1. INTRODUCTION

The Ministry of Agriculture of Mozambique is preparing a national agricultural development programme, specifically addressed to the family sector which represents about 90% of the rural population. A Pre-programme phase, which started in April 1993, is elaborating and testing methodological approaches in a few pilot districts. Successful methodologies are to be incorporated in the full-scale agricultural development programme. Land use planning is one of the main components of the Pre-programme. It is hosted by the Land and Water Department (DTA) of the National Institute for Agronomic Research (INIA).

The purpose of this study is to develop and test, in the district of Xai-Xai, a low cost participatory land resources appraisal methodology that provides an information base which may serve for land use planning as well as for farming systems research and extension.

The study shows that informal investigation techniques when used together with conventional land resources appraisal procedures, allow to understand farmers' land use strategy and to take into account their experience and aspirations. Indeed, in the conditions of subsistence agriculture, farmers' lives depend on delicate land use systems that must be well understood to avoid introducing disturbing innovations.

The field work and the reporting were done by A. Souirji, L. Amós, J. Mafalacusser and V. Lefebvre. The soil analyses were made by the staff of the laboratory section of DTA, while map production, including GIS operations, was done by the cartography and GIS section. The staff of the DPA of Xai-Xai have also made valuable contributions to this study.

This report is comprised of two volumes:

- Volume I, which is titled "Main Report", includes all the information that may be useful for readers who are not soil specialists.
- **Volume II** is titled "Typical pedons" and includes a collection of descriptions of representative soils of the district.

2. METHODOLOGY

2.1 Introduction

The methodology was developed after careful examination of the existing studies and methodologies, especially of their adequacy for the family sector. Farmers' knowledge and participation were given a particular importance.

2.2 Available information

2.2.1 Available soil information

When this study was started in April 1994, the most recent soil maps of the district were those published by DTA in 1992-1993. They are compilations at scale 1:250,000 and 1:50,000 of all the available information that could be found, complemented by minimal field investigations wherever the difficult war situation permitted. The maps legend and the accompanying report cover the Maputo province and a major part of the Gaza province.

These maps provide useful information, have the merit of covering a large part of the south of the country, and seem adequate for regional planning. However, due to the fact that they rely largely on existing data, their accuracy depends essentially on the quality and the geographical coverage of available soil maps. Therefore the following shortcomings for district level land use planning in the specific area of Xai-Xai were noted:

- about 3/4 of the district do not include any field observations
- the alluvial levees and terraces are not sufficiently accurately delineated in part of the plain
- the wetlands are grouped as one unit and no differentiation is made between peat soils and humic clays.
- the red earthy sands, locally called Giho, having a more favourable moisture regime than other sandy soils are not identified in the maps
- Vertisols, which are the dominant soils in the plain are not identified as such.
- the legend is not sufficiently detailed in term of slope in the sandy area, probably because of the very large area covered by the legend
- analytical data, which is necessary for land evaluation, is scarce.

We have also managed to assemble a collection of maps which were produced by Russian teams working for DINAGECA and the SEHA during the early eighties. They cover most of the alluvial plain at scale 1:25,000. They have the following shortcomings:

- except for 2 of the studies, no reports were found.
- texture analysis and classification are according to Russian standards e.g. clay is <1 micron and sand <1 mm, hence difficulty in correlation.
- the various maps and legends do not match. For instance some recognise Vertisols where other identify Fluvisols.
- some of the legends have missing symbols or are in Russian.
- some of the limits are unreliable.
- a small part of the plain and all the Serra are not covered.

However, these maps proved very useful, especially to get information for some swampy areas that we could not access. The differentiation between clayey and peaty wetlands is clearly indicated in these maps.

Also available were two soil studies done by consulting firms which cover smaller areas. One is the "Estudo de viabilidade e anteprojectos do complexo agroindustrial do Lumane" done by Geotecnica in 1981 in the northern part of the plain and part of the western Serra, between the road to Maputo and rio Lumane. The other is that of the "Projecto de Recuperacao do Machongo de Chongoene (Longue) em Xai-Xai", done by the consulting firm SANAQUA (1982), which concerns essentially the depression of Chongoene and its' surroundings.

It must be noted that none of the above-mentioned soil studies, which were not oriented toward the family sector, provides specific information about the local land management and soil classification system.

2.2.2 Available land evaluation information

The above mentioned soil maps published by DTA in 1992-1993, include land capability assessment for rainfed arable farming, grazing and forestry according to the USDA-SCS system, and for irrigation according to the USBR system. However, these systems do not take into account animal traction and hand tools-based agriculture which are practised in Mozambique. The same short-coming exists with all the other existing studies as they were all oriented towards commercial agriculture. The land evaluation systems available in DTA in April 1994 were:

- AEZ, which is not directly useable at 1:50,000, since little variation in climate occurs at that scale over the study area.
- A comprehensive set of ALES semi-quantitative models for individual crop suitability estimation. Attainable yields may be estimated, including under animal traction or hand tools-based agricultural systems for some crops. These models require further validation and refinement, as shown by some testing done earlier by DTA. Also, they cannot be used easily for the zonation of the district into management units as required for land use planning.
- ALES land capability model based on the USDA-SCS system, which as said earlier is not adapted to Mozambique.
- ALES land capability model for irrigated agriculture based on the USBR system.
- guidelines for land evaluation in the crystalline part of Mozambique (Voortman) which are partly and extension of the AEZ methodology. They do not apply to Xai-Xai area.

2.2.3 Available base documents

The following base documents were available:

- full coverage of topographic maps at scale 1:50,000 and 1:250,000.

- panchromatic aerial photographs at scale 1:40,000 of 1989 for the western and central part of the district and of 1958 for the eastern part.
- full coverage of panchromatic SPOT satellite imagery at scale 1:50,000 and false colour MSS LandSat imagery at scale 1:250,000.
- full coverage of geologic maps at scale 1:250,000.

2.3 Adopted methodology

2.3.1 Soil survey

Given the small-scale and scattering of individual plots, a soil map that would provide farm-level information, would have to be done at a fairly large scale, the cost of which would be prohibitive. Also, in small-scale agriculture, most development work is done at community level. Communities generally know well their natural resources and their location. Therefore, in this situation, mapping detail is of lesser importance. It was therefore felt that to gather global soil information on the districts and to produce a zonation into land management units (i.e. landscape units having similar productive potential and constraints), an exploratory¹ soil survey at scale 1:50,000 is sufficient.

The soil survey followed the morpho-pedological approach in order to speed-up the execution while ensuring a good technical standard. The photo-interpretation was done on the SPOT satellite imagery and on the aerial photographs. The excellent newly acquired SPOT panchromatic satellite imagery proved very useful as levee soils, which have a thin surface structural sandy crust show much better than on the aerial photographs used by earlier studies, thanks to the higher albedo. The ground truthing was carried out by transecting, during which 400 observations were described, out of which 46 were sampled (214 soil samples analyzed in the laboratory, and more than 200 soil salinity measurements were done in the field).

Twelve detailed farmers interviews and more than 50 shorter ones were done and permitted to elicit the local soil classification system which was included in the map legend, together with the FAO system. The American Soil Taxonomy classification is also given for individual typical profiles.

One set of soil maps was draughted and digitized, using the GIS software ILWIS, at scale 1:50,000. A generalized soil map was also compiled and published at scale 1:250.000.

2.3.2 Water survey

Given the importance of lakes in the study area, 23 of them were sampled and farmers' interviews were conducted to find out what each one of them is used for by the population. A well was also sampled in the Baixa of Banhine.

^{1.} Although scale 1:50,000 is normally a semi-detailed one, we use the term exploratory because of the low density of augerings and profiles, which is in the order of 1 per 400 ha.

2.3.3 Land evaluation

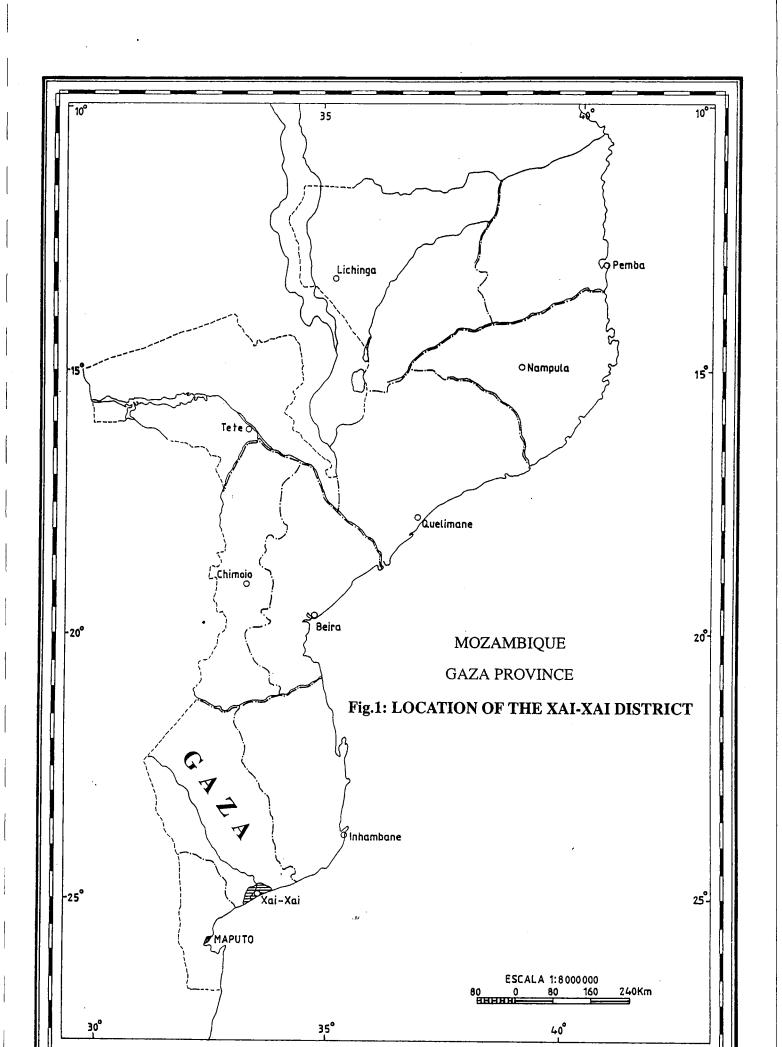

In the conditions of the family sector in Mozambique, farmers give priority to risk minimising and therefore potential crop yield estimation is not a high priority. Also, the refinement and validation of the existing land evaluation models would necessitate several years. However, the on-going development activities cannot await the conclusion of the validation process.

It was decided to build an ALES-based new land capability system which takes into account the conditions of the Mozambican family sector conditions and allows to produce a zonation of the district into management units having similar productive potential and constraints. The rules for these land capability procedures were elicited from farmers, observation of local crops behaviour and from available secondary information. Fourteen ALES models were built, 8 for the current situation and 6 for the potential one, i.e. after drainage and/or fertilization. The 14 resulting land evaluation maps were produced with ILWIS at scale 1:100,000. The global district zonation map was also produced with ILWIS at scale 1:100,000.

Farmers interviews were carried out in order to tap their knowledge and make them participate in the assessment of their land. These interviews yielded comprehensive information about the strategy of family sector small-scale farmers as well as farmer generated specific land evaluation information.

2.3.4 Dissemination of results

Besides the maps and the report, which are required to record and present soil information, practical training was organized for government and NGOs extensionists in order to enable them to recognize the main soil types of the district and to know their distribution, limitations and potential. For this purpose a 2 days seminar followed by 3 days field excursion was held in June 1995.

3. ENVIRONMENTAL SETTING

3.1. Location of the Study Area

The district of Xai-xai is located in the south of the province of Gaza of which the city of Xai-Xai is the capital. It is roughly located between longitudes 33° 19' and 33° 45' east and latitudes 24° 48' and 25° 12' south.

3.2 Physiography and Geology

The study area extends over two major landforms which are the alluvial flood plain (known as **Vale**) of the Limpopo river and its' tributaries, and the surrounding sandy high plain (known as **Serra**), of mostly aeolian origin. The contact between the two landforms consists generally of quite steep slopes, though more gradual transitions do exist in certain locations, e.g. at aldeia Emilia Dausse. Both the Vale and the Serra include a variety of landscapes associated with specific local conditions.

3.2.1 The alluvial plain

The alluvial plain is relatively flat and its' altitude decreases from about 14 m a.m.s.l., at the level of aldeia Julius Nyerere, to 0 when the limpopo reaches the Indian ocean. The plain includes typical features associated with coastal flood plains i.e. abandoned meanders, alluvial levees, point bars, backswamps and mangroves. The presence of peaty areas is associated with permanent high water table due to water seepage from the sandy plain.

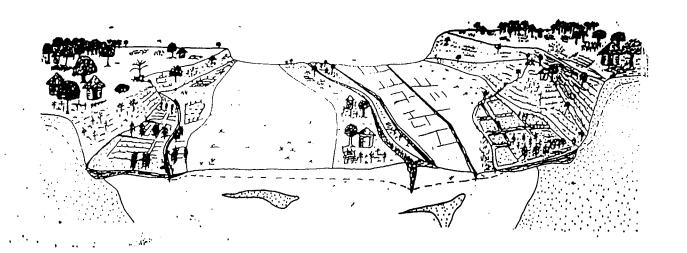

Abandoned meanders are found in various parts of the alluvial plain but they are more frequent at the level of aldeia Julius Nyerere, where the valley is narrower. They are associated with rapid changes in the course of the Limpopo during major floods, resulting in an irregular topography with an alternation of depressions and higher levees. Lakes formed in the largest abandoned meanders.

The levees are higher well drained alluvial lands, generally located on the outer bank at river bends, along active rivers and abandoned meanders. Point bars complexes are often found on the inner bank of river bends. The alluvium which constitutes the levees is of somewhat coarser texture than the rest of the alluvial plain.

The flood plain and the back-swamps are lower more poorly-drained and flat clayey areas situated behind the levees. Unless they are artificially drained, water stagnates in the back-swamps for protracted periods.

The more or less peaty areas, called **machongos** by the farmers, are found in areas of water seepage, at the foot-slopes of the scarps which form the transition between the serra and the valley. They may be at a lower, or higher, altitude than the levees depending on the slope of the sandy terrain. The machongos sometimes extend as narrow veins within the back-swamps.

Figure 2 Typical Landscape in the Study Area

Mangroves are densely vegetated swampy areas, influenced by sea-water during high tides. They are extremely saline.

After the 1:250,000 scale geological map of the region (sheets SUL-G-36/D and SUL-G-36/J), all the alluvial plain belongs to unit QAI, which corresponds to the recent quaternary period. Clays are the dominant deposits but lenses of sand occur frequently.

3.2.2 The serra

The serra can be divided in several landscapes according to the orientation of sand dunes, topography, presence of lakes and degree of mobility of sand formations.

Along the coast there is a narrow strip, less than 3 km wide, of relatively active sand dunes having a strongly undulated relief. They belong to the recent quaternary (QDc geological unit)

Following the active coastal sand dunes there is another inner strip of high and strongly undulated dunes, oriented perpendicular to the seashore, interspersed with sweet water lakes, some of them covering areas of several hundreds hectares.

More inland, in the south-western part of the serra (localidade of Zongoene), the dunes are oriented perpendicular to the sea and alternate with poorly drained elongated depressions.

The north-western part of the serra, between rio Lumane and rio Munhuana (localidades of Chirrindzene, Chicumbane, Novunguene and Muzingane), has a relatively flat or gently undulating relief and lower altitudes than the rest of the serra lands, generally between 30 and 60 m a.m.s.l.

The rest of the serra has an undulated topography and altitudes generally between 60 and 130 m a.m.s.l, except for the localidades of Banhine and Nhacutse which have a mixture of flat and undulated relief.

After the geological maps, apart from the coastal dunes, all the serra sands are of Pleistocene age (QDi unit). Aeolian sands are the dominant deposits.

3.3 Climate

3.3.1 Introduction

According to Köppen's classification, the climate of the district of Xai-Xai is subtropical (type **Aw**) with one wet season, during the hottest months, from October through April, and a drier season during the coolest months, from May through September. During the hot season, the study area is mostly influenced by continental tropical depressions coming from the southwest bringing heavy rains, while during the cool season, the Atlantic and Indian oceans anticyclones determine a dry climate.

Rainfall data is available for four weather stations which are Chilaulene, Chongoene, Maniquenique² and Xai-Xai. It must be noted that the data series vary in length, therefore comparisons between stations must be considered with some caution.

² The station of Maniquenique is located a few hundreds meters outside the extreme northern corner of the district.

Table 1 Coordinates of the Weather Stations

Name of station	Latitude (S)	Longitude (E)	Altitude (m)
Chilaulene (*)	25° 09'	33° 63	3
Xai-Xai (**)	25° 03	33° 38'	4

(*) Source: DNA

(**) Source: INAM (in the SUIVI climatic database at DTA)

(***) Source: (FAO/MOZ/75/011; 1981)

3.3.2 Precipitation

As shown in table 2, the average annual rainfall ranges roughly between 850 and 1150 mm. Table 2 and figure 4 show that rainfall decreases in quantity from the littoral towards the interior and from the high sandy plain down to the valley. The minimum observed annual rainfall is in the order of 350 mm and the maximum varies between about 1400 and 1900 mm. Dependable³ annual rainfall is everywhere higher than 700 mm.

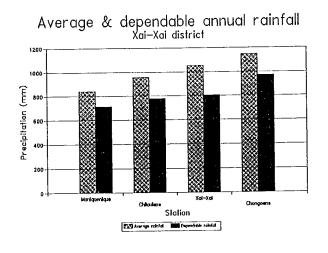

The precipitation in the district of Xai-Xai is characterized by a high irregularity (see figure 5). The coefficient of variation ranges from 22 to 33 percent for annual rainfall and from 60 to 140 percent for monthly rainfall (see tables 2, 3 and 4). Most of the rainfall occurs during the hot season, mainly from November to April, with the peak being in January/February. August and September are the driest months in all four weather stations.

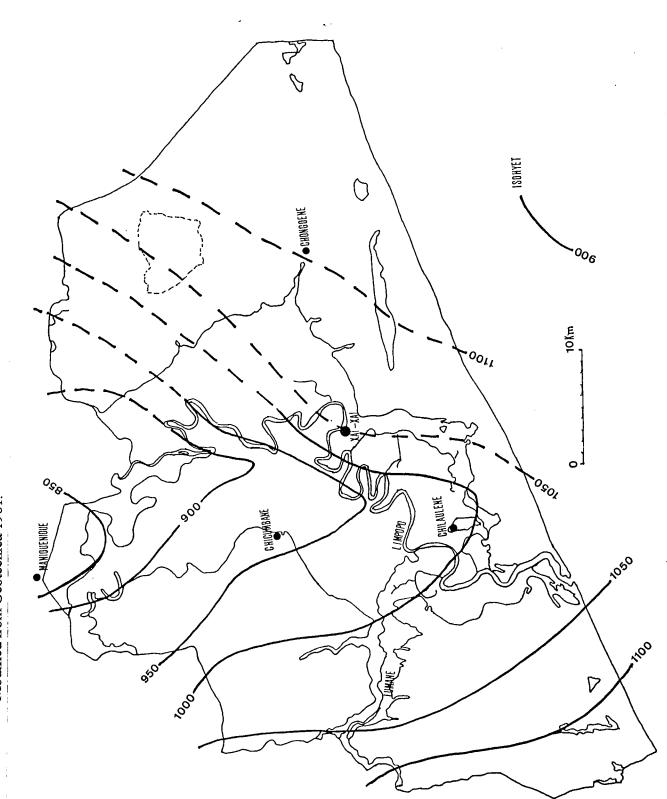

³ Rainfall that is attained or exceeded 3 years out of 4.

Table 2 Annual Rainfall and Dependable Rainfall

Station	Number of years		Rainfall (mm)								
		Average	Coefficient of variation (%)	Minimum	Maximum	Dependable

3.3.3 Temperature

Data is available for Chongoene, Xai-Xai and Maniquenique. Table 5 shows that:

- monthly average temperatures range from 18 to 27°C
- monthly maximum temperatures range from 24 to 34°C
- monthly minimum temperatures range from 11 to 22°C
- monthly thermic amplitude range from 9 to 15°C

December, January and February are the hottest months while June, July and August are the coolest. Maniquenique is hotter than Xai-Xai and Chongoene, due to its longer distance from the littoral. The thermic amplitude is bigger during the cool season in all station and is also bigger inland (maniquenique) than nearer to the coast.

3.3.4 Wind speed

Wind speed data is only available for Chongoene, Xai-Xai and Maniquenique. It appears from table 6 that wind speed is mostly controlled by the distance to from the littoral. Chongoene and Xai-Xai, which are at about the same distance from the ocean have nearly exactly the same wind speed pattern and intensities. Maniquenique which is the most inland station has much lower wind speeds, though the difference is clearly marked only from August to February. In all stations the windiest months are August/September through February, with the peak being in November/December.

Table 6 Average Wind Speed Source: FAO/MOZ/75/011; 1981

Station	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Year
Chongoene	2.2	2.3	2.3	2.0	1.9	1.6	1.4	1.2	1.2	1.4	1.7	2.1	1.8
Xai-Xai	2.2	2.3	2.2	2.0	1.9	1.6	1.4	1.2	1.2	1.4	1.7	2.1	1.8
Maniquenique	1.5	1.7	1.8	1.5	1.5	1.3	1.4	1.1	1.1	1.3	1.3	1.6	1.4

3.3.5 Relative air humidity

Relative air humidity data is only available for Chongoene, Xai-Xai and Maniquenique. Table 7 shows that the relative air humidity varies between 65 and 85% in all three stations. Chongoene is the most humid, followed by Maniquenique and Xai-Xai. The fact that the Limpopo river is very close to Maniquenique may be the reason why the latter is more humid than Xai-Xai although it is located farther from the ocean.

During the cool season, from April to September, the wind blows mostly from the sea and dew forms early in the morning, hence the cool season is more humid that the hot season. June and July are the most humid months while October and November are the driest.

Table 7 Average Relative Air Humidity Source: FAO/MOZ/75/011; 1981

Station	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Year
Chongoene	74	74	76	77	76	78	79	81	84	84	80	75	78
Xai-Xai	65	65	67	68	70	72	74	78	81	80	74	68	72
Maniquenique	70	69	71	71	73	73	76	78	81	80	77	71	74

3.3.6 Bright sunshine hours

Data is available⁴ only for Xai-Xai and Maniquenique. Hours of bright sunshine are in the range of 50 to 70% for Xai-Xai and 60 to 80% for Maniquenique. As can be expected, the cool season, from May through September, is more sunny than the hot season during which cloudiness is more frequent. Xai-Xai being closer to the ocean and having a higher rainfall, has less sunshine than Maniquenique.

Table 8 Average Hours of Bright Sunshine (in percent) Source: FAO/MOZ/75/011; 1981

Station	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Year
Xai-Xai	52	50	51	51	52	56	57	67	62	64	63	59	57
Maniquenique	63	61	61	70	64	60	65	78	72	71	68	72	67

Note: The hours of bright sunshine are expressed as a percentage of maximum possible sunshine hours.

3.3.7 Evapotranspiration

The evapotranspiration (ETP) was calculated, for the stations of Xai-Xai and Maniquenique, with CROPWAT, the specialized software developed by the FAO, using the climatic data stored in CLIMWAT. CROPWAT uses the new modification of the Penman formula proposed by Monteith.

Table 9 shows that for both stations the annual ETP is in the range of 1400 to 1450 mm and that the monthly ETP is highest in December/January and lowest in June July. Though ETP is only slightly higher in Maniquenique than in Xai-Xai, the moisture deficit is clearly bigger in the former. In Maniquenique, rainfall never exceeds the ETP on a monthly basis, but it does in Xai-Xai in February and May.

It should also be noted that in Xai-Xai, rainfall exceeds ETP during the period from February to June (P=534 mm; ETP=515 mm). This means that the cool season crops sown in April-May will generally have adequate moisture supply from the soils. We have indeed noticed during the soil survey that all the sandy soils of the district were moist at depth throughout the cool season. On the contrary, hot season crops sown in october to November find a soil with depleted from its deep water reserves, hence the impact of a drought is more damaging during the hot season than the cool one.

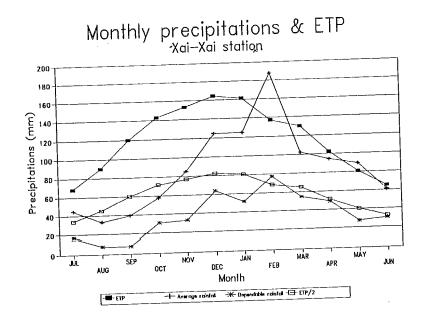

⁴ Project FAO/MOZ/75/011 (1981) did mention sunshine data for Chongoene but actually these were those of Xai-Xai which were used because of the similarity of location.

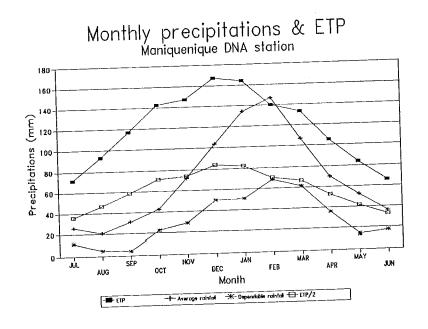

Table 9 Evapotranspiration in Xai-Xai and Maniquenique

Figure 6 Evapotranspiration and Rainfall in Xai-Xai and Maniquenique

3.3.8 Length of growing period

The AEZ project, implemented by the FAO and INIA's department of land and water during the early 1980's, has calculated the growing periods for numerous stations throughout Mozambique including Chongoene, Xai-Xai and Maniquenique for which the results are shown in table 10 (FAO/MOZ/75/011; 1981). It appears that as for precipitation, the total length of growing period decreases from the littoral towards the interior and from the serra to the valley:

- Chongoene: On the average, there is at least one growing period of 170-318 days, followed by another one of 70 to 80 days, the occurrence of a third growing period of about 65 days has a probability of only 18 percent.
- Xai-Xai: On the average, there is at least one growing period of 127-307 days, followed by another one of 73 to 85 days, the occurrence of a third growing period of about 49 days has a probability of only 26 percent.
- **Maniquenique**: On the average, there is a 95 probability of having at least one growing period of 118-245 days, followed by another one of 46 to 65 days, the occurrence of a third growing period of about 58 days has a probability of only 19 percent.

A fourth growing period was very rarely observed at Xai-Xai and Maniquenique. Whatever the number of lengths of growing periods, two cropping seasons, the first of at least 185 days and the second of at least 70 days, are always possible at Chongoene and Xai-Xai.

The average starting date of the first growing period is usually October for Xai-Xai (the range is August-January) and November for Chongoene (the range is September-January) and Maniquenique (the range is October-January). The second growing period usually starts between March and June at Chongoene, February and June at Xai-Xai and April and June at Maniquenique.

It must be kept in mind that the calculated lengths of growing period are only rough estimates of the potential of the climate to supply moisture for plant growth. A number of simplistic assumptions are made in the AEZ methodology such as considering that rainfall infiltrates entirely and that the soils have all the same water holding capacity of 100 mm. These assumptions are necessary at very small scale (1:1,000,000 or smaller) but lead to erroneous results at more detailed levels. Indeed many Vertisols in the alluvial plain of Xai-Xai have a water holding capacity of more than 200 mm and receive runoff from the surrounding Serra's sandy soils which hardly reach 100 mm of water storage capacity.

Table 10 Length and frequency of growing periods Source: FAO/MOZ/75/011; 1981

Number of growing periods	Chongo	ene	Xai-Xa	i	Maniquenique			
	LGP (days)	Frequency	LGP (days)	Frequency	LGP (days)	Frequency		
1 Growing period	318 (12)	36	307 (9)	26	245 (11)	15

Length 1			51		75			
Length 2]	133		39			
Length 3			6		58			
Length 4			75		39			

LGP = length of growing period

⁽⁾ coefficient of variation in percent.

^{(*) 4} growing periods occurred only once in Xai-Xai and Maniquenique during the period of observation, therefore no coefficient of variation is given.

3.4 Water resources

3.4.1 Surface hydrology

3.4.1.1 Rivers and streams

The Limpopo is the main permanent watercourse in the district of Xai-Xai. Its' watershed covers about 412,000 km², and extends over the Republic of South Africa, Zimbabwe, Botswana and Mozambique. Its' main tributaries in the district of Xai-Xai are Rio Chégua, R. Umbapi and R. Ingluxane on the left bank, and R. Munhuana, R. Lumane and R. Chaiane on the right bank.

The water discharge of the Limpopo varies between 8 and 7800 m³/s. Big floods occur periodically however the city of Xai-Xai and part of the left bank are protected by man-made dikes. The water of the Limpopo in most of its' course in the study area is brackish during high tides when the river's water discharge is too low to counter the seawater influx.

R. Lumane has a permanent water discharge of 3 to 25 m³/s. It has good quality except in its lower course where it is influenced by saline tide water. R. Chégua has also a permanent discharge of good quality water.

3.4.1.2 Lakes

Due to the high permeability and thickness of the aeolian sand deposits, to the presence of underlying impervious deposits, and to the relatively high rainfall in the area, sizeable aquifers occur in the serra. These aquifers surface in numerous lakes and springs as well as in the machongos. Lakes also occur in abandoned meanders in the Limpopo's valley. The largest permanent lakes in the district are the Lagoa Pave, L. Ualute and L. Sauce.

A campaign of sampling of lakes and depressions and interviews about their uses, was carried out during the last week of February 1995. The results are shown in tables 11 and 12. The water analyses results should be considered with care because their chemical characteristics are likely to fluctuate with the precipitation and evaporation regimes, especially for small lakes. The water of lakes Muzingane and Vumbe near the aldeia Julius Nyéréré, which are influenced by saline mananga deposits, are known to experience periods of high salinity. We have once measured and EC of 4.7 dS/m in lake Muzingane. However the data give a good idea of the chemical composition of the lakes of the Serra.

Except lake Sane, near Nhabanga village, all lakes have water that is suitable for human and cattle drinking, washing, irrigation and pisciculture. Lake Sane's water may only be used for cattle drinking and pisciculture. The interviews have shown that lakes are a vital source of water for domestic utilisation (drinking, cooking, washing etc.), for small-scale irrigation, and a source of fish.

Utilization of lakes and depressions Source: farmers' interviews Table 11

Geomorphic unit	Name	Water Regime			Uses	Remarks		
			Drink human	Drink animal	Wash.	Irrig.	Fish.

EC= electrical conductivity, SAR= sodium absorption ratio
(*) This is a large dry baixa. The water sample was taken from a shallow well.

Lakes are also refuges for wild animals such as birds. Drinking water is usually taken from shallow dug wells located on the margins of lakes and wet depressions.

3.4.2 Groundwater

There are two types of aquifers in the study area, those of the fluvio-marine sediments of the Limpopo's valley and those of the eolian sand dunes formations.

The aquifers of the valley are shallow, mostly between 0.2 and 1.5 m, but may reach 5 m in some of the alluvial levees and in the north of the plain. These aquifers are recharged by rainwater, floods and water seepage from the surrounding high sandy plain. Water is saline and contains up to 30 g/l of mostly sodium chloride.

The aquifers of the eolian sand formations are sweet and contain less than 1 g/l. They are recharged by the infiltration of atmospheric precipitation.

4. THE SOILS OF THE STUDY AREA

4.1 Soil formation

Due to the highly pervious nature of the aolian sands and to the relatively high rainfall, there is active clay illuviation in upland Serra soils which show prominent deep lamellae of clay and sesquioxides, generally at a depth of 130 to 200 cm.

Rubefaction is also widespread among Serra sands, but seems to be associated with the oldest deposits. On footslopes and margins of depressions there are generally grayish to whitish sandy soils, due to deep leaching of sesquioxides.

In the valley soil formation is controlled by the moisture regime and the geomorphic position. Stratified young alluvial soils form on the well drained alluvial levees and terraces, while swelling montmorillonitic clays form in the flood plains and backswamps, hence the wide occurrence of Vertisols. Gleyification due to water stagnation and high watertables is also wide spread.

In areas not reached by the Limpopo's flood waters and where there is a high watertable, peat soils through the accumulation of organic material which cannot decompose in anaerobic. Hydromorphic and relatively organic soils of the lower course of the Limpopo often show some jarosite mottles.

4.2 Soil classification

4.2.1 Scientific soil classification

The soils were classified according to the FAO legend (FAO, 1990; 1993) and to Soil Taxonomy (Soil Survey Staff, 1994). The reader is referred to the literature for details on these classification systems.

4.2.2 Farmers' soil classification

The interviews showed that the farmers of the area have a well defined soil classification system. The most important diagnostic criteria are the moisture regime, topsoil texture and topsoil colour. The following soils are identified by the farmers:

- <u>Bila (Bilene)</u>: Cracking compact clayey valley soils, black to brownish. Remain wet and sticky after a rainy episode for at least a week, if there is no stagnation of water. After a rainy episode, it takes about a week before they are dry enough to allow ploughing and remain ploughable only about 2-3 weeks before becoming too hard. They have a good water holding capacity and a good fertility.
- <u>Giho</u>: Red (dark reddish brown or brown topsoil and reddish brown to dark red subsoil) earthy sandy soils which has a better moisture retention than other upland sandy soils of the Serra. Farmers describe Giho as follows: "When you sit on Giho and rise your clothes get the soils' colour". "During the hot season, cars driving on Giho provoke such a red dust that the face of a person can change (of colour)".
- <u>Mananga (Manangene)</u>: Fine textured Soils that contain sand in the topsoil (sandy clay loam to loamy sand) above finer (marine?) material, generally clay loam or sandy clay. They are typically covered with scattered large termites mounds that contain saline material brought up from the substratum. These soils are only extensive on a high terrace in the northwest of the district. They are associated with large patches of Bila soils to which they intergrade in depressions. They can be ploughed during or shortly after rainy episodes, and have a saline water table at about 3 meters depth. Most tall tree species remain stunted.

There is also a small area of Mananga soils in the Serra north of the aldeia Agostinho Neto. They have a sandy or loamy sand topsoil above finer material, generally sandy clay loam. They are also typically covered with scattered large termites mounds that contain saline material brought from the substratum.

- <u>N'Tlava (N'Tlavene</u>): Other upland sandy soils having low moisture retention. N'Tlavene is also used in Shangana to refer globally to land outside urban areas ("the country side").
- <u>N'Tlangua (N'Tlangoene)</u>: Blackish to brownish soil, relatively organic and of sandy clay loam to sandy loam texture in the topsoil, with often a sandy subsoil. Very similar to XiN'Tlavane but occur in narrow drainage ways inside the serra instead of at the footslopes of the scarps. The water table is within 150 cm but stagnation is only occasional. This name is mostly used in the localidade de Chilaulene and is not well known in other areas.
- Puwa (Upwene): Yellowish to whitish loose sandy soil of coastal shifting dunes.
- <u>T'Lavate (T'Lavatene)</u>: Somewhat droughty medium-textured soil with surface crusting and segregation of whitish fine sand which occurs on the alluvial levees and high terraces. Dries out quickly after rainy episodes and water does not stagnate. It can be ploughed moist.

In the Serra the name T'Lavate is used for whitish washed sand in the margins of lakes and depressions. Relatively similar to Xixefo from which it differs by somewhat whiter colour and the nearby presence of water. The name T'Lavate is not used consistently in the Serra and sometimes the farmers use it as synonymous with XiN'TLavane or N'Tlangoene which are rather earthy sands. The T'Lavate usually has a water table at relatively shallow depth (1 to 5 m).

- <u>T'Sovo</u>: Black generally peaty or mucky soils, which contain some clay, that have a permanent water table (seepage from the serra) within rooting depth, and that suffer from stagnation for protracted periods. The subsoil maybe peat, sand or clay. Animal traction cannot normally be used for ploughing because the animals sink, unless the organic layer is thin or the soil dries out thoroughly, which happens very rarely. The word <u>T'Sogoene</u> is sometimes used to designate T'Sovo but it actually means swampy area (physiographic unit), where T'Sovo soils occur.
- Xiboa, T'Seve-T'Seve, Xitseve, Ximucunhe (synonims): Peat soils with permanently stagnating seepage water. The difference with T'Sovo is not always made by the farmers.
- <u>Ximunhuanine</u> (syn. Xivumbane). From the Shangana word munhu meaning salt. Saline, generally clayey, soils where crops do not grow. Often with temporary salt crusts.
- XiN'TLavane (XiN'Tlavanene): Transition soil between the N'Tlava of the footslopes of the Serra and the T'Sovo of the adjoining wetlands. The topsoil is a grayish to brownish mixture of sand with black earthy and organic material of the wet depressions. The water table is usually within 150 cm but there is no stagnation.
- Xiruka: Actually this term is used for finer-textured subsoil layers which are rich enough in fines that they can be used as plaster (kutsula in Shangana). It is also sometimes used to designate a brownish to reddish brown sandy soil wich has loamy sand to (rarely) sandy loam layers in the subsoil. It is normally less red than Giho.
- <u>Xixefo</u>: Grayish sandy soils of dry depressions and toeslopes. This term is mostly used near Banhine. Little or not used in other areas.

4.3 Soil map units description

The soil map units components descriptions were generated with the ALES software in a tabular and coded form. The legend of the codes is shown in table 13, part 1 and 2. Tables 14 Parts 1,2 and 3 show the coded map units descriptions, while tables 15 and 16 give the aereal coverage of each map unit, respectively in hectares and in percent. Table 17 (parts 1,2,3,4,5,6,7 and 8) show the legend of the soil map. Map units which have a component that makes 80 percent or more are considered nearly pure and the inclusions are not mentioned.

                                                                                                                                                                     EL (Extremely low) [0-3 meq/100g]
VL (Very low) [3-6 meq/100g]
I. (Low) [6-10 meq/100g]
M (Moderate) [10-20 meq/100g]
H (High) [20-500 meq/100g]
 Vl (Very low) [0-2 percent]
L (Low) [2-5 percent]
M (Moderate) [5-15 percent]
H (High) [15-40 percent]
VH (Very high) [40-80 percent]
EH (Extremely high) [80-100 percent]
                                                                                                                                                                      Exchangeable sodium percentage of topsoil
                                                                                                                                                                     N (Non sodic) [0-6 percent]
SL (Slightly sodic) [6-15 percent]
M (Moderately sodic) [15-30 percent]
S (Strongly sodic) [30-50 percent]
VS (Very strongly sodic) [50-70 percent]
E (Extremely sodic) [70-100 percent]
  Topsoil salinity
 N (Non ) [0-2 ds/m]
SL (Slightly) [2-4 ds/m]
M (Moderately) [4-8 ds/m]
S (Strongly) [8-16 ds/m]
VS (Very strongly) [16-32 ds/m]
E (Extremely) [32-500 ds/m]
                                                                                                                                                                      Exchangeable sodium percentage of subsoil
                                                                                                                                                                     N (Non sodic) [0-6 percent]
SL (Slightly sodic) [6-15 percent]
M (Moderately sodic) [15-30 percent]
S (Strongly sodic) [30-50 percent]
VS (Very strongly sodic) [50-70 percent]
E (Extremely sodic) [70-100 percent]
   Subsoil salinity
  N (Non or slightly) [0-4 dS/m]
SL (Slightly) [4-8 dS/m]
M (Moderately) [8-16 dS/m]
S (Strongly) [16-32 dS/m]
VS (Very strongly) [32-64 dS/m]
E (Extremely) [64-500 dS/m]
                                                                                                                                                                       Vegetation cover density
   pH of topsoil
                                                                                                                                                                       H (High)
M (Medium)
L (Low)
  ULTAC (Ultra acid) [0-3.4 units]
EXTAC (Extremely acid) [3.4-4.4 units]
VSTAC (Very strongly acid) [4.4-5 units]
STRAC (Strongly acid) [5-5.5 units]
MODAC (Moderately acid) [5-5.5 units]
SLIAC (Slightly acid) [6-6.5 units]
NEUTR (Neutral) [6.5-7.3 units]
MILAC (Mildly alkaline) [7.3-7.8 units]
MOALK (Moderately alkaline) [7.8-8.4 units]
STALK (Strongly alkaline) [8.4-9 units]
VSALK (Very strongly alkaline) [9-14 units]
```

5. LAND EVALUATION

5.1 Introduction

We have used simultaneously formal land evaluation methods and indigenous knowledge.

5.2 Formal land suitability evaluation

5.2.1 Methodology

The objective in this case is to identify the land suitability for broad land use types. We have built 14 different computer (ALES) models to determine the suitability for the following land utilization types:

- mechanized (surface) irrigation farming (current and potential)
- mechanized irrigated rice production (current and potential)
- mechanized rainfed farming (current and potential)
- animal traction-based rainfed farming (current and potential)
- hand tools-based rainfed farming (current and potential)
- traditional wetland farming (current and potential)
- extensive grazing (only current)
- forestry (only current)

The ALES programme was used to build expert systems (the above mentioned models) which consist of decision trees based on rules elicited from farmers, from the observation of local crops behaviour and from available secondary information. The models together constitute a land capability system.

The ALES land evaluation computer software follows the FAO Framework for Land Evaluation (FAO, 1976) which defines the following suitability categories:

- suitability orders reflecting kinds of suitability, namely S which is suitable, and N which is unsuitable.
- suitability classes, reflecting degree of suitability within orders. Usually but not necessarily 4 which are S1, S2, S3 and N^5 .
- suitability subclasses reflecting kinds of limitation, or main kinds of improvement measures required, within classes. For example in S2d, d means require drainage.
- land suitability units reflecting minor differences in required management within subclasses (not used in Xai-Xai).

In order to determine the land suitability for a particular LUT, we first computed the suitability rating of each land quality, then combined the ratings of all the relevant land qualities, using the maximum limitation method. For details, the reader is invited to consult the models which are available in digital form in DTA.

⁵ Here we do not distinguish between N1 and N2 as no economic evaluation is contemplated, at this stage

5.2.2 Results

Table 18 (parts 1 and 2) shows the suitability evaluation for the current situation whereas table 19 (parts 1 and 2) shows the suitability after drainage and fertilization, wherever relevant.

5.3 Farmers generated land suitability evaluation

5.3.1 Methodology

Semi-structured interviews and ranking techniques were used to elicit farmers knowledge. We asked farmers to rank the soils of their area according to their productivity for various local crops.

Land suitability as predicted by farmers is extremely valuable because it is the result of the accumulated experience of many generations. However, it covers only locally known crops, grown with the techniques that are locally known. Therefore it must be seen as a complement to conventional land evaluation techniques. It can also be used to fine-tune conventional land evaluation expert systems.

5.3.2 Results

Table 20 shows farmers generated land suitability evaluation for the main local crops. Table 21 (parts 1, 2 and 3) shows the detailed suitability rating in each individual interview, by type of crops and by season.

5.4 Crop selection

5.4.1 Methodology

In order to recommend crops that may be grown in the area, we have used FAO's **ECOCOCROP1** computer crop database. ECOCROP1 gives climatic and soil requirements as well as potential uses for 1200 plants, including crops, fruit trees, forage species, timber and fuelwood tree species etc. Once the programme user enters land information, a list of suitable crops is automatically generated upon request. We have also used various crop monographs which include information on crop land requirements.

5.4.2 Results

Table 23 (part 1, 2, 3 and 4) give the list of selected crops for each soil grouping, as defined in table 22. Table 23 gives in sequence: the scientific name, the common english name, type of crop (I= industrial crop; f= food crop; g= grass; t= tree), presence of the plant in Mozambique indicated by M, comments, references and soil groupings in which the plant would normally grow.

Table 25 (part 1,2 and 3) shows the uses that can be made of each plant. The legend of uses is given in table 24.

Table 22 Soil Groupings for Crop Selection

Grouping number	Definition	Map unit components
	Soils of the Serra	
1	Somewhat excessively to excessively drained sandy soils	DEC3; DEC4; DEC5; DEC7; DUI1; DUI2; DUI3; DUI4; DUI7; DUI8; DUI9; DUI10; DUI11; DUI12; DEM; DES; PLA-1; TEA1
2	Imperfectly drained sandy soils having a high water table	DEC2; DEH1-2; PLA-2; TEA2; VAL1-2, VAL2-3
3	Seasonally waterlogged humic sandy soils	DEH1-1; VAL1-1
4	Very erodible sandy soils	DUC4; DUC5; DUC6; DUI5; DUI6
5	Extremely erodible sandy soils	DEC6; DUC1; DUC2; DUC3; DUC7
	Soils of the Valley	1
6	Well drained medium to fine textured soils	COM1; COM2-1; COM4; TE2 (*)
7	Medium to fine textured soils of seasonnally flooded wetlands	BAD4; BAD5; BAD6; DEC1; PLI8-1; PLI9; RIS2; VAL2-2
8	Wetland peat soils (after drainage)	MAC1; MAC2; MAC3-1; VAL2-1
9	Moderately well drained, not or slightly saline medium and fine textured soils	COM2-2; COM3; PBC1-1; PBC2-1; PBC3-1; PLI1; PLI2; PLI3; PLI4; PLI12; TE1; TE3; TEM (**)
10	Imperfectly drained, not or slightly saline medium and fine textured soils	PBC4-1; PLA-2; PLI5; PLI8-2; PLI10-1; RIS1; TE4; TE5
11	Imperfectly to poorly drained, moderately saline fine textured soils	BAD7; BAD8; BAD9-1; BAD10; PBC1-2; PBC2-2; PLI6; PLI10-2; TE6
12	Imperfectly to poorly drained, very saline fine textured soils	BAD9-2; PLI7; PLI11; TE7
13	Very poorly drained moderately to strongly saline fine textured soils	BAD3; MAC3-2 (both drainable); BAD1; BAD2; PBC3-2; PBC4-2; TE8 (not drainable)
14	Mangrove soils periodically flooded by seawater	MAN

^(*) TE2 is included in this grouping because it is located in high alluvial terraces, has a coarse textured topsoil and the internal drainage limitation is only due to textural discontinuity.

^(**) TEM is included although it differs in having a moderate exchangeable sodium percentage.

6. LAND MANAGEMENT

In the following sections we will examine first the main physical limitations to agriculture, see what farmers do about them and then see what else can be done to improve agriculture production. The last section describes each land management unit and gives specific recommendations for them.

6.1 Main soil and climate limitations to crop production

We have identified the following major soil aspects that are limiting crop production:

- inadequate soil moisture regime
- low soil fertility
- high soil salinity and sodicity
- low soil workability
- active soil erosion

6.1.1 Soil moisture regime

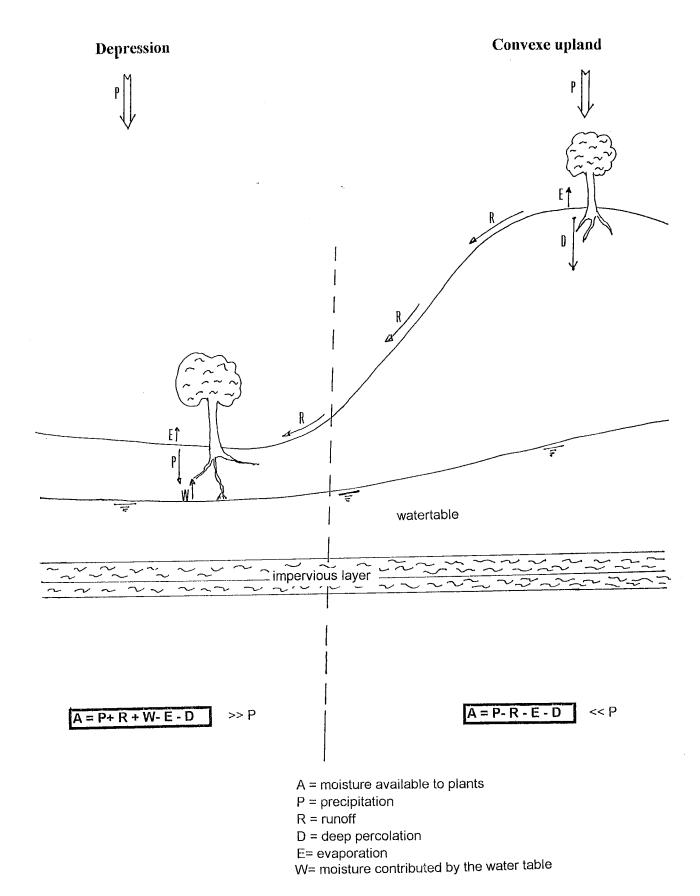

The availability of moisture to plants is the most important factor controlling their growth. Although some plants can make use of atmospheric moisture, most of the water consumed by plants is usually provided by the soil. Figure 7 gives a schematic representation of the soil water balance in the study area.

The water supply of upland soils is only comprised of the atmospheric precipitation <u>minus</u> the water that runs off, evaporates and percolates deeply. The water supply of lowland soils, and of those of concave slopes, is comprised of the atmospheric precipitation <u>plus</u> the water that runs off the uplands <u>minus</u> water lost through evaporation and deep percolation. This means that lowland soils not only do not loose water through runoff, but also that they gain the runoff water lost by the uplands. When a water table occurs at shallow depth, as is the case in the machongos, it further increases the water supply of lowland soils.

It is clear from the above that there is a tendency for upland soils to be droughty and for those of the lowlands to be too wet. However, the soil's permeability, slope and water holding capacity may improve or worsen it's moisture regime. A high permeability or a steep slope decrease the water supply, whereas a low water holding capacity reduces the moisture storage.

In the Serra uplands, sandy soils having a high permeability and low water holding capacity, dominate. They are droughty and only have an adequate moisture regime during the rare years when there is a good rainfall distribution over the growing period.

In the valley, fine-textured slowly-permeable soils having a high water holding capacity, and often a shallow water table, are dominant. These soils are excessively wet during rainy years, but have adequate moisture during normal and moderately dry years. Among the soils of the valley those of the alluvial levees are better drained and generally have a good moisture regime, but may be droughty during moderately dry years.

The high seasonal and interannual variability of the atmospheric precipitation further aggravates the negative impact of the above mentioned soils' characteristics on the moisture supply to plants.

6.1.2 Soil fertility

The fertility problem exists mostly in the Serra and in the machongos.

The sandy soils of the Serra have a low reserve of weatherable minerals which are usually the main source of calcium, magnesium and potassium. They also have a low organic matter content and a low nutrients retention capacity. Their high permeability allows the rain water to percolate and leach nutrients below the rootzone. The natural low fertility of the Serra is further aggravated by the short duration of the fallow, or often even its' absence, and by the cultivation of maize repeatedly, season after season for several years. Maize is a crop which is known for rapidly depleting the soil's nutrients.

The organic soils of the Machongos are very acid (pH of 4.2-5.5), therefore the exchange complex is mostly saturated by H⁺ and Al⁺⁺⁺, hence little calcium and potassium is held in the exchange sites. The exchangeable aluminum is also toxic for many crops and causes empty panicles in rice. The subsistence farmers of the area do not use chemical fertilisers, and only manure is sometimes used for vegetables or maize in the wetlands.

6.1.3 Soil salinity and sodicity

Salinity affects to various levels most valley soils with the exception of those of the levees and high terraces. This situation is due to the following reasons:

- the influence of the ocean which floods regularly the mangroves, invades the lower course of the Limpopo and its' lower tributaries such as the rio Lumane, and infiltrates its' saline waters into the water table of much of the plain which has altitudes that are mostly less than 2 m.
- the occurrence of saline and sodic parent material, namely the Mananga deposits, where sodicity induces strong soil dispersion and the formation of thick structural crusts that reduce germination.
- irrigation with brackish water pumped from rivers during high tides at a time when their discharge is low.

6.1.4 Soil workability

Most valley soils are Vertisols which are heavy swelling clays. When these soils are dry they are very hard and compact, hence difficult to work by hand tools and even with animal traction. During rainy periods they quickly become too wet and too sticky to be ploughed and necessitate much time to dry out. In these conditions very little time is available for land preparation.

6.1.5 Soil erosion

Three types of erosion were observed in the district of Xai-Xai, namely erosion caused by water, by wind and by creep.

6.1.5.1 Water erosion

Water erosion is active on most sloping Serra soils. This situation is due to:

- lack of vegetative cover because of the destruction of the natural vegetation and the sparse cultivation of crops.
- soil compaction, due to animal and human traffic on the numerous tracks that go from the villages, that are on the edge of the Serra, down to the footslopes where are located many wells. This compaction reduces water infiltration, hence increasing runoff and erosion.
- the ditches evacuating the drainage water of asphalt roads are often ill protected and are sometimes transformed into enormous gullies during big storms (see figure 8).
- the villagers, mostly the women, make shallow excavations in roads and steep lands to extract clayey sandy material to be used as plaster on the walls of their houses. These excavations very often turn into gullies during intense rainfall occurrences.
- in certain areas such as along the road from the city of Xai-Xai to its beach, land has been distributed in hilly terrain according to geometrical patterns. It was observed that rainfall water concentrates along the parcels limits that are perpendicular to the contours.

Water erosion is also active on the concave banks of the main rivers, especially of the Limpopo.

6.1.5.2 Wind erosion

Due to their loose topsoil, the sandy soils of the Serra are strongly affected by wind erosion wherever the vegetative cover is reduced by destruction or replacement with sparse crops (see photographs next page). Wind erosion is especially severe in the coastal zone where winds are stronger.

6.1.5.3 Creep

This type of erosion is caused by land preparation with hand tools. This type of land preparation is done from the footslope up to the top of the hills. Hence, the hoe moves the soil downslope, each time a little bit lower see (figure 8). It is however difficult to see the effect of creep in the fields because the fluidity of sands allows all excavations to be levelled quickly.

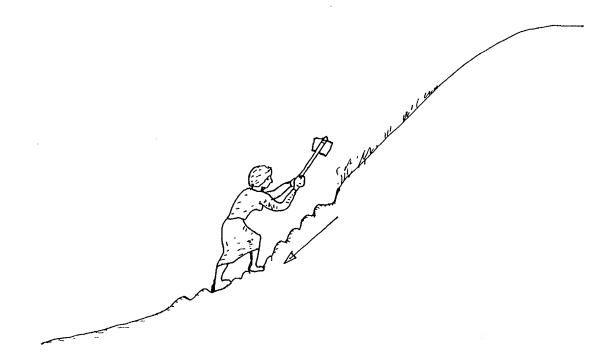

Photograph showing wind erosion in a maize field in sandy soils

Photograph showing wind erosion in a maize field in sandy soils

Figure 8 Erosion by creep due to land preparation with a hoe

6.2 Farmers' strategy to overcome the soil and climate limitations

Subsistence farmers try to ensure that food is available to them at all times. Indeed their storage capacity is very low, both physically (low cellars capacity and destruction of stored produce by pests and diseases) and financially since they sell very little (they do not store excess production in the form of money which could be used the bad years to buy food). Therefore, excess production of the good years cannot be used substantially to compensate the deficit during the bad years. This explains why minimizing production risks is the main objective of subsistence farmers who deploy an efficient strategy to achieve food security. The pillars of this strategy are:

- genetic diversity: farmers grow a variety of herbaceous and tree crops. If a given crop does not produce under given environmental conditions, another one will.
- <u>environmental diversity</u>: whenever possible farmers cultivate fields having complementary edaphic conditions. They often cultivate uplands and lowlands, hence if the weather is too wet, the uplands will produce and vice-versa in case of drought. The "Xin'tlavane", which is a narrow strip of land in the footslopes of the Serra, is particularly liked by farmers because it is too high to be flooded but low enough to benefit from moisture provided by the relatively shallow water table (see figure 9)
- <u>temporal diversity</u>: farmers prefer to grow 2 crops during both the cold and the hot seasons rather than a single crop which extends across both seasons, hence if weather conditions are not favourable during one season, they may be better during the next and the chances of getting a harvest are thus increased.
- <u>high mobility</u>: Farmers shift their cropping activities to the most appropriate locations according to the prevailing weather. If there is a protracted drought, they would concentrate their cropping activities in the wetlands. If there is excessive precipitation they would on the contrary concentrate on the uplands. This is only possible with fast growing crops such as **sweet potato** which once transplanted allows to start eating the leaves within 2 weeks and tubers after a few months. This emphasises the role of sweet potato in food security.
- <u>utilization of adapted crops</u>: Drought resistant crops in the Serra, such as pigeonpea, groundnut, cowpea, and flood resistant crops in the wetlands, such as rice and yams.
- <u>land use diversity</u>: Farmers diversify their activities and may practice simultaneously crop production, animal husbandry, fishing, fabrication of alcoholic drinks, collection of reeds in the swamps, firewood etc... Thus if they face difficulties with one activity another may compensate.
- <u>adapted nutritional habits</u>: The large place occupied by leaves in the diet is an important food security measure. Indeed, in case of drought, crops such as cowpea, sweet potato or squash give no or little fruit/tuber, but their leaves will be eaten.

Ecological diversity in the district of Xai-Xai

Figure 9

- <u>adapted management practices</u>: Farmers cultivate several crops on raised beds in the wetlands, in spite of the hard labour involved. Burning the bush and weeds is a measure by which farmers make available to crops, from the ashes, calcium, potassium and phosphorus, and control weeds, pests and diseases.

This food security strategy is very labour-intensive, thus the availability of labour becomes often a major constraint.

6.3 Proposed measures to overcome the soil and climate limitations

To be accepted by farmers all action proposals at their level must increase directly the food availability, therefore the proposals which reduce the cultivated area are unlikely to be accepted by them. They must also be little demanding in labour because, as we have seen, farmers have many labour intensive activities.

6.3.1 Measures to remedy the inadequate soil moisture regime

6.3.1.1 Irrigation development

The most efficient way to prevent the destructive effects of periodic droughts is to irrigate all the lands that are suitable.

- In the valley

The main physical obstacle to the expansion of irrigation in the Limpopo valley is the lack of sufficient water and its' episodically high salinity.

The volume of available water can be increased by building the long-planned Mapai dam, and use existing untapped or little tapped water resources such as those of Rio Lumane and Rio Chégua. Feasibility studies for such use are already available in the Ministry of agriculture.

Water quality in the Limpopo and the Lumane can be improved by building a dam in the lower course of the Limpopo in order to prevent the intrusion of saline ocean water.

Also, since most irrigation is done by gravity, land levelling would improve the efficiency of irrigation hence saving water.

- In the Serra

The many lakes existing in the coastal strip of the Serra constitute an appreciable good quality water resource that can be used for irrigation. However, the terrain around the lakes is hilly and the available relatively flat land consist generally of narrow strips on their margins. There is often enough room to accommodate small irrigated fields for the production of vegetables. The depression of Banhine has large expanses of land suitable for overhead or drip irrigation and irrigation by hand-carried watering-cans. However, it is necessary to know the yield capacity of the aquifer.

<u>Note</u>: Given the importance of the wetlands for the food security strategy of the family sector, it is necessary to declare these as "key resources" protected by law against acquisition by external persons or institutions.

6.3.1.2 Drainage development

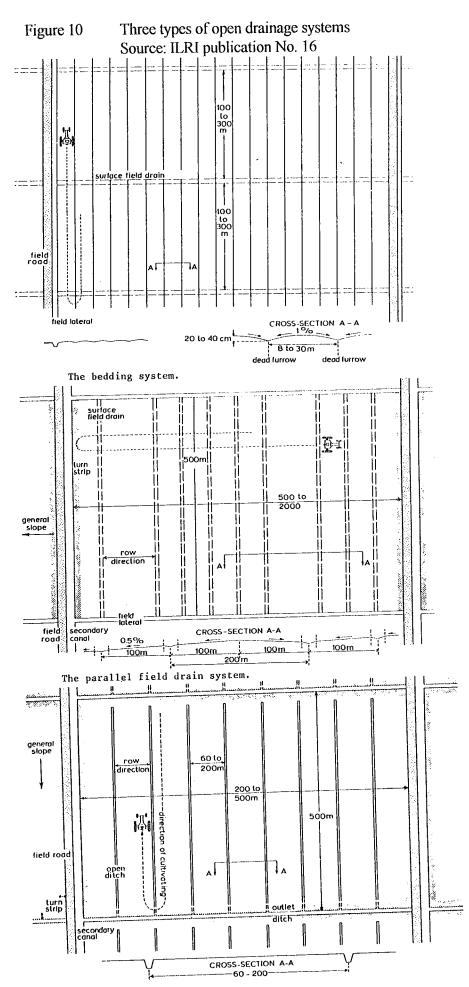

The majority of valley lands suffer from poor drainage, and this fact has been recognized and dealt with since the early 1950s. There are several drainage schemes in the plain, with or without irrigation.

The existing drainage networks suffer from a number of deficiencies, probably because they were constructed hastily with minimal technical and financial means. The main problem is that they aim at lowering the water table and do not answer the important problem of the <u>bad surface drainage</u>. Indeed the evacuation of stagnating rain water is prevented by the lack of land forming (levelling but keeping a slight slope toward surface drains) and by the frequent existence of dikes on both sides of the drains. It is not clear whether these were done during the construction or are the result of the cleaning of the drains, the moved earth being piled in-situ. The existence in certain areas of above ground level earthen irrigation canals also prevent the circulation of runoff water. The near absence of bridges for the cattle and farmers to cross the canals and collectors, force these to walk across them, hence causing damage than often result in their complete obstruction.

Due to war and to the lack of financial resources, maintenance has been neglected during several years. The problem of deciding who should pay the maintenance is still to be resolved.

It is recommended to carry out a general drainage (and irrigation) study of all the plain taking into account surface drainage requirements. A detailed topographic map at scale 1:5000 or larger must be prepared beforehand. As shown in figure 10, there are various open drainage systems that can be used (based on ILRI publication No. 16):

- <u>Parallel open ditch system</u>: Preferable in areas where it is necessary and possible to lower substantially the water table (down to 125-150 cm for mineral soils and 50-75 cm for organic soils). Ditches are at least 60 to 100 cm deep and have steep side slopes, usually 1:1 or 1.5:1 depending on soil stability. The distance between ditches is usually between 60 and 200 m. As the ditches cannot be crossed by machinery, all farm operations have to be made parallel to them. The parallel open drain system is both a surface and a deep drainage system.
- <u>Parallel field drain system</u>: This method as well as the bedding system described below are strictly surface drainage systems, to be used when deep drainage is not necessary or not possible. The parallel field drainage system is recommended in flat poorly drained areas with many irregularities. This system requires precise land forming to give a proper slope to the rows to allow them to discharge runoff water into the parallel field drains

The parallel open ditch system.

which are perpendicular to row direction. The field drains are shallow channels that can be crossed by machinery and which have a minimum depth of 25 cm, side slopes of 8:1 to 10:1 and a cross-sectional area of 0.5 m² and a grade of 0.1 to 0.3 percent.

- <u>Bedding system</u>: This system is used on flat poorly drained land with low permeability. The land is shaped by ploughing several consecutive years into beds separated by dead furrows which run in the direction of the prevailing slope. Ploughing must always be done parallel to the furrows, whereas sowing and other farm operation can be done either parallel or perpendicular to them. Bedding is possible on lands with up to 1.5 percent slope. For the soil of the Xai-Xai plain the recommended bed width is 10 to 20 m and the bed length 100 to 300 m. The height difference between the top of the beds and the bottom of the furrow is about 20 cm for arable lands and 40 cm for pastures. This bed height can be obtained either by repeated ploughing with the furrow remaining always in the same place, or by using earth moving machinery.

The water from the dead furrows is collected into a field drain which is constructed at the lower end of the field in direction perpendicular to that of the furrows. The field drains discharge their water into field laterals which in turn discharge their water to the main drains. The field drains have a depth of about 25 cm, side slopes of 6:1 to 10:1 and a grade of 0.1 percent or more.

When crops have to be sown parallel to the field drains, the bedding system will function only in case the beds surface is left smooth. This is often a serious limitation for mechanized arable farming, but not for pasture or traditional agriculture where sowing is done by hand.

<u>Note</u>: In the peaty areas it recommended to avoid lowering the water table below 50-75 cm, and to design the drainage as a surface drainage one. Indeed the real problem in the machongos is the flooding and not the high water table which is rather an asset for the types of crops that are grown and allows to dispose of soil moisture during dry periods. It is less costly and more productive to grow adapted crops such as vams, rice and vegetables rather than spend money on deep drainage.

6.3.1.3 Rainfed agriculture in sandy areas

It is necessary to test mulching techniques to help conserve soil moisture. Some farmers already use these techniques but some of them spoke of problems with termites.

The best way to cope with drought is to cultivate drought resistant crops. Among these, deep rooting plants such as fruit trees and ligneous legumes (e.g. pigeonpea), are particularly indicated. It would be necessary to develop local food processing, to prepare jams (techniques completely ignored by the villagers as shown by our interviews) and dry fruits.

6.3.2 Measures to remedy the high soil salinity and sodicity

The implementation of an efficient land drainage system will induce a rapid diminution of soil salinity. It is also recommended to avoid irrigating with brackish water and grow crops that are relatively resistant to salinity such as cotton, wheat, soya, rice and tomato. In case of irrigation it is better to alternate crops that require basin irrigation (e.g. rice) with those that require furrow irrigation (e.g. cotton). When there is a good drainage, basin irrigation ensures a more efficient salt leaching.

The soils affected by high sodicity could be treated with gypsum to substitute exchangeable sodium with calcium. However, this costly operation is probably not economically justified in Xai-Xai.

6.3.3 Measures to remedy the low soil fertility

Fertility recommendations are different for the Serra, the mineral valley soils and the machongos.

6.3.3.1 Serra

Given the fact that mineral fertilizers are unlikely to be presently economical for subsistence farming, fertility must be improved by adequate management rather than by using inputs external to the household. We will examine successively the various possible measures in the next sections:

- <u>Incorporation of crop residues</u>: Some farmers incorporate crop residues during land preparation, after letting them decompose at the soil surface after the harvest. However, the majority gather the dry crop residues with weeds in heaps and burn them, then incorporate the ashes. Although there is much criticism of the practice of burning it has great advantages in that the ashes:
 - * provide several nutrients, including calcium and potassium, in a form that is readily available to crops.
 - * raise the soil pH, hence improving the general chemical environment of the rootzone. This is important since many Serra soils have pHs between 5 and 5.5.

The burning also helps control weeds, pests and diseases and is less labour intensive than incorporation.

Considering the low yield levels achieved in subsistence agriculture due to reasons other than fertility, and the important share of leguminous crops in the cropping pattern, the above mentioned benefits of burning outweigh the loss of an important part of nitrogen and sulphur with the burning.

Therefore it is unwise to advise farmers to abandon this practice unless an alternative is found which provides <u>all</u> the benefits of burning and not only the fertility aspects. Some research should be done to explore ways to carry out the burning more efficiently by ensuring a better distribution of the ashes in the fields and preventing the fire from extending to nearby fields and/or natural vegetation, thus causing important destructions. It is also likely that fire damages the cashew and other trees that are nearly always present in the fields.

- <u>Animal manure</u>: The first obstacle to wide application of manure in the fields is that little of it is available due to:
 - * small cattle population due to war and stealing.
 - * dispersion due to the fact that cattle spends most of the daytime grazing, mostly in communal lands.

* bad quality of the manure produced in the corrals because the animal dropping fall directly in sand and the urine infiltrates deeply into the soil, wasting many nutrients.

Besides its' rarity, manuring is labour intensive and requires transportation means that are often unavailable. This is why the use of manure is reserved for intensive crops such as vegetables.

Increased use of manure will depend on the increase of the cattle population, development of animal traction for transportation and on the introduction of types of corrals that produce a better manure.

- <u>Composts</u>: Besides being labour intensive and requiring transportation means, composting cannot be done efficiently without application of water in droughty sandy soils. Water being scarce in the Serra, there is very little scope for developing the use of composts.
- <u>Green manure</u>: The main obstacles to this practice are that it is labour and inputs intensive (seeds, land preparation). Therefore there is little scope for developing the use of green manure (the case of green manure from trees will be discussed under agroforestry).
- <u>Agroforestry</u>: It consists of adding trees or bushes to annual or perennial crops and/or grasses to foster their overall productivity. In the conditions of the study area the ideal agroforestry species should:
 - * not compete with crops for nutrients and water. This means that a vertical rooting system is better.
 - * not shade crops too much. This means small or sparse canopy or leaves falling during the crops growing season.
 - * render multiple services and not only improve soil fertility, such as providing fruit, drinks, fodder, pollen for bees, firewood, windbreak, firebreak, shade etc.

A number of agroforestry species were mentioned as suitable for the study area (see section 5.4.2). We can however mention Acacia albida and Albizzia lebbeck for the sandy depressions such as that of Banhine, and canhu and papaya for use in Serra uplands. However, the best solution in the Serra is by far to introduce rotations including pigeonpea.

Pigeonpea is a bushy crop which is drought resistant, has a deep rooting system with a central taproot which can fetch nutrients and water from deep soil substratums. Besides fixing nitrogen it also produces protein-rich food and the leaves can be used as fodder. It is well-known by farmers and productive varieties are available in Mozambique. A suitable rotation could be:

- * pure stand of pigeonpea. 2 years (regrowth of the shoots the 2nd year).
- * maize consociation (with cowpea or groundnut etc.) followed by pure maize during the cool season. 1 year.
- * maize-cassava-cowpea (or groundnut) during the hot season, the cassava continuing alone during the cool season. 2 years.

It must be noted that such rotations with pure stands of pigeonpea cover extensive areas in Zambezia, especially in the district of Mocuba. There are also isolated cases in the district of Xai-Xai, near the aldeia "3 de Fevereiro".

- <u>Fallow</u>: Given the high population density, fallow is very short or non existent. However, the rare farmers who have enough land could benefit from 2 years of grazed fallow.
- <u>Dispersion of the population</u>: Dispersed habitat prevents a high concentration of the population thus helping to increase fallow duration.

<u>Note</u>: Introducing new high-yielding crop varieties may lead to accelerated depletion of soil fertility because they export more nutrients, unless adequate accompanying measures are taken.

6.3.3.2 Valley mineral soils

All the valley mineral soils have adequate available potassium but there are phosphorus deficiencies in the south of the district and of nitrogen in the north. These deficiencies could be easily corrected with the application of chemical fertilisers. Phosphorus could be incorporated during land preparation but only a small fraction of nitrogen should be applied this way, leaving the rest of it to be applied at suitable crop physiological stages, whenever there is enough soil moisture (in rainfed agriculture). We have noticed that the fertilization of rice is not properly done. Indeed nitrogen must be incorporated at 7-10 cm below the soil surface before flooding otherwise it is mostly lost. It is however unlikely that the application of chemical fertilisers would be economical, except for irrigated crops.

6.3.3.3 Machongo soils

Machongo soils have guarantied moisture, therefore the application of chemical is probably economically justified. It is recommended to use NPK fertilisers and to apply CaO to raise the pH to reduce aluminum toxicity.

6.3.4 Measures to remedy soil erosion

The following measures are proposed:

- maintain or restore the prevailing mixture of tree (mostly cashew) and herbaceous crops. According to several interviewed farmers, a distance of 20 to 25 m between trees is optimal for the associated crops.
- plant a network of windbreaks in the coastal strip of the Serra (see details in section 6.4.2.1).
- total afforestation of active coastal sand dunes with Casuarina equisetifolia which can establish itself even where there are strong winds.
- define a protection zone along the coast and around the lakes where the natural vegetation should be left to grow. These areas could be considered as natural parks.
- protect the paths in sloping areas, in particular by avoiding straight lines.
- reserve specific areas in the main villages for the extraction of plastering material.
- plant trees on the external banks in river bends to limit fluvial erosion. These areas can help reduce the problem of firewood in the plain.

6.3.5 Measures to remedy soil workability problems

Motorized mechanical means are the best way to fully exploit the heavy clay soils in the valley because the growing season is often lost because of late land preparation. Therefore, tractors should be made available for rent to small farmers. If the operation does not prove economically viable, at least animal traction should be made available.

6.4 Description of the management units

This section is meant to give a broad idea on the characteristics of each land management unit. Land management units are lands that have similar potential uses and require similar management. Table 26 shows to which management unit belongs each map unit. Figure 11 is a generalized zonation map of the district of Xai-Xai into management units.

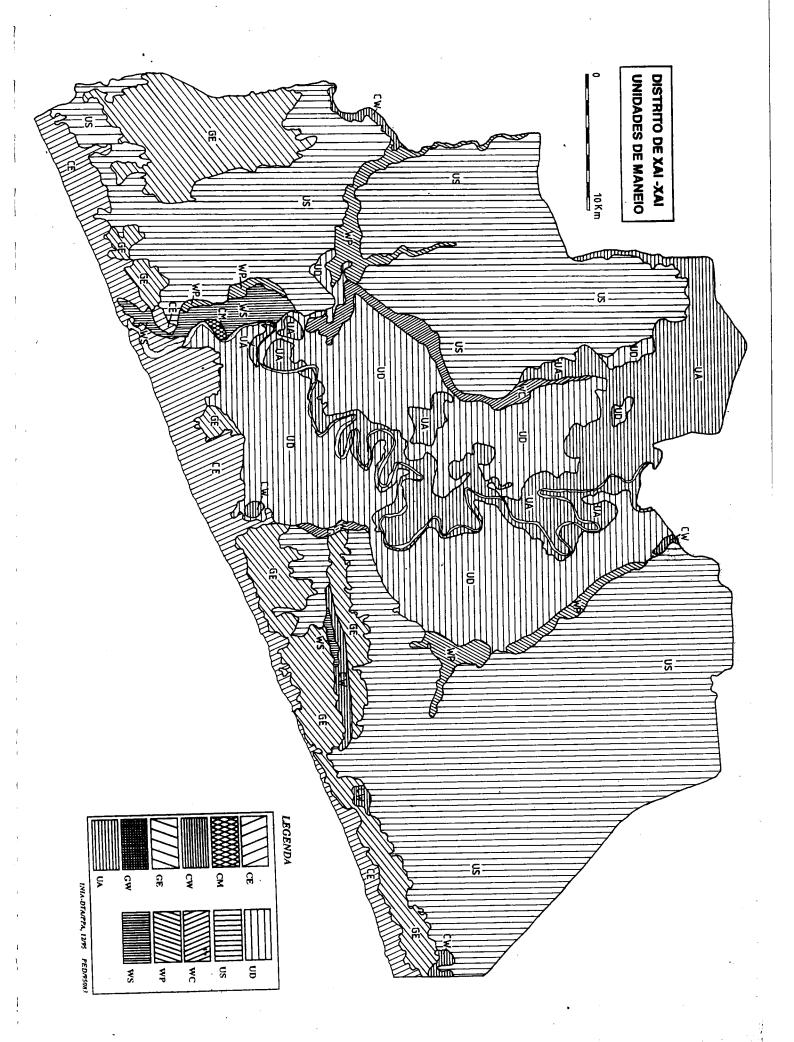

Figure 11 Generalized zonation map of the district of Xai-Xai

6.4.1 Conservation areas (C)

6.4.1.1 Areas of strict erosion control (CE)

Strict erosion control is compatible with partial use for wildlife, recreation and tourism.

- Areas requiring total reforestation (CE1)

This is mostly map unit **DUC1** which consists largely of coastal shifting aeolian sands, threatening inner arable and grazing lands and lakes. Total reforestation is the best way to fix these sands and prevent further damage.

- Areas requiring protection of the existing woody vegetation and partial reforestation (CE2)

These are mainly map units DUC2, DUC3, DUC7, which are fixed coastal aeolian sand dunes which, given their exposure to the strong winds blowing from the sea, will start drifting if the natural vegetation is destroyed.

Steep risers linking the Serra to the valley require similar management. Map unit **DEC6** is the only steep riser shown on the map because, given the very narrow width of these land units, they are not mappable at 1:50,000.

6.4.1.2 Areas of mangrove conservation (CM)

Mangroves represent a special ecosystem which requires protection of it's flora and fauna. If properly controlled, a partial use for fuelwood supply may be allowed. The map unit concerned is **MAN**.

6.4.1.3 Areas of inland water bodies (CW)

- Permanent lakes (CW1)

These are map units **DEL** and **RIL**. A campaign of sampling of lakes and depressions and interviews about their uses, was carried out during the last week of February 1995.

Except lake Sane, near Nhabanga village, all lakes have water that is suitable for human and cattle drinking, washing, irrigation and pisciculture. Lake Sane's water may only be used for cattle drinking and pisciculture.

The investigations have shown that lakes are a vital source of water for domestic utilization (drinking, cooking, washing etc...), for small-scale irrigation with hand-carried watering-cans, and a source of fish. They are also refuges for wild animals such as birds.

These areas require protection from sand deposition (the surrounding areas must be vegetated, preferably wooded), from pollution and adequate management of the fish resources. This may include a comprehensive pisciculture programme and/or regulation and control of fishing activities as fishermen are presently using nets with too small mesh-size. Forbidding fishing with nets may improve the situation, but a preferable solution may be to organize and train the fishermen to implement a sustainable fish exploitation.

Permanent lakes, especially those of the Serra, have also a definite value for recreation and tourism. The lack of good access, due to the lack or the bad condition of roads, is a major limitation for the development of these activities.

- Temporary lakes and very humid closed depressions (CW2)

These are map units **BAD1**, **BAD2**, **DEH2** (examples of DEH2 are lakes Chevise and Nhambozi), **RIH** and **TE8**. They represent also an interesting source of water for small-scale irrigation, and less so, for domestic utilization (drinking, cooking, washing etc). An additional interesting feature is the frequent presence of reeds. These serve as building material and, when sold, as a source of cash. During droughts, these areas may be grazed or even partly cultivated. The reeds are also refuges for wild animals such as birds.

Only protection from excessive reeds exploitation is required.

- 6.4.2 Areas only suited for forestry and/or grazing (G)
- 6.4.2.1 Excessively drained sparsely vegetated sloping sands (GE)

These are map units DUC4, DUC5, DUC6, DUI5 and DUI6. They consist of excessively drained sloping infertile sands having a low water holding capacity and little woody vegetation. Both wind and water erosion are active in these soils. Destructive uncontrolled fires are often provoked by hunters and/or honey collectors. They are mostly used as grazing lands though arable farming is locally practised.

These soils may be used for extensive grazing or for forestry. However, in conformity with the current land use, it is recommended to reserve these lands for silvopastoral use (grazing and exploitation of trees). Partial afforestation with adequate tree mixes may provide the following advantages:

- serve as wind breaks hence reducing wind erosion. For this purpose the hedges should be relatively permeable, oriented perpendicular to the dominant winds and spaced at not more than 120 meters (about 12 times tree height).
- if planted on contours, the trees would also limit water erosion.
- serve as firebreaks.
- increase available soil moisture through increased infiltration, reduced evapotranspiration due to the reduction of wind speed, and retention of night dew.
- improve soil fertility through foliage residues scattered by wind.
- provide additional fodder, especially during droughty years.
- provide extra revenue through the production of honey (apiculture), poles and fuelwood.
- facilitate a rational rotation of cattle grazing in the various blocks delimited by the hedges.
- provide shade to cattle during the hot hours.

The above mentioned advantages will largely outweigh the loss of grazing space due to the presence of hedges.

Marginal traditional farming, with intensive soil fertility and water conservation measures, may be authorized in favourable sites such as footslopes and toeslopes.

6.4.2.2 Wet flooded and saline clays (GW)

This is map unit **TE7**. It has a poor drainage, a high water table, strong salinity and is subject to frequent flooding. These lands are presently used for extensive grazing. They are moderately suitable for grazing and marginally suitable for forestry. It is suggested to maintain their present use for grazing.

Simple land forming (raised beds) through adequate mechanical ploughing may improve durably the drainage and salinity situation, hence improving the nutritive quality of the grass.

6.4.3 Areas suited for upland farming, grazing and forestry (U)

6.4.3.1 Alluvial lands not requiring deep drainage (UA)

- Well to moderately well drained lands (UA1)

These are map units COM1, COM2, COM3, COM4, PLI12 and TE3. These soils are well to moderately well drained, have a moderate to high water holding capacity and a good natural fertility status. They are rich in potassium and phosphorus and poor to moderately rich in nitrogen, which makes them highly suitable for leguminous and tuber crops.

They are mostly used by the family sector for intensive traditional dryland farming, generally with annual crops intercropped with fruit trees. Many smallholders have dwellings in this management unit, especially in map units COM1, COM2 and COM4, where flood waters do not stagnate, hence the presence of many homesteads gardens.

These map units are highly to moderately suitable for all types of rainfed agriculture and highly suitable for grazing and forestry. Except for the heaviest component of map unit COM3 (COM3-2), hand tools cultivation is feasible in all other map units of this management unit. However, since farmers often also own lands in the neighbouring heavy clay soils, animal traction, owned or hired, is widely used.

Map units PLI12, TE3 and part of COM3 are also moderately to marginally suitable for surface irrigation while the other map units are unsuitable mainly due to unfavourable microtopography. No deep drainage is required and only map unit PLI12 and the heavy clay component of COM3 (COM3-2), require surface drainage. Cultivation on raised beds, as a measure to improve surface drainage, is largely practised in map unit PLI12.

Given the good P and K status of these soils, only nitrogen fertilizers may prove economical on non-leguminous crops such as maize. It is therefore recommended to use N fertilizers during the growing season as top-dressings provided sufficient rainfall has fallen. Given the availability of water from the river or from shallow wells, and the presence of homesteads, use can also be made of compost of crop residues and domestic waste.

- Imperfectly drained lands (UA2)
- * Drainage impeded by unfavourable topography and heavy texture (UA2-1)

These are map units **RIS1** and **TE4**. The soils of map unit RIS1 formed in shallow abandoned meanders while those of map unit TE4 formed in depressions within the Limpopo's lower terraces.

The restricted drainage of the soils of both map units represents an advantage during frequent droughty years and makes them important resources for the family sector.

These soils have good fertility and water holding capacity. Given their good P and K status, only nitrogen fertilizers may prove economical on non-leguminous crops such as maize. It is therefore recommended to use N fertilizers during the growing season as top-dressings provided sufficient rainfall has fallen. Wherever water is available, use can be made of compost of crop residues and domestic waste.

Drainage is not feasible or only at a very high cost. These units are moderately suitable for all types of rainfed farming, moderately to marginally suitable for irrigated agriculture, highly suitable for grazing and marginally suitable for forestry.

* Drainage impeded by textural heterogeneity (UA2-2)

This is map unit **TE2**. The subsoil is clayey but the topsoil is sandy, hence the formation of a temporary perched water table during heavy rainy episodes. In moderately dry years this soil will benefit from its' impeded drainage. However, during very dry years, the sandy nature of its' topsoil will be a disadvantage.

This soil is moderately rich in P and K but very poor in nitrogen. Nitrogen fertilizers may prove economical on non-leguminous crops such as maize. It is therefore recommended to use N fertilizers during the growing season as top-dressings provided sufficient rainfall has fallen. Since water is available in the neighbouring Munhuana river, use can be made of compost of crop residues.

Drainage will not solve the problem of the perched water table. Only repeated deep ploughing may improve the situation by mixing the upper soil. However this operation is not feasible wherever the sandy topsoil is thicker than 30 cm, because special ploughing equipment, unlikely to be available, is required.

This unit is moderately suitable for traditional rainfed farming, grazing and forestry, marginally suitable for general irrigated agriculture and mechanized rainfed farming. The sandy topsoil permits growing groundnuts.

- Complexes of moderately well and imperfectly to poorly drained lands (UA3)

These are map units **PBC1**, **PBC2**, **PBC3**, **PBC4**. These soils formed in point bar complexes that have a moderate to strong microtopography. The better drained components are on convex terrain and the poorly drained ones in depressions. They all have a very high water holding capacity and a good natural fertility status. They are rich in potassium and phosphorus (except PBC4 which is poor in phosphorus) and rich to moderately rich in nitrogen.

Convex components: (PBC1-1, PBC2-1, PBC3-1 and PBC4-1) They are mostly used by the family sector for traditional dryland farming, generally maize, beans and pumpkins. Some smallholders have dwellings in these lands. They consist of moderately well to imperfectly drained non to slightly saline soils.

These map unit components are highly suitable for grazing, highly to moderately suitable for animal traction-based rainfed agriculture, highly to marginally suitable for hand tools-based and mechanised rainfed agriculture and forestry, and marginally suitable to unsuitable for irrigated agriculture.

Given the good P and K status of these soils, only nitrogen fertilizers may prove economical on non-leguminous crops such as maize. It is therefore recommended to use N fertilizers during the growing season as top-dressings provided sufficient rainfall has fallen. Given the availability of water from the river or from shallow wells, and the presence of homesteads, use can also be made of compost of crop residues and domestic waste. PBC4-1 however will benefit from a basal application of phosphorus.

Depressions components: (PBC1-2, PBC2-2, PBC3-2 and PBC4-2) They are mostly used for grazing. They are poorly to very poorly drained moderately to strongly saline soils. They are not drainable due to their topography.

These map unit components are moderately suitable for grazing, marginally suitable for irrigated rice production, marginally suitable to unsuitable for forestry and unsuitable for all other uses.

- Moderately well drained heavy clay soils (UA4)

These are map units PLI1, PLI2, PLI3, PLI4 and TE1. These soils formed in level to nearly level flood plains and generally have a slight to moderate microrelief. They all have a very high water holding capacity and a good natural fertility status. They are rich to very rich in potassium and phosphorus and moderately rich in nitrogen. They are not or only slightly saline.

They are mostly used by the family sector for traditional dryland farming, generally maize, beans and pumpkins.

These map units would benefit from surface drainage. They are highly suitable for grazing, moderately suitable for animal traction-based and mechanised rainfed agriculture, moderately to marginally suitable for irrigated agriculture, marginally suitable for hand tools-based rainfed agriculture and forestry, and unsuitable for wetland agriculture.

Given the good P and K status of these soils, only nitrogen fertilizers may prove economical on non-leguminous crops such as maize. It is therefore recommended to use N fertilizers during the growing season as top-dressings provided sufficient rainfall has fallen.

- Mananga of high terraces (UA5)

This is map unit **TEM**. It consists of moderately well drained and moderately sodic lands which formed on high alluvial terraces and have a moderate microrelief due to the presence of high but sparse termites mounds. They have a very high water holding capacity and a good natural fertility status. They are rich to very rich in potassium and phosphorus and moderately rich in nitrogen.

They are not saline but have a strong tendency to crust hence causing acute germination problems.

They are mostly used by the family sector for grazing but are also locally cultivated generally with maize, beans and pumpkins.

This map unit would benefit from surface drainage. It is moderately suitable for grazing, unsuitable for wetland farming, and marginally suitable for all other uses.

Given the good P and K status of these soils, only nitrogen fertilizers may prove economical on non-leguminous crops such as maize. It is therefore recommended to use N fertilizers during the growing season as top-dressings provided sufficient rainfall has fallen. Gypsum could be applied to reduce crusting but it is unlikely that it would be economically justified.

- Imperfectly drained and periodically flooded alluvial lands (UA6)

These are map units **TE5** and **TE6**. These soils formed in level terraces of the lower course of the Limpopo and generally have a slight to moderate microrelief. They all have a high to very high water holding capacity and a moderate natural fertility status. They are rich to very rich in potassium, moderately rich in phosphorus and poor to moderately rich in nitrogen. They are slightly saline in the topsoil and slightly to moderately saline in the subsoil.

They are mostly used by the family sector for traditional dryland farming, generally maize, beans and pumpkins, and for grazing.

These map units would benefit from surface drainage. They are highly suitable to moderately suitable for grazing, moderately to marginally suitable for forestry, marginally suitable for all types of dryland farming and irrigated rice farming, marginally suitable to unsuitable for general irrigated farming and unsuitable for wetland agriculture.

Given the good P and K status of these soils, only nitrogen fertilizers may prove economical on non-leguminous crops such as maize. It is therefore recommended to use N fertilizers during the growing season as top-dressings provided sufficient rainfall has fallen.

6.4.3.2 Alluvial upland farming areas that require deep drainage and salinity control (UD)

- Imperfectly drained, slightly to strongly saline, clayey over sandy soils (UD1)

These are map units **PLI10** and **PLI11**. These soils formed in clayey alluvium overlying aeolian (?) sands. They are imperfectly drained and generally have a water table at about 75-100 cm. They have a moderate to high water holding capacity, are very rich in potassium, rich in nitrogen and very poor in phosphorus.

These soils are presently mostly used for grazing. Once deep drainage is implemented, these soils would be moderately to marginally suitable for irrigated agriculture, marginally suitable for wetland farming, and moderately suitable for animal traction-based rainfed traditional and mechanized farming. In their present state they are moderately suitable for grazing and marginally suitable for hand tools based-farming and forestry.

- Imperfectly to very poorly drained, not to moderately saline heavy clay soils (UD2)

These are map units BAD3, BAD7, BAD8, PLI5 and PLI6. These soils formed in heavy swelling clays. The are imperfectly drained and generally have a water table at about 75-100 cm. They have a very high water holding capacity, are very rich in potassium and moderately rich to rich in nitrogen and phosphorus.

These soils are presently mostly used for grazing or, if drainage permits, maize and beans. They used to be largely irrigated before the collapse of the drainage system. Once deep drainage is implemented, these soils would be moderately suitable for irrigated rice farming, animal traction-based and mechanised rainfed agriculture. They would be also moderately to marginally suitable for general irrigated farming and marginally suitable to unsuitable for wetland farming. In their present state they are highly to marginally suitable for grazing and marginally to unsuitable for forestry.

- Imperfectly drained strongly saline heavy clay soils (UD3)

These are map units **BAD9**, **BAD10** and **PLI7**. These soils formed in heavy swelling clays. The are imperfectly drained and generally have a water table at about 25-50 cm. They have a very high water holding capacity, are very rich in potassium, rich in nitrogen and poor to rich in phosphorus.

These soils are presently mostly used for grazing or, if drainage permits, maize and beans. They used, especially PLI7, to be largely irrigated before the collapse of the drainage system. Once deep drainage is implemented, these soils would be moderately to marginally suitable for irrigated rice farming, animal traction-based and mechanised rainfed agriculture. They would be also marginally suitable for general irrigated farming and marginally suitable to unsuitable for wetland farming. In their present state they are highly to moderately suitable for grazing and marginally suitable for forestry.

6.4.3.3 Sandy upland areas (US)

They are suitable for both animal traction and hand tools-based agriculture. They all require erosion control and fertility improvement.

- Somewhat excessively drained, strongly sloping moderately fertile red earthy sands (US1)

These are map units **DEC4** and **DUI10**. These soils have a low water holding capacity, are slightly acid (pH 6 to 6.5), moderately rich in nitrogen, poor in phosphorus and rich in potassium. Their moderate fertility status is mostly due to the dense tree cover and, less so, to their higher clay content.

Due to their tendency to compact (higher clay content) these soils may undergo severe water erosion and therefore require intensive soil conservation measures, which may consist primarily in conserving the existing tree cover. Moderate fertility and moisture conservation measures are also required.

The soils of this management unit are marginally suitable for traditional upland arable farming and grazing and moderately suitable for forestry.

- Excessively drained, strongly to gently sloping poor sands (US2)

These are map units **DEC5**, **DUI3**, **DUI4** and **TEA1**. These soils have a very low water holding capacity compounded by excessive runoff. They are slightly to strongly acid (pH 5 to 6.5) and have a very low fertility status.

These soils require intensive soil, fertility and water conservation measures.

The soils of this management unit are marginally suitable for traditional upland arable farming and grazing and moderately suitable for forestry.

- Somewhat excessively drained, very gently to gently sloping poor brownish sands (US3)

These are map units **DEC3**, **DUI1**, **DUI2**, **DUI7** and **DUI12**. These soils have a very low water holding capacity, are slightly to strongly acid (pH 5 to 6.5) and have a very low fertility status.

These soils require intensive fertility and moderate soil and water conservation measures.

The soils of this management unit are marginally suitable for traditional upland farming, marginally to moderately suitable for grazing and moderately suitable for forestry.

- <u>Somewhat excessively drained poor greyish sands of margins of lakes and dry depressions</u> (US4)

These are map units **DEM** and **DES**. These soils have a low to very low water holding capacity, are moderately acid (pH 5.5 to 6) and have a very low fertility status. They have a sweet water table at depths varying between 3 and 15 m.

These soils require intensive fertility and moderate soil and water conservation measures. Acacia albida is particularly interesting in this unit.

The soils of this management unit are marginally suitable for traditional upland farming and grazing and highly to moderately suitable for forestry. Small-scale "manual" irrigation is often possible from the neighbouring lakes or shallow dug wells.

- Somewhat excessively drained, strongly acid very gently to gently sloping sandy soils (US5)

These are map units **DEC7** and **DUI11**. These soils have a low to very low water holding capacity, are strongly acid (pH 5 to 5.5) and have a low fertility status.

These soil require moderate fertility, soil and water conservation measures.

The soils of this management unit are moderately suitable for traditional upland farming, grazing and forestry.

- Somewhat excessively drained, very gently to gently sloping red earthy sands (US6)

These are map units **DUI8** and **DUI9**. These soils have a low water holding capacity, are slightly acid (pH 6 to 6.5), moderately rich in nitrogen, poor in phosphorus and rich in potassium.

These soils require moderate fertility, soil and water conservation measures.

The soils of this management unit are moderately suitable for traditional upland farming, highly suitable for forestry and highly to moderately suitable for grazing.

- Sandy plain soil association (US7)

This is map unit **PLA**. It is heterogenous and includes somewhat excessively nearly level to very gently undulated upland sands and fine-loamy soils that have a seasonally high water table in narrow depressions.

* PLA-1. These soils are somewhat excessively drained, have a very low water holding capacity, are moderately acid (pH 5.5-6), poor in phosphorus and nitrogen and rich in potassium.

These soil require moderate fertility, soil and water conservation measures. The water table being within 3-15 m, Acacia albida may assist in restoring and maintaining fertility.

The soils of this management subunit are moderately suitable for traditional upland farming, grazing and forestry.

* PLA-2. These soils are imperfectly drained, have a moderate water holding capacity, are moderately acid (pH 5.5-6), moderately rich in phosphorus and nitrogen and rich in potassium.

These soil require moderate fertility, soil and water conservation measures and some surface drainage. Wherever water is available, they can be irrigated.

The soils of this management subunit are moderately suitable for upland, wetland and irrigated farming and forestry, and highly suitable for grazing.

- Sandy soils that have a seasonally high water table (US8)

These are map units **DEC2** and **TEA2**. These soils are imperfectly drained, have a low water holding capacity and a sweet water table at 75-125 cm, are moderately to strongly acid (pH 5-6), moderately rich in potassium, poor in nitrogen and poor to rich in phosphorus.

These soil require moderate fertility, soil and water conservation measures and some surface drainage. Wherever water is available, they can be irrigated.

The soils of this management unit are moderately suitable for traditional upland farming and forestry, and moderately to marginally suitable for grazing.

6.4.4 Wetland farming areas (**W**)

6.4.4.1 Clayey wetlands (WC)

- <u>Drainable imperfectly to poorly drained fine-textured soils</u> (WC1)

These are map units BAD4, BAD5, DEC1, PLI8 and PLI9. These soils have a high water holding capacity and a sweet water table at 50-125 cm, are moderately to slightly acid (pH 5.5-

6.5), poor to moderately rich in phosphorus, rich to moderately rich in nitrogen and rich to very rich in potassium.

These soils require drainage and P fertilizer.

Once drained the soils of this management unit are suitable for all types of rainfed, wetland and irrigated farming. In their present state they are also highly suitable for grazing and moderately to marginally suitable for forestry.

- Non drainable poorly drained fine-textured soils (WC2)

This is map unit **RIS2**. These soils formed in poorly drained abandoned oxbows. They have a high water holding capacity and a moderately saline water table at 50-75 cm, are slightly acid (pH 6-6.5), moderately rich in phosphorus and rich in nitrogen and potassium.

These soils require drainage but are not drainable at a reasonable cost. They may respond to P fertilizer.

The soils of this management unit are marginally suitable for wetland farming and forestry, and moderately suitable for grazing.

6.4.4.2 Peaty wetlands (WP)

- Peat wetlands (WP1)

These are map units MAC1 and MAC2. These soils are poorly to very poorly drained, have a very low fertility, particularly map unit MAC2 which is very strongly acid (pH 4.4 to 5).

These soils require drainage to lower the water table to a depth of 50-75 cm. Deeper drainage would cause rapid mineralization and subsidence of the peat. NPK fertilization is also recommended, especially PK. Map unit MAC2 would benefit from lime application to increase the pH.

Once drained, the soils of this management unit are suitable for wetland farming and traditional upland farming. However, it is better to reserve it for wetland farming as it is more productive.

- Clayey and peaty wetlands soils association (WP2)

This is map unit MAC3 which is heterogenous and is composed of peat soils similar to those of map unit MAC2 and of saline heavy clay soils. These soils are presently permanently flooded by the waters of rio Lumane.

* MAC3-1 The peat soils are very poorly drained, very strongly acid (pH 4.4 to 5) and have a very low fertility.

These soils require drainage to lower the water table to a depth of 50-75 cm. Deeper drainage would cause rapid mineralization and subsidence of the peat. NPK fertilization is also recommended, especially PK. Lime application would help increase the pH.

Once drained, these soils are moderately suitable for wetland farming and traditional upland farming. However, it is better to reserve it for wetland farming as it is more productive.

* MAC3-2 The heavy clay soils are very poorly drained, very strongly acid (pH 4.4 to 5), moderately saline, and have a moderate fertility status.

These soils require drainage, leaching of salts and P fertilization. Lime application would help increase the pH.

Once drained, these soils are moderately suitable for traditional animal traction-based upland and mechanized rainfed farming. They are also moderately suitable for wetland, hand tools-based agriculture and all types of irrigated agriculture.

- Clayey, peaty and sandy wetlands soils association (WP3)

This is map unit VAL2 which is heterogenous and includes a very poorly drained peat soil and a poorly drained humic fine-loamy soil in the valley floor, and an imperfectly drained grey sandy soil on the toeslopes of the surrounding reliefs.

* VAL2-1 The peat soil component is very strongly acid (pH 4.4-5) and has a very low fertility.

These soils require drainage to lower the water table to a depth of 50-75 cm. Deeper drainage would cause rapid mineralization and subsidence of the peat. NPK fertilization is also recommended, especially PK. Lime application would help raise the pH.

Once drained, these peat soils are highly suitable for wetland farming and moderately suitable for traditional upland farming. However, it is better to reserve them for wetland farming as it is more productive.

* VAL2-2 The fine-loamy soil component is moderately acid (pH 5.5-6) and has a good fertility status.

These soils require drainage and moderate PK fertilization to sustain high yields.

Once drained, these soils are highly suitable for wetland farming and moderately suitable for all types of upland farming, mechanized general irrigation and marginally suitable for mechanized irrigated rice production. However, it is better to reserve them for wetland farming as it is more productive. In their present situation, these soils are moderately suitable for grazing.

* VAL2-3 The imperfectly drained grey sandy soils of the toeslopes are moderately acid (pH 5.5-6) and have a low fertility status.

These soils do not require drainage but NPK fertilization is necessary to sustain high yields.

These soils are moderately suitable for traditional upland farming, grazing and forestry, marginally suitable for wetland farming.

6.4.4.3 Sandy wetlands (WS)

- <u>Drainable sandy wetlands of narrow valleys</u> (WS1)

This is map unit VAL1 which is heterogenous and includes a poorly humic sandy soil in the valley floor, and an imperfectly drained grey sandy soil on the toeslopes of the surrounding reliefs.

* VAL1-1 The poorly drained humic sandy soils are slightly acid (pH 6-6.5) and have a moderately high fertility status. They have a sweet water table at 75-100 cm.

These soils require moderate drainage and minimal NPK fertilization to sustain high yields.

Once drained, these soils are moderately suitable for traditional upland farming and marginally suitable for wetland farming, mechanized rainfed and general irrigated agriculture. In their present situation they are moderately suitable for grazing and marginally suitable for forestry.

* VAL1-2 The imperfectly drained grey sandy soil of the toeslopes are moderately acid (pH 5.5-6) and have a low fertility status. They have a sweet water table at 75-100 cm.

These soils do not require drainage but NPK fertilization is necessary to sustain high yields.

These soils are moderately suitable for traditional upland farming, grazing and forestry and marginally suitable for wetland farming.

- <u>Drainable sandy wetlands</u> (WS2)

This is map unit **BAD6**. They are moderately acid (pH 5.5-6) and have a moderate fertility status. They have a sweet water table within 25 cm.

These soils require drainage and P fertilization to sustain high yields.

Once drained, these soils are moderately suitable for all types of farming. In their present situation they are moderately suitable for grazing.

- Non drainable sandy wetlands (WS3)

This is map unit **DEH1** which is heterogenous and includes a poorly humic sandy soil in the bottom of the depressions, and an imperfectly drained grey sandy soil on the toeslopes of the surrounding reliefs.

* **DEH1-1** The poorly drained humic sandy soils are slightly acid (pH 6-6.5) and have a moderately high fertility status. They have a sweet water table at 50-75 cm.

These soils are not drainable and NPK fertilization is unlikely to be economical.

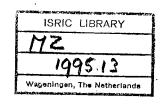

They are marginally suitable for wetland farming and forestry and moderately suitable for grazing.

* DEH1-2 The imperfectly drained grey sandy soil of the toeslopes are moderately acid (pH 5.5-6) and have a low fertility status. They have a sweet water table at 75-100 cm.

These soils do not require drainage but NPK fertilization is necessary to sustain high yields.

These soils are moderately suitable for traditional upland farming, grazing and forestry and marginally suitable for wetland farming.

Maputo, Mozambique

INTRODUCTION

The profiles were described on SDB (Soil Database) formats, as adapted by the Department of Land and Water. The terms used are largely compatible with those of the Guidelines for Soil Profile Description (FAO, 1990).

The soil classification is given in three systems:

- FAO system, according to the "Revised Legend of the Soil Map of the World" (FAO, 1990)
- Soil Taxonomy system, according to "Keys to Soil Taxonomy" (Soil Survey Staff, SCS-USDA, 1994)
- Local soil classification, as elicited from farmers through interviews. The system is presented in section 4.2.2, page 27 of volume I of this report.

The attention of the reader is drawn on the fact that due to the lack of mineralogical information, it was not possible to ascertain if for Soil Taxonomy, the sandy soils of the study area are Ustipsamments or Quartzipsamments. Therefore both possibilities are included.

Thionic properties are assumed in some profiles in accordance with field evidence, in the absence of relevant laboratory data.

The profiles were described in 1994 by:

- J. Mafalacusser
- L. Amós
- A. Souirji

Publications in this study:

This report is the first in a serie of two volumes:

- FAO : Gleyi-Mollic Fluvisol - ST : Aquic Haplustoll - Local : T'Sovo

Soil Climate: aquic

Topography : gently undulating Blement/Pos.: narrow valley floor, middle part Micro Top. : irregular medium

Land Form: sandy plateau Slope : 0 - 1% , straight Slope

: 28/04/94

Land Use

Crops:

Human Infl.

: drained

Vegetation Species

: reeds and grasses (abandoned)
: Phragmites sp. and gramineae

Grass cover:

Parent Material: alluvial deposits

Bff. Soil Depth : > 150 cm

Surface Stones : nil Sealing/Crusting : none

Drainage class : poor External drainage: slow

Flooding Moist. Conditions: 0-130 moist Rock Outcrops : nil Erosion

Permeability: moderately slow Watertable : observed at 110 cm

Catchment: Limpopo

Remarks: non decomposed organic debris in second and third horizons.

- 0 16 cm; black (5YR 2.5/1) moist; loam; moderate medium granular structure; very friable (moist), slightly sticky (wet), slightly plastic (wet); many fine and medium pores; many fine-medium roots; not calcareous; gradual straight boundary.
- 16 41 cm; black (5YR 2,5/1) moist; coarse distinct evident brownish mottles; clay loam; strong medium granular structure; very friable (moist), slightly sticky (wet), plastic (wet); many fine and medium pores; many fine and medium and few coarse roots; not calcareous; clear straight A2 boundary.
- 41 77 cm; black (7.5YR 2/0) moist; sandy clay loam; massive; very friable (moist), slightly sticky (wet), plastic (wet); few fine pores; few distinct clay and sesquioxides coatings along root channels; many fine and medium and common coarse roots; not calcareous; clear straight boundary. Сq
- 77 110 cm; very dark grey (5YR 3/1) moist; sandy clay loam; very friable (moist), slightly sticky (wet), plastic (wet); few fine pores; common distinct clay and sesquioxides coatings along root channels; few fine and medium roots; not calcareous; gradual straight boundary. Cr1
- 110 130 cm; black (5YR 2.5/1) moist; sandy loam; very friable (moist), slightly sticky (wet), plastic (wet); no pores; very few fine roots; not calcareous; Cr2

Permeability: very slow Watertable : at 20 cm (BC > 20 dS/m)

: nil

: 25 08 57 S ; 33 30 05 E

Rock Outcrops : nil

Remarks: The description was made on an augering. Dry parts of the soil surface have a salt crust.

Samples: at 0-13, 13-38 and 50-120 cm.

0 - 13 cm; dark brown (7.5YR 3/2) moist; abundant coarse distinct diffuse yellowish brown mottles; clay;

13 - 38 cm; very dark gray (7.5YR 3/0) moist; many coarse distinct diffuse yellowish brown mottles; Cr1 clay;

38 - 50 cm; dark gray (7.5YR 4/0) moist; many coarse prominent sharp reddish mottles; clay; Cr2

50 - 150 cm; very dark gray (5YR 3/1) moist; common coarse distinct diffuse yellowish brown Cr3 mottles; clay;

PROFILE: GX0097 UNIT: MAC2 STATUS: 3

Sheet/Grid : 1171 Location : Zongoene (T50). Survey Area: Xai-Xai district : 25 05 10 S ; 33 28 07 B Coord.

Elevation: 6 m

Author(s) : L. Amós : 12/09/94

Classification: - FAO : Dystri-Terric Histosols - ST ST : Typic Troposaprists Local : T'Sovo

Soil Climate: aquic

Topography : nearly level
Blement/Pos.: swampy area
Micro Top. : irregular moderate
Land Use : traditional wetland agriculture Land Form: alluvial plain : 1 - 2% , straight Slope

Crops:

Human Infl.: drainage and burning
Vegetation: burned reeds and herbaceous
Species: Phragmites spp. Grass cover:

Parent Material: peat

Eff. Soil Depth : > 150 cm Rock Outcrops : nil Surface Stones : nil Sealing/Crusting : nil Erosion : nil

Permeability: moderate

Drainage class : poor External drainage: slow Watertable $\dot{}$: at 35 cm, sweet (EC 0.32 dS/m)

Flooding : rare Moist. Conditions: moist 0-30, wet 300-120 cm Catchment: (Lumane) Limpopo

Remarks: the description was made on an augering (special peat auger).

Samples: 0-30, 30-60, 60-100 cm

0 - 30 cm; black (10YR 2/1) moist; well decomposed peat; strong fine to medium crumb structure; friable (moist), slightly sticky (wet), plastic (wet); not calcareous; H1

H2 30 - 60 cm; dark reddish brown (5YR 2.5/2) moist; well decomposed peat; not calcareous;

нз 60 - 100 cm; dark reddish brown (5YR 2.5/2) moist; well decomposed peat; not calcareous;

100 - 120 cm; water with little peat material.

STATUS: 3 PROFILE: GX0098 UNIT: MAC2
