5.8

lated by use of equations (5-50), (5-51) and (5-52), whereas ψ_d (Overbeek) is obtained from equation (5-56). Next, the ψ_d values in combination with equation (5-17) are used to calculate σ_o (Dukhin) and σ_o (Overbeek).

Accepting equation (5-49), the theory of Dukhin and Shilov and the theory of Overbeek means that the potential ψ_d would increase with increasing electrolyte concentration. However, from equation (5-17) it must be concluded that ψ_d decreases with increasing electrolyte concentration at constant σ_o . Not only the application of the theory based on the parameter M_e , but also the use of the theories treated in section 5.2 leads to a discrepancy between theory and experiment. This discrepancy gives rise to doubt as to the quality of the model system used for our investigations, i.e. the monodispersed polystyrene latices.

Therefore, as a next step in testing the theories it may be worthwhile to perform measurements on another type of colloid sys-

tems, e.g. chromium hydroxide sols. Matijević et al. (1971) describe the preparation and characterization of this colloid. According to Matijević et al., it is possible to obtain spherical particles of narrow size distribution. Furthermore the same order of magnitude for the particle radius may be obtained compared with the lattices used in our investigations.

5.4. Some remarks on the relaxation time

From the table (4-2) it follows that the characteristic relaxation time τ for a distribution of relaxation times is independent of c_b within the experimental accuracy.

To compare theory and experiment again use is made of the measurements with latex A_1 with $c_b = 0.644 \text{ mol/m}^3$ and the theoretical considerations of the authors as treated in section 5.2.

De Backer (1966) gives an expression for the relaxation time obtained by applying the procedure as described in section 5.2.1.:

$$\tau = \epsilon_0 \frac{\epsilon_h + 2\epsilon_w - \phi(\epsilon_h - \epsilon_w)}{\sigma_h + 2\sigma_b - \phi(\sigma_h - \sigma_b)} \quad (5-57)$$

where ϵ_h and σ_h are given by the equations (5-2) and (5-3).

Schwarz (1962), Schurr (1964), Einolf and Carstensen (1971) all use the following expression for the relaxation time:

$$\tau = a^2 / (2D_c) \quad (5-58)$$

The expression for the relaxation time in the theory of Ballario et al. (1976) has already been given as equation (5-29), which may be transformed into equation (5-58) by use of equation (5-5).

The relaxation time occurring in the theory of Dukhin and Shilov (1974) may be obtained when use is made of the definition that the relaxation time relates to the frequency at which

$$\Delta\epsilon'(\omega) = \frac{1}{2} \Delta\epsilon_{st} \quad (5-59)$$

This particular frequency is called the critical frequency ω_{cr} , with

$$\omega_{cr} = \frac{1}{\tau} \quad (5-60)$$

With equation (5-36) the following expression for τ is obtained:

$$\tau = \frac{a^2}{2D_e W^2} \quad (5-61)$$

Combining the equations (5-35) and (5-59), W may be obtained when a value for β , given in equation (5-37), is calculated from the data of our measurements ($\beta = 0.705$).

Finally, the relaxation time relating to the correction of the theory of Schwarz by Dukhin and Shilov (1974) reads, for $z_+ = z_- = 1$:

$$\tau = \frac{a^2}{2D_c (1 + 2k\sigma_o c_b^{-1} F^{-1})} \quad (5-62)$$

In table (5-8) results are shown for relaxation time calculations with the relevant formulas.

TABLE (5-8). Comparison of the results for τ .

Theory	Equation used	τ (μs)
De Backer	(5-57)	0.047
Schwarz	(5-58)	12.4
Schwarz, corrected	(5-62)	0.28
Schurr	(5-58)	12.4
Einolf and Carstensen	(5-58)	12.4
Ballario, Bonincontro and Cametti	(5-58)	12.4
Dukhin and Shilov	(5-61)	37.0
Calculated from our experiments (latex A_1 , $c_b = 0.644 \text{ mol/m}^3$)		20.3

From table (5-8) it is observed that the relaxation times calculated with the equations (5-58) and (5-61) are of the right order of magnitude. As with the results for $\Delta\epsilon_{st}$ given in table (5-4), the theory of De Backer and the correction of Dukhin and Shilov on the theory of Schwarz lead to a discrepancy between theory and experiment which is far beyond the accuracy of our experiments. Based on the results for $\Delta\epsilon_{st}$, we concluded in section 5.2.7. that the theory of Schurr leads to a better agreement with experiment than the theory of Dukhin and Shilov. This is not contradicted by the results for τ . Schwan et al. (1962) concluded from their experiments that τ is proportional to a^2 . Both equation (5-58) and equation (5-61) show this proportionality.

In the calculations use is made of the values for the diffusion coefficients of ions in the bulk. However, in Schurr's theory the unknown diffusion coefficients of the ions in the double layer occur, whereas in the theory of Dukhin and Shilov the diffusion coefficients of ions in the bulk occur. It is reasonable to suppose that the diffusion coefficient of a certain counterion in the double layer is smaller than the diffusion coefficient of the same ion in the bulk. This would increase the calculated value for τ in the theory of Schurr. As a consequence, based on the results for the relaxation time, it is impossible to discriminate between Schurr's theory and that of Dukhin and Shilov. However, in both theories τ is in good agreement with the experimental value.

With respect to $\Delta\epsilon_{st}$, we demonstrated in this thesis that a better agreement with experiment is obtained with the theory of Schurr than with the theory of Dukhin and Shilov. This may be caused by an overestimation of the radial fluxes by Dukhin and Shilov. However, because their theory is very complicated, it is difficult to estimate the influence of this eventual overestimation. Therefore, further consideration of the theory is desired.

APPENDIX A. Capacitance corrections on the conductance box (see section 2.4)

In the first three columns the values of the three decades are given. In the last column the calculated correction factors ΔC are listed. From the measurements it became clear that the influences of the resistors of the lowest conductance decade on the two other decades is negligibly small. Therefore, the corrections of the different settings of the box are obtained by adding the value x for a particular setting of the lowest conductance decade to the listed value of the highest decades. Conductances above 4.0 mS were not calibrated, because they were not needed in our measurements of polystyrene latices.

Summary

The main aim of the investigations, described in this thesis is to provide data which can be used to test theories of dielectric phenomena in dilute colloid systems.

The possibility of preparing homodisperse polystyrene latices with surfaces uncontaminated by emulsifiers, means that dielectric methods can be applied to these colloid dispersions. The equipment used and the latices which were prepared are described in chapters two and three respectively.

The experimental results for latex A_1 , with KCl as the added electrolyte, are particularly relevant. These results, which are characteristic of the dielectric behaviour of dilute polystyrene latices, are used in chapter five for calculations with different theories. Based on the dependence of the static dielectric increment $\Delta\epsilon_{st}$ on c_b , the concentration of added electrolyte, it appears that until now no theory exists, by which the experimental results obtained are explained conclusively. The best agreement between theory and experiment is obtained both with the theory of Dukhin and Shilov and with that of Schurr. Using the calculated relaxation times, it is impossible to discriminate between these two theories, because in both cases a relaxation time is calculated which is of the right order of magnitude compared with the experimental value.

Figure (5-2) demonstrates that Schurr's theory is the best in accordance with the experimental results. However, in Schurr's theory the diffusion fluxes of the ions in the diffuse part of the double layer are not taken into account. In view of their theoretical starting points the theory of Dukhin and Shilov must be considered as the best one. The larger discrepancy between the theory of Dukhin and Shilov and the experimental results for $\Delta\epsilon_{st}$ as a function of c_b may be caused by an overestimation of the influence of radial fluxes in their theory.

In conclusion, based on the established discrepancies between theory and experiment it is thought to be pertinent to perform further dielectric measurements on other colloid model systems such as chromium hydroxide sols. Probably, a part of these discrepancies is due to irregularities in the polystyrene latices used. On the other hand, it is necessary to develop the theory further. In this case special attention must be paid to the role played by the diffusion coefficients and diffusion fluxes around the colloid particles.

Samenvatting

Het hoofddoel van het in dit proefschrift beschreven onderzoek is: het verkrijgen van gegevens uit experimenten om hiermee theoriën over diëlectrische eigenschappen van verdunde kolloïdale systemen te testen.

De mogelijkheid om homodisperse polystyreen latices te bereiden zonder gebruik te maken van emulgatoren maakte het zinvol om diëlectrische onderzoeksmethoden op deze kolloïdale systemen toe te passen. De voor dit doel opgebouwde meetopstelling en de gebruikte latices zijn beschreven in respectievelijk hoofdstuk twee en hoofdstuk drie.

Met name de meetresultaten voor latex A_1 , waarbij KCl als elektrolyt gebruikt is, zijn van belang. Deze resultaten, die karakteristiek blijken te zijn voor het diëlectrisch gedrag van verdunde polystyreen latices, dienen in hoofdstuk vijf als basis voor de berekeningen met verschillende theoriën. Met name op basis van de afhankelijkheid van het statisch diëlectrisch increment $\Delta\epsilon_{st}$ van c_b , de concentratie aan toegevoegd elektrolyt, blijkt dat er nog geen theorie bestaat die in afdoende mate de verkregen meetresultaten kan verklaren. De beste overeenstemming tussen theorie en experiment wordt verkregen met de theorie van Dukhin en Shilov enerzijds en die van Schurr anderzijds. Op grond van de berekende relaxatietijden kan geen onderscheid tussen deze theoriën gemaakt worden, omdat met beide theoriën een relaxatietijd berekend wordt, die van de juiste orde van grootte is in vergelijking met de waarde, die uit de metingen berekend is.

Figuur (5-2) toont aan, dat de theorie van Schurr het beste op de experimentele resultaten aansluit. Hier staat echter tegenover dat in Schurr's theorie de diffusie fluxen van de ionen in het diffuse deel van de dubbellaag niet in beschouwing worden genomen. Op grond van de theoretische uitgangspunten moet geconcludeerd worden dat de theorie van Dukhin en Shilov beter is dan die van Schurr.

De grotere discrepantie tussen de theorie van Dukhin en Shilov en de experimentele resultaten voor $\Delta\epsilon_{st}$ als functie van c_b zou veroorzaakt kunnen worden door een overschatting van de invloed van de radiële fluxen in hun theorie.

Op grond van de geconstateerde verschillen tussen theorie en experiment is het enerzijds gewenst om diëlectrische metingen te gaan verrichten aan andere kolloïdale modelsystemen, zoals chroomhydroxide solen. Wellicht is een deel van de geconstateerde discrepanties toe te schrijven aan onregelmatigheden in het als modelsysteem gebruikte polystyreen latex. Anderzijds is het nodig om de theorie verder te ontwikkelen waarbij met name aandacht besteed zal moeten worden aan de rol die de diffusie coëfficiënten en de diffusie fluxen rond de kolloïdale deeltjes spelen.

Curriculum Vitae

Op 4 juni 1940 ben ik geboren te Leiderdorp.

Mijn middelbare schoolopleiding kreeg ik aan het Praedinius Gymnasium te Groningen, het Coevorder Lyceum en het Leids Gymnasium.

Aan laatstgenoemde school behaalde ik in juni 1960 het diploma gymnasium- β . Na vervulling van de militaire dienstplicht bij de Koninklijke Luchtmacht van augustus 1960 tot augustus 1962 begon ik in september 1962 de studie scheikunde aan de Rijksuniversiteit te Leiden. Het kandidaatsexamen, studieletter *f*, werd in juni 1966 afgelegd. De studie werd voortgezet onder leiding van de hoogleraren Dr. C.J.F.Böttcher, Dr. L.J.Oosterhoff, Dr. P.Mazur en Dr. E.Havinga. Het doctoraalexamen scheikunde, omvattende het hoofdvak fysische chemie, het bijvak theoretische natuurkunde en het bijvak organische chemie, werd afgelegd in april 1969.

Van juli 1966 tot april 1969 vervulde ik een student-assistent-schap bij de afdeling Fysische Chemie II van de Rijksuniversiteit te Leiden.

Van april 1969 tot augustus 1971 ben ik als wetenschappelijk werker verbonden geweest aan de groep Fysische Chemie van het Unilever Research Laboratorium te Vlaardingen.

Van augustus 1971 tot april 1979 ben ik in dienst geweest van de Landbouwhogeschool te Wageningen, afdeling Fysische en Kolloïdchemie, aanvankelijk als wetenschappelijk medewerker in tijdelijke dienst, sinds augustus 1975 als wetenschappelijk medewerker I in vaste dienst. Tijdens dit dienstverband werd, naast onderwijskundige en organisatorische werkzaamheden, het in dit proefschrift beschreven onderzoek verricht.

Van augustus 1977 tot augustus 1978 ben ik docent scheikunde bij de avondopleiding van de STOVA te Wageningen geweest.

Sinds april 1979 vervul ik de functie van adjunkt-directeur van de Laboratoriumschool Zeeland te Goes.
